MR. GARNETT'S second edition does not differ in appearance from its predecessor. There is the same number of chapters, the headings of which for the most part are also the same, but new matter and more detailed explanation have resulted in the addition of some twenty-five pages. It may be noted as a feature of Mr. Garnett's work that there is a chapter on "The Dynamical Theory of Gases," and a good one on "The Dimensions of Units." We have used the first edition with great advantage, as the author fully discusses and illustrates the *cruces* of this subject, which is often so difficult to beginners, and we commend this improved edition to such readers and to all others.

Elementary Applied Mechanics. By Thomas Alexander, C.E. (London: Macmillan, 1880.)

THE object of Mr. Alexander's work is to serve as a companion volume to the late Prof. Rankine's "Applied Mechanics and Civil Engineering." This *first part* treats of internal stress and strain, the divisions being elasticity, resilience; pure strain, simple and compound; the ellipse of stress; and the application of earthwork. All these points appear to us to be well illustrated by the numerous worked-out exercises, with carefully drawn figures, and by the exercises left for the student to try his skill upon. This small book, drawn up, we presume, with reference to Prof. Alexander's Japanese students at the Imperial Engineering College at Tokei, is likely to be of service, the more so as it appears, to the extent we have tried it, to be correctly printed.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Recent Gas Explosion

"THE explosion took place *by the conversion of potential energy into motion.*"

It may be fairly asked whether physicists are really satisfied with this account of the tremendous development of energy recently witnessed in the neighbourhood, or whether this phrase "potential energy" is not a useless bugbear which is closing the door to discovery. Why not believe rather that the motion exhibited was not really created (as motion) at all, but already existed in a concealed form? For we have plenty of proof that motion can be stored up to any intensity and yet be quite imperceptible to the senses, so long as all is in equilibrium. Why assume a supernatural (?) cause, when we have a natural one of transferred motion? Why rush into the inconceivable assumption of the existence of an energy *without motion*, when the conceivable remains for appreciation? An important and highly interesting problem in the discovery of the *modus operandi* of the transference of the motion from matter in space would thus be ever present to the mind (which is the sole condition for hoping to solve it) in place of an unrealisable and—may we not justly add?—therefore shallow and pretentious mysticism which obstructs the pathway of progress. S. TOLVER PRESTON

July 8

[It seems to us that Mr. Preston makes rather too much of a chance newspaper expression, probably employed (for the sake of appearing scientific) by a writer who had no notion of the tremendous metaphysical problem which underlies it. It is very probable that all energy is kinetic, but this has not yet been proved.—ED.]

THE dangers of an explosion of gas, such as that which occurred on the evening of the 5th inst. in Bedford Street, are not, it would seem, limited to the immediate vicinity of the accident.

At about 7 p.m. on that day I was reading in a room, which from its position at the back of the house being rather dark, required a light, when I was startled by a sudden rush of the flame from the single gas-burner upwards for about two feet—it immediately subsided, again blazed up, and repeating this a third time sank, and went out altogether.

I thought something had gone wrong in the pipe, and that the passage of the gas was interrupted, but on applying a match it ignited and burned naturally, though with a feebler flame than before.

It was fortunate that I was in the room to turn off the escaping gas, or some serious mischief might have occurred when next any one had entered the room to find gas and air mingled into an explosive compound. I found that two other gas lights in passages had been extinguished at the same time, attention having been called to them by the smell of escaping gas.

As the distance of my residence—Granville Place, Portman Square—is more than a mile from the site of the explosion, it is interesting to note the distance to which the impulse extended.

As no further disturbance occurred, and as the phenomena noted happened synchronously or nearly so with the explosion, and as the gas-pipes here are, I believe, branches of the same source of supply, I assume that what I observed and have described was in some way caused by the explosion.

Fortunately it was at an hour when the gas was not generally burning, or other accidents might have resulted. It would be interesting to know if others observed similar effects of the explosion.

July 10

The Tay Bridge

THERE are two interesting scientific questions, apart from engineering proper, which are suggested by the late inquiry, although no reference seems to have been made to them in the reports.

The first is the origin of the extraordinary flash seen at the moment of the downfall of the bridge by many spectators several miles away. It is scarcely doubtful that an impact was the only possible cause.

The second is the important question of the amount of wind-pressure which would suffice to force a train bodily off from the top of the bridge at a place where it was *not within* the girder. No strength of columns could then prevent an accident.

The flash seems to prove that the train had been blown off the rails, and had come into violent contact with the sides of the high girders. Then, and not sooner, the piers were subjected to a strain they were unable to bear.

G. H.

"Geology of the Henry Mountains"

I LATELY received, through the Home Office at Washington, a "Report on the Geology of the Henry Mountains," by G. K. Gilbert, being a portion of the "Geography and Geology of the Rocky Mountains." With the merits or demerits of this paper I am not concerned. I am not prepared, however, to pass in silence and without protest the following paragraphs, which I find at p. 76:—"Bischof attempted, by melting eruptive rocks in clay crucibles, to obtain their ratios of expansion and contraction, but his method involved so many sources of error that his results have been generally distrusted. He concluded that the contraction, in passing from the molten to the crystalline state, is greater in acidic than in basic rocks. Delesse, by an extended series of experiments in which crystalline rocks were melted and afterwards cooled to glasses, showed that acidic rocks increase in volume from 9 to 11 per cent. in passing from the crystalline state to the vitreous, while basic increase only 6 to 9 per cent. Mallet concluded, from some experiments of his own, that the contraction of rocks in cooling from the molten condition is never more than 6 per cent., and that it is greater with basic than with acidic rocks; but considering that the substances which he treated were artificial and not natural products, that his methods were not uniform, and that he ignored the distinction between the vitreous and the crystalline, of which Delesse had demonstrated the importance, no weight can be given to his results."

It would be difficult to compress into the same number of lines a greater amount of erroneous statement than is to be found in the above quotation. Bischof's results were never distrusted by geologists, by whom they were repeatedly quoted, until in my paper on the "Nature and Origin of Volcanic Energy," read to the Royal Society, June, 1872, and printed in *Phil. Trans.*, I pointed out the errors incidental to Bischof's method of experiment, and at the same time directed attention to the strange arithmetical blunder of Bischof himself, by which his deductions from his own experiments are rendered still wider from the truth.

The experiments of Delesse, which I presume are referred to, were made on so small a scale that no deduction as to the total contraction between the liquid and solid state of any rock can be inferred from them. Coming now to Mr. Gilbert's summary condemnation of my own experiments on the total contraction of basic slags from the iron-smelting furnaces of Barrow (Cumberland), an account of which is given in my paper already referred to, and printed in the *Phil. Trans.* for 1873, some of the chief results of which are to be found in p. 201, I have to remark that no other experiments on the subject, conducted on the same great scale, and with equal precautions to insure exactness, have ever been made and published. No experiments have ever been made upon the contraction of lava as flowing from a volcano and its solidification on cooling, but I have given comparative analyses of natural lavas, and shown their almost identical composition with that of the slags employed by me. It is incorrect to state that I have ignored the difference between the vitreous and crystalline condition; all the melted matter experimented on by me having, from the large bulk of melted matter, cooled in the crystalline state. Whether then any justification can be adduced for Mr. Gilbert's sweeping and unsupported statement that "no weight can be given" to the results of my experiments I leave to the judgment of men of science who have impartially read my results.

ROBERT MALLET

London, July 7

Intellect in Brutes

THE Central Prison at Agra is the roosting-place of great numbers of the common blue pigeon; they fly out to the neighbouring country for food every morning, and return in the evening, when they drink at a tank just outside the prison walls. In this tank are a large number of freshwater turtles, which lie in wait for the pigeons, just under the surface of the water and at the edge of it. Any bird alighting to drink near one of these turtles has a good chance of having its head bitten off and eaten; and the headless bodies of pigeons have been picked up near the water, showing the fate which has sometimes befallen the birds. The pigeons, however, are aware of the danger, and have hit on the following plan to escape it. A pigeon comes in from its long flight, and, as it nears the tank, instead of flying down at once to the water's edge, will cross the tank at about twenty feet above its surface, and then fly back to the side from which it came, apparently selecting for alighting a safe spot which it had remarked as it flew over the bank; but even when such a spot has been selected the bird will not alight at the edge of the water, but on the bank about a yard from the water, and will then run down quickly to the water, take two or three hurried gulps of it, and then fly off to repeat the same process at another part of the tank till its thirst is satisfied. I had often watched the birds doing this, and could not account for their strange mode of drinking till told by my friend, the superintendent of the prison, of the turtles which lay in ambush for the pigeons.

The same friend had a couple of Hill Mynahs (*Gracula religiosa*) the most wonderful bird for mimicry which I have come across, not excepting the grey parrot of the West African coast. One of these birds, when hung out in the verandah during the afternoons, used to amuse itself by calling the fowls together, imitating the call of their keeper so well that they used to flock together under the cage, when the bird would burst out into a very good imitation of a human laugh, as if it quite enjoyed the fun of taking in the fowls. Have birds the sense of amusement? This one certainly seemed to derive gratification from the way in which it had cheated the fowls.

Roorkee, June 21

W. W. NICHOLLS

The Volcanic Dust from Dominica

SOME months ago, through the kindness of Messrs. Alexander Agassiz and S. H. Garman, some of the volcanic ashes which fell in Dominica on January 4 were placed at my disposal. On

account of the notices that have appeared in NATURE (vol. xxi. pp. 330, 372, and vol. xxii. p. 77) and in *Comptes rendus* (xc. 622–26), this note would be needless, were it not that some may regard these ashes as of recent origin.

Microscopically the material (already described by Prof. Delesse) is seen to be decomposed to a considerable extent. The materials evidently filled an old crater, and have been subjected to secondary action, so that of the original constituents only the feldspar and augite are left. The other constituents are the results of the alteration of this andesitic (probably) *débris*. No trace of *recent* volcanic material could be found in that examined by me. In no sense can these ashes be called a recent product; they have simply been transferred from one place to another. The transfer is recent, but the ashes have for ages been at or near the surface of the earth. M. E. WADSWORTH

Museum of Comparative Zoology, Cambridge, Mass., U.S.A., June 30

Large Meteor

ON Friday evening last, July 9, at 9h. 45m., I saw a very fine meteor about equal in brightness to Venus at her maximum, moving very slowly from nearly west to south-west. I did not see its origin. It passed about 4° above *Spica*, and disappeared soon afterwards, as nearly as I could estimate, in altitude 16° and azimuth 50° west of S. Its apparent course was only slightly inclined to the horizon, approaching it at an angle of about 1 in 10.

Its apparent angular velocity was about 8° in a second, its light yellowish till the moment of extinction, when it became blue and fainter, and disappeared without any sign of explosion. Its course was somewhat wavy, and the trail it left behind it very evanescent. My latitude and longitude was 51° 25′ and 0° 14′ W. F. C. PENROSE

Coleby Field, Wimbledon, July 14

Ball Lightning

ON Saturday night, the 17th inst., an instance of this form of lightning came under my observation.

The day had been hot, the thermometer registering a temperature of about 71° F. in the shade during the middle of the day, which was bright and clear. In the evening, however, a curious haze or mist spread rapidly over the landscape, while the temperature had fallen to about 68° F. This haze was very much denser and more analogous to the smoke-fog of a town than I have ever observed in the country at this time of year, yet the air did not seem particularly damp or chill.

About 9 p.m. frequent flashes of sheet-lightning occurred, with rumblings of distant thunder at intervals, both of which continued more or less up to midnight, about which time, the mist having somewhat cleared off, I saw when returning home, apparently about a quarter of a mile ahead, a ball or globe of fire of considerable size descend slowly from the clouds, and when near to or touching the earth suddenly disappear, its disappearance being accompanied by two slight but quick concussions, which may have been an explosion and its echo. The fire-ball could not have been visible more than five or six seconds. I cannot ascertain that any damage was done by it.

As this somewhat rare and curious phenomenon seems to be manifesting itself at this period, accompanying the thunderstorms we are having (see NATURE, vol. xxii. p. 193), may I be permitted to suggest that those interested in electrical science should be on the alert to observe any repetition of the occurrence with its concomitant circumstances? W. F. SMITH

Sutton Valence, Kent

E. M. F. should read Prof. Ayrton's Sheffield lecture on "Electricity as a Motive Power" (see NATURE, vol. xx. p. 568); any decent text-book—Noad's, *for example*—will tell of the older attempts of Jacobi to propel boats by electricity.

THE RECENT EXPLOSIONS

ALTHOUGH it is difficult to say anything new on the subject, or give instructions more effective than such as have been given over and over again, still the recent remarkable and destructive explosions in London, Wolverhampton, and Monmouthshire seem to call for some remarks at our hands.

Two serious explosions of gas following close on each other, in the streets of large towns, announce to every one that the difficulties of supplying gas to large numbers of consumers have not been completely overcome.

The special feature in the London accident was the occurrence of a series of explosions, at first at nearly regular, and then at increasing intervals, along the gas main. The first explosion blew out the "cap" of the main with great violence; the rush of heated air, doubtless mingled with more or less gas, in the other direction seems to have carried the flame—probably by a rapidly occurring series of small explosions—to a point at which a mass of explosive gas was again reached and fired. The mass of gaseous mixture fired in the second explosion appears to have been about equal to that in the first, but towards the close of the series either the gas became much more diluted with air, or the air became much more charged with gas. It seems just possible that vibrations propagated by the first explosion passed rapidly through a gaseous medium, consisting of much air and little gas, until they came in contact with a mass of gas and air, which they threw into rapid vibration, and so caused to explode. But from the experiments of Abel and others one would scarcely expect this to occur under the conditions which—judging from the evidence given at the inquest—appear to have existed.

A second point, illustrated more markedly by the Wolverhampton explosion, is the apparent readiness with which a soil may be charged with coal-gas and retain this gas for long periods of time. The passage of such gas into drain-pipes, and perhaps even into unfilled gas-mains, seems to be of ready occurrence.

Experiments might well be instituted by the gas companies to determine the power of soils for absorbing and retaining coal gas, and secondly, the conditions of diffusion of mixtures of gas and air through the walls of pipes of different materials. If it can be shown with certainty that the valve at the junction of the main in which the explosion occurred with the Howland Street main was absolutely impervious to gas, then the explosion may almost be regarded as proving the permeability of the material of gas mains to mixtures of air and coal-gas.

The practical lesson of the explosions is that some means of certainly determining whether a gas main does or does not contain gas must be found at once, and that this means must *not* be the application of a light to an opening in the main. The foreman who applied the fatal match said that the pressure gauge showed the absence of gas in the main; but as the main contained a quantity of gaseous mixture at rest, and not flowing through the pipe, the gauge could not be expected to indicate the presence of this mixture.

It is almost amusing to read of the simple astonishment of the two foremen when the fact was announced to them that mixtures of coal-gas and air are explosive: twenty or twenty-five years' experience in gas-works had failed to teach them this fact. Yet the lives of the inhabitants in the neighbourhood of Tottenham Court Road were practically in these men's hands for the last three or four months.

With regard to the Risca disaster, of a different and unhappily more fatal kind than the former, clouds of smoke are said to have accompanied the explosion which devastated the pits soon after midnight on Thursday last (15th inst.), and we have it from the lips of a credible eye-witness that fused and coked coal-dust is found adhering to the timbers in those parts of the workings which have been already visited, though not so conspicuous as in some cases. In these respects therefore the recent explosion is only a repetition of similar events which have

taken place before, and we need not again go over the ground which we have already traversed several times in these pages, when we have endeavoured to point out their most probable origin and mode of propagation.

We propose, however, in this place to devote a few lines to the discussion of a question which we think has not as yet received the attention it deserves, namely: When is a mine in such a state that it may be termed *well-ventilated?* and our principal reason for doing so is that a statement has been already put forth to the effect that the ventilation of Risca Colliery was as perfect as it well could be, the total volume of air passing through it being considerably over 100,000 cubic feet per minute.

An air-current of given dimensions may be sufficient to thoroughly ventilate the workings of a fiery mine at one time, and it may be quite insufficient at another: for the degree of sufficiency is obviously wholly dependent on the amount of fire-damp given off per unit of time. Each unit of volume of coal contains a certain volume of fire-damp in a state of great compression—it may be in a liquid or solid condition—and this gas begins to be given off when the workings approach to within a certain distance of the space within which it is confined. The greater proportion of the fire-damp is probably given off immediately before the coal is laid bare, and at the instant it is being detached from the face; but some of it still continues in the coal long after it has left the mine.

If the workings of a fiery mine are stopped abruptly and allowed to remain unworked for a considerable time, we find that the amount of fire-damp given off gradually decreases, until in the course of a year or so it is not more than one-tenth of what it was when the mine was in full work. If, on the other hand, the output of a fiery mine is largely increased, we find that the workings soon lapse into a dangerous condition unless the ventilation has been largely in excess of its requirements in the first place. The character of the ventilation is thus dependent upon the output of coal for the time being as well as on the amount of air.

The daily output of Risca Colliery is stated to have been 1,000 tons, and supposing the amount of gas given off to have been 2,880 cubic feet per ton of coal, which is the actual amount we have found by observation and calculation in similar mines, then we know that, if the volume of the ventilating current had amounted to 30,000 cubic feet per minute, the whole of it would have been explosive as it returned from the workings; if it amounted to 50,000 cubic feet per minute it would show a cap half an inch high in the small oil-flame of a lamp, and when charged with coal-dust it would form a *highly explosive* mixture; if it amounted to 100,000 cubic feet per minute it would still show a small cap $\frac{1}{8}$ to $\frac{3}{16}$ inch, and it would still produce an explosion when mixed with coal-dust, and ignited.

It is notorious, however, that as a rule the volume of air which reaches and passes round the working faces is much less than that which descends the down-cast and ascends the up-cast shaft; and when we are told that the ventilation of a mine is represented by a certain number of cubic feet of air per minute, we are on the safe side if we estimate the useful volume to be little more than two-thirds of the stated one.

It is further notorious that the practical miner of almost every grade regards a small cap on the flame of the lamp, even if $\frac{1}{4}$ to $\frac{1}{3}$ inch high as a very trivial matter, so long as he finds little or no explosive gas in the mine; and he only begins to speak of the return air as being heavy or rather heavy when the size of the cap on the small oil-flame reaches or exceeds a height of $\frac{3}{8}$ of an inch; but still even in this case he is not much troubled with thoughts of immediate danger.

What then constitutes a well-ventilated mine?

We say in reply that no mine containing dry coal-dust is well-ventilated when the cap on the small oil-flame of a lamp is over $\frac{1}{8}$ or $\frac{3}{16}$ inch in height, that is to say, when the return air contains more than 2 per cent. of gas. Even with that amount, as we know, it will form an explosive mixture with coal-dust, and we should prefer to see a standard insisted upon in which not more than 1 per cent. was allowed.

This aspect of the question is well worthy of the attention of the Royal Commissioners on Accidents in Mines, and we hope they will not allow their present opportunity to pass without endeavouring to arrive at some definite settlement of such an important question.

NORTH AMERICAN GEOLOGY—IDAHO AND WYOMING[1]

IN spite of the revolution that was recently effected among the Government geological surveys of the American Union, provision has wisely been made for the completion of the Reports of the different corps which have been abolished. It is pleasant to welcome still another of the stout black volumes issued annually by the Geological and Geographical Survey of the Territories. On the completion of the Survey of Colorado in 1876 Dr. Hayden and his corps of active coadjutors moved northwards across the belt of country included in the Survey of the 40th Parallel under Mr. Clarence King, with the intention of mapping the territories of Idaho and Wyoming to the north and west. A number of reconnaissances had been made by various observers in these regions since the days of Bonneville and Fremont, some of the earlier work of Hayden's Survey having been accomplished there. But no general survey of the whole area had been attempted, and many parts of it had never been penetrated by white men. It was a vast territory, including within its borders the sources of the Green, Snake, and Yellowstone Rivers, and embracing the most varied forms of surface and the greatest diversities of geological structure. To survey this unknown domain and bring its geography, geology, mineralogy, ethnology, zoology, botany, and general economic capacity to the knowledge of the world was the aim with which Dr. Hayden and his staff started in the summer of 1877. During the season the primary triangulation was extended over an area of 28,000 square miles, from West Long. 107° to 112° and between North Lat. 41° 10′ and 43° 50′, and was connected with the stations made by the Survey of the 40th Parallel, and by the Boundary Survey of Wyoming. Topographical field-work was carried on by three parties, each having an area assigned to it of about 11,000 square miles. The total area thus surveyed amounted to about 29,000 square miles. The geological staff was likewise divided into three divisions, each being intrusted with a separate district, viz., the regions of the Sweetwater, Teton, and Upper Green River.

In the report of Dr. Endlich of the Sweetwater division, one of the most interesting features is his account of the structure of the Wind River Mountains. This important portion of the true Rocky Mountain range is formed of three parallel chains, of which the western, and chief, rises to heights of more than 13,000 feet and forms the watershed of the continent. Even now its huge snow-fields, which, through the clear summer air can be seen gleaming from a distance of more than 100 miles, suggest the presence of glaciers. When Dr. Endlich and his party traversed these mountains in 1877 they found, indeed, no recognisable glacier, but abundant freshly-grooved and polished rocks and moraine mounds, showing the comparatively recent existence of land-ice in these elevated regions. On the west side of the

[1] "Eleventh Annual Report (1877) of the United States Geological and Geographical Survey of the Territories, embracing Idaho and Wyoming." (Washington: F. V. Hayden, 1879.)

mountains the evidences of glacial action are specially striking, one valley in particular bearing witness to the former presence of a glacier sixteen to eighteen miles long, extending for several miles into the low country, where it threw down its heaps of moraine-stuff in mounds a mile and a half broad, and from 800 to 900 feet high. Next summer, however, the covering of snow having partially melted, true glaciers of small extent were found in the Wind River and Teton ranges.

East of the Wind River Mountains there lies a suite of palæozoic formations from the Potsdam sandstone to the top of the Permian group, having a united thickness of 3,350 to 3,750 feet, and covered by 2,500 to 2,920 feet of Triassic, Jurassic, and Cretaceous rocks. Dr. Endlich computes the total depth of stratified formations in the Sweetwater region at more than 16,000 feet. Underneath them in the Wind River range lies a great series of crystalline rocks. According to Dr. Endlich the Potsdam rocks have been converted into quartzites by the same metamorphic action which has changed the rocks immediately below them into granites and schists. His section shows three zones of granite in descending order, the lowest of all being what he terms prozoic, while the youngest, from its stratified or schistoid character, and the coincidence of the inclination of its strata with that of the overlying stratified formations, he classes as of metamorphic origin.

The researches of Prof. St. John were devoted to the exploration of that wonderfully interesting region round the head waters of the Snake River and the Teton Mountains. The traveller who journeys wearily over the vast desert lava-fields of the Snake River plains looks wistfully from time to time at the great snow-rifted peaks which the Teton range far to the east raises into the sky. What would he not give for a glass of the cool water which dashes down so profusely among these far mountains and disappears so utterly before it reaches that thirsty desert? Extending the observations of Hayden, Bradley, Comstock, and others, Mr. St. John has given us an interesting narrative of the structure of the mountain region and of the lower territory on its flanks. The core of the Teton range, culminating in Mount Hayden, consists of massive granites, gneisses, and schists, flanked by quartzites and slates. On these ancient rocks lie from 500 to 1,000 feet of limestones, shales, and sandstones, containing Lower Silurian fossils, and from 400 to 600 feet of a buff-coloured magnesian limestone referable to the Niagara group of the Upper Silurian. The Carboniferous system, consisting mainly of limestones and sandstones, reaches a thickness of from 2,500 to 5,000 feet. Secondary formations, referred to the Triassic, Jurassic, and Cretaceous systems, attain depths of from 2,300 to more than 5,000 feet. The volcanic history of this portion of America is specially noticeable. According to Mr. St. John's observations the usual chronological sequence obtains in the areas traversed by him. The early eruptions have been of a trachytic nature, great variety of aspect and lithological structure being traceable among the various outflows. The surface presented by the trachytic areas is markedly uneven—the result doubtless partly of original irregularities of extrusion and partly of subsequent extensive denudation. The latest eruptions were of basalt, which has flooded the bottoms of the valleys, and now covers an area of many thousand square miles. Mr. St. John speaks of the difference of level between different plateaux of basalt as being due to subsequent elevation. But it is not necessary to suppose that there ever was any common level for the outflows. Some were no doubt poured out at much higher elevations than others even in their vicinity. The same observer calls attention to the remarkable volcanic conglomerates described by Hayden from this and the Yellowstone region, and by Whitney from the Territories lying further west. These deposits, 3,000 feet or more in thickness, consist of angular and subangular or rounded blocks of trachytes, basalts, and other volcanic rocks imbedded in a dull brown tuff-like matrix. They cover wide tracts of country in the volcanic districts, and point to a phase of volcanic or inter-volcanic action which is not yet well understood.

Dr. A. C. Peale contributes an interesting report on the varied region lying to the north of the 41st Parallel between Green River City, Wy., and Ogden, Utah. He estimates the total mass of stratified formations in that region from the base of the Lower Silurian system to the top of the Quaternary series at upwards of 30,000 feet. He has added some additional fossils to the list of Lower Silurian forms collected from the district in 1872 by the late Prof. F. Bradley. He has likewise made important additions to the Carboniferous fauna of that area, and has shown how dominant a part is taken by the 6,000 feet or more of Carboniferous limestones and quartzites. The Jura-Trias attains a depth of between 5,000 and 6,000 feet, consisting of the usual red sandy and argillaceous strata below, and passing up into laminated limestones and shales. A considerable number of organic remains were obtained from several zones in these beds, but they do not yet appear to be sufficient for drawing a satisfactory line between the Trias and Jurassic series in the Rocky Mountain region. To our knowledge of the Cretaceous and Tertiary geology of the district Dr. Peale was enabled to make some valuable additions.

Besides these geological reports, the labours of the Survey in 1877 included a detailed palæontological research in the field by Dr. C. A. White, who contributes an important report of his work, and the first of what we hope will be a series of papers on invertebrate palæontology. He specially treats of the Cretaceous fossils of the Western States and Territories. The topographical work of the year was well done by Messrs. Nelson and Gannett. As subsidiary but very valuable parts of the work accomplished by the Survey, reference may be made to the researches on fossil insects by Mr. Scudder of Boston, which have been aided by the Survey and will be published among its memoirs; to the great monograph by Dr. Leidy on the Rhizopods, which has already appeared as one of the Survey's quarto volumes; and to the interesting particulars collected by the Survey regarding the archæology of the San Juan and South-Western Colorado.

There will be, we presume, one further Report for 1878—the last year of the existence of the Geological and Geographical Survey of the Territories. Though this mode of annual publication necessarily involves incompleteness, and is apt to overload the reports with unimportant detail, there can be no doubt that the series of volumes issued by this Survey form a permanent record of great value, which for the districts to which they refer will serve as the basis of all subsequent work. It is not without regret that one can regard the cessation of these volumes. On this side of the Atlantic, where they can be calmly considered apart altogether from scientific rivalry and political entanglements, they have been received with general approbation. It is impossible not to be struck by the largeness of the plan conceived by Dr. Hayden for the scope of his survey. Not geology merely, but every branch of inquiry touching the natural history, archæology, geography, and meteorology of the Territories, was embraced within his plan, and has been illustrated as far as the means at his disposal would allow. To have conceived this broad and scientific scheme, and to have possessed the administrative power to secure and keep in working concert so large and able a body of observers, are qualities of no mean order, and deserve grateful recognition wherever an intelligent interest is taken in the general progress of science and in that human advancement which scientific progress insures.

ARCHIBALD GEIKIE

THE RUSSIAN IMPERIAL YACHT, "LIVADIA"

IT is not surprising that the character of the great steam-yacht *Livadia*, just launched upon the Clyde for the service of the Emperor of Russia, is exciting wide-spread interest. Since Noah built the Ark, no floating and moving structure has been constructed in such direct contrast as this vessel with all that has gone before it. Every other ship afloat has, in its chief features, been a development of the ships that preceded it, not excepting even the circular ironclads of Russia, for they were not the first circular vessels that had been designed and constructed, and although they had some steaming pretensions, these were too moderate to challenge seriously either the principles or the practice of naval architects. In the new yacht of Admiral Popoff's design, however, we have a steamship that, by its very existence, challenges the fundamental principles upon which fast passenger steamers are constructed by all the rest of the world.

We give herewith illustrations, of which the first (Fig. 1) is an external view of the *Livadia* as seen out of water; it is taken from a model which was constructed under the care of Admiral Popoff, and shows at a glance the general form of the ship. Another (Fig. 2) is a cross section, showing among other things the transverse distribution of the boilers and machinery. The third (Fig. 3) is a plan showing the horizontal distribution of the same, and indicating more clearly than the other the positions of the three propelling screws.[1] It is obvious that such a form of vessel, propelled in the manner exhibited, suggests many questions of scientific interest; but most of these will be best discussed after the steam trials of the vessel have taken place. For the present it will be sufficient to take notice of the general characteristics and qualities which she presents to view.

It is desirable at the outset for the reader to observe that the *Livadia* consists of a shallow hull 235 feet long, 153 broad, and drawing, when supporting all its burdens, but 6½ feet of water. From a foot or two above the water's surface arch upwards and inwards with considerable curvature until they each meet (at about one-sixth of the whole breadth of the ship from the side amidships) the fore and aft sides of a naval palace, which extends from stem to stern. Although the width of the ship at the water-line is 153 feet, her width at a few feet above the water-line is therefore much less—about 110 feet, we believe. In smooth water, therefore, the resistance to onward motion will be those encountered by a vessel 153 feet broad and 235 feet long; but when the ship gets into heavy seas they will be free to pass over her low sides, and the ship that will have to divide and encounter them will be 110 feet by 225. As the object of this vessel is to furnish ample accommodation for the Emperor and his suite at sea, it may be fairly presumed that the width of the superstructure has been kept greatly within that of the hull proper, and the accommodation thus restricted, for the purpose of materially improving the behaviour of the vessel at sea. The arrangement will doubtless contribute greatly both to the speed and to the steadiness of the ship in great waves, its value for diminishing rolling having already been demonstrated in the circular ironclads, which have superstructures of less width than the ship, and which are remarkably steady even in seas that roll freely along the decks of the hulls proper.

The primary and chief fact concerning the anticipated steadiness of this exceedingly short, broad, and shallow ship, is that it is to be secured by means the very opposite of those which have lately obtained in this country, viz., by aid of enormous stability. Since the general acceptance of Mr. Froude's theory of rolling, the aim of the naval architect has been to send his ship to sea with sufficient stability for safety, and with no more than is ample for that purpose; because steadiness at sea is, under the modern theory, promoted by keeping the stability or righting force as small as possible, within the limit just named. The metacentric height, which is from 12 to 15 feet in the American monitors, which have great proportionate breadth of water-line, has been restricted to 6, 5, 4, and even less than 4 feet in many of our large war ships; indeed the *Sultan*, which is one of the steadiest of our large ironclads, has a metacentric height of only 2½ feet, while the *Inconstant's*, the steadiest of our unarmoured ships, is but very slightly in excess of this. This reduction of metacentric height increases proportionately the "period of oscillation," and makes vessels reluctant to accept the disturbances which waves endeavour to impose upon them. But while the tendency of modern science has thus been to diminish metacentric height and stability, the effect of the *Livadia's* form and proportions will be to give her enormous metacentric height and stability, the object in both cases being identical, viz., improved steadiness in waves. Nor is this course pursued, strange as it may seem to some, and violently antagonistic as it is to modern practice, without the sanction of science. For while a ship with very small stability, and consequently very long natural period of oscillation, is ordinarily secured against rolling by her slowness to accept the wave impulses, the ship with very large stability, and consequent very short period of oscillation, is ordinarily secured against excessive rolling by the very readiness with which she accepts those impulses and conforms to the mean movements of the waves. It is true that in the latter case the exemption from rolling motions is not so great as in the former, because a certain considerable amount of rolling is undoubtedly and necessarily involved in this conformity to wave motions; but this amount of rolling is very much less than that to which a ship is exposed which has neither stability so small as to render her comparatively indifferent to wave-pressures, nor stability so large as to force her to keep her decks approximately parallel to the wave-surface. Ships with intermediate degrees of stability are liable to roll much and to accumulate large rolling motions, especially when subjected to successive impulses from similar waves, whereas the ship of enormous stability, while always obeying each wave, is by that very means exempted from the tendency to accumulate the effects of a succession of waves. In all this reasoning—the generality and meagreness of which we fully recognise—it is of course assumed that the waves in question are of sufficient magnitude in proportion to the size of the ship to stand in individual relation to her. The immense breadth of the *Livadia* will doubtless preserve her from being rolled by small waves, including under that designation waves which would cause many ordinary ships to roll with violence. As regards longitudinal rolling, which is usually called pitching, if we neglect the onward motion of the ship, and consider the matter from the same point of view as that just adopted in speaking of transverse rolling, we may say with confidence that the longitudinal stability of the *Livadia* will be in excess of the transverse, and that no excessive pitching need be feared. Owing to the shortness and light draught of the vessel, she would probably (if not advancing) tend to accompany pretty closely the motions of the wave-surface when heading to waves of sufficient size to cause her to pitch. As her length is so small (less than half that of several transatlantic steamships now at sea), the vertical motions of the bow and stern will of course be correspondingly small for given angles of pitching.

It is when we come to consider the case of her enormous steam power being applied to force her ahead through large waves that we experience some difficulty in predicting her behaviour. For we here touch upon a question which has been but very imperfectly investigated; we might even say, has scarcely been more than

[1] We are indebted for the second and third engravings to the kindness of the editors of *Engineering*; the first has been specially engraved for us.

mentioned. A few facts and figures bearing upon it may nevertheless be given. It is estimated that a wave with a 4-seconds period and 82 feet long advances at a speed of 12 knots an hour; an 8-seconds wave 328 feet long has a speed of 24 knots; a 12-seconds wave 740 feet long a speed of 36½ knots; and a 16-seconds wave 1,300 feet long a speed of 48½ knots. If the *Livadia* were steaming at 14 knots against waves equal in speed to her own, she would of course encounter them at a speed of 28 knots, and that is a speed corresponding to a length of wave of about 450 feet, whereas the waves which she would actually be meeting would be but little over 100 feet in length. Again, if we may for a moment imagine her to be steaming at 18 knots an hour, and encountering similar waves, she would of course be meeting them at a speed of 32 knots an hour. But a wave of that speed would be nearly 600 feet long, whereas that which she would, under the last hypothesis, be encountering would be only 100 feet long, as before. It is obvious, therefore, that so short a ship, steaming at high speeds, would develop conditions unknown alike to vessels of low speed (such as sea-going vessels of her small length usually are when steaming against head seas) and to vessels of high speed but of great length. If we take for example the case of waves about 500 feet long from hollow to hollow, and therefore of a half-length of about 250 feet, it is obvious that whereas a fast steamship 500 feet long would receive the support of a second wave while the crest of a previous one still gave her bodily support, the *Livadia* is so short as to be capable of steaming down the wave slope, at an angle to the horizon approximately equal to that of the slope itself. If doing this at a speed of 15 knots an hour, or 25 feet per second, with the on-coming wave advancing upon her, as it would be, at 30 knots an hour, or 50 feet per second, it is easy to see that the behaviour of the vessel would be of an unusual kind. We do not give this as by any means the most notable or critical of the cases which might be selected, but it will serve to show that Mr. Froude was not speaking heedlessly when he said that the purely circular ships would tend to "dive," and to indicate that those persons are probably correct who see in departure from the circular form in the present case evidence, not so much of a desire to diminish resistance, as of a desire to correct the diving propensities of very short ships.

And this brings us to notice the steaming qualities of the *Livadia*. The enormous steam-power with which she is being supplied has naturally excited much notice, and the *Times* gave an interesting comparison between her power and proportions and those of the *Shah*. It will assist the further elucidation of the subject if we invite attention to a different kind of contrast, and compare the *Livadia* with the largest and most powerful of our finished armoured turret-ships, the *Dreadnought*. This huge ship, which steams at 14½ knots per hour, although very much more than twice the immersed size (displacement) of the *Livadia*, has very much less steam-power. The following is a comparison between the two ships:—

	Dreadnought.	*Livadia.*
Length	320 feet ...	235 feet.
Breadth, extreme	64 ,, ...	153 ,,
Immersed depth of hull (mean)	23 ,, ...	6½ ,,
Displacement	9,100 tons ...	3,900 tons.
Indicated horse-power	8,200	10,500

Allowing for the curvature in the form of the hull at and near the bottom, we should of course more than double the *Livadia's* displacement by carrying her sides at the load-water line vertically upwards, and immersing her another 6½ feet; we should probably, by this process, bring her displacement up nearly to that of the *Dreadnought*. As between the two ships, all this extra displacement is, so to speak, saved in the *Livadia*, while, as regards the steam power, hers is in excess of that of the *Dreadnought* by more than 25 per cent. It will be seen from these conditions under what immense advantages the experiment of driving a broad and shallow ship very fast is to be carried out in the Imperial Russian yacht. So far as is known, the designer of the *Livadia* has not promised more than 14 knots of speed; but if we allow her the same speed as the *Dreadnought* (14½ knots) she will have a large excess of steam power (no less than 2,300 I.H.P.) applied to the propulsion of a hull weighing very much less than one-half the weight of the ironclad. The speed reached by the latter vessel was sustained throughout a six hours' trial.

As the *Shah* is a long fine-lined ship, 15 feet longer than the *Dreadnought* and 12 feet narrower,[1] with about the same mean depth, the *Dreadnought* may be regarded as a considerable departure from her in the direction which has been pursued so very much farther in the *Livadia*. It will be instructive therefore to compare these two vessels—

	Shah.	*Dreadnought.*
Length	335 feet ...	320 feet.
Breadth, extreme	52 ,, ...	64 ,,
Depth (mean)	23 ,, ...	23 ,,
Displacement	5,900 tons ...	9,100 tons.
Indicated horse-power	7,500	8,200
Speed	16½ knots ...	14½ knots.

If we compare the performances of these two extremely different ships—different as regards length and breadth, but not as regards depth—we shall find a material reduction in the steaming efficiency of the short and broad ship, but not one of so marked a character as many might anticipate. Applying to both the well-known formula for comparing displacements, powers, and speeds, viz.:—

$$\frac{\text{Speed}^3 \times \text{Disp.}^{\frac{2}{3}}}{\text{Ind. H.-power}},$$

we have—

Shah ... ... 195 | *Dreadnought* 163

Or, viewing the matter with reference to the midship sections propelled through the water, or to the volumes of the excavated channels, and adopting the Admiralty formula—

$$\frac{\text{Speed}^3 \times \text{Mid. Sec.}}{\text{Ind. H.-power}},$$

we have—

Shah ... ... 587 | *Dreadnought* 480

Here we have a loss of, say, 16 per cent. upon the performance constants as regards displacement, and a loss of more than 20 per cent. as regards midship section, by passing from the fine narrow form of the *Shah* to the broader and bluffer form of the *Dreadnought*, observing that the loss would probably have been in greater proportion had the *Dreadnought* been of no more than equal size or displacement with the *Shah*.

Although the *Dreadnought*, as compared with the *Shah*, advances towards the *Livadia* type, the advance is but very small indeed, the *Livadia* being much more than double the breadth of the *Dreadnought* upon a length of 75 feet less. We have in the great Russian yacht an experiment lying far outside of all former experience, and ranging itself under no laws or formulæ with which naval architects are familiar. But it may be well to exhibit her in the guise of the formulæ which we have just employed, and to do this first upon the assumption of a 14 knots speed, and secondly upon that of a speed of 17 knots—the highest, perhaps, which Admiral Popoff has allowed himself to hope for even in his most sanguine moods, and equal probably to that which his ardent disciple and assistant, Capt. Goulaeff, has ever evolved from the most plastic of his calculations—although we must acknowledge that we cannot say this with any great confidence in view of the published paper of the latter

[1] The *Dreadnought's* breadth diminishes by some feet, we believe, at a depth of 6 or 7 feet below the water's surface, but this will not materially interfere with the comparison about to be given.

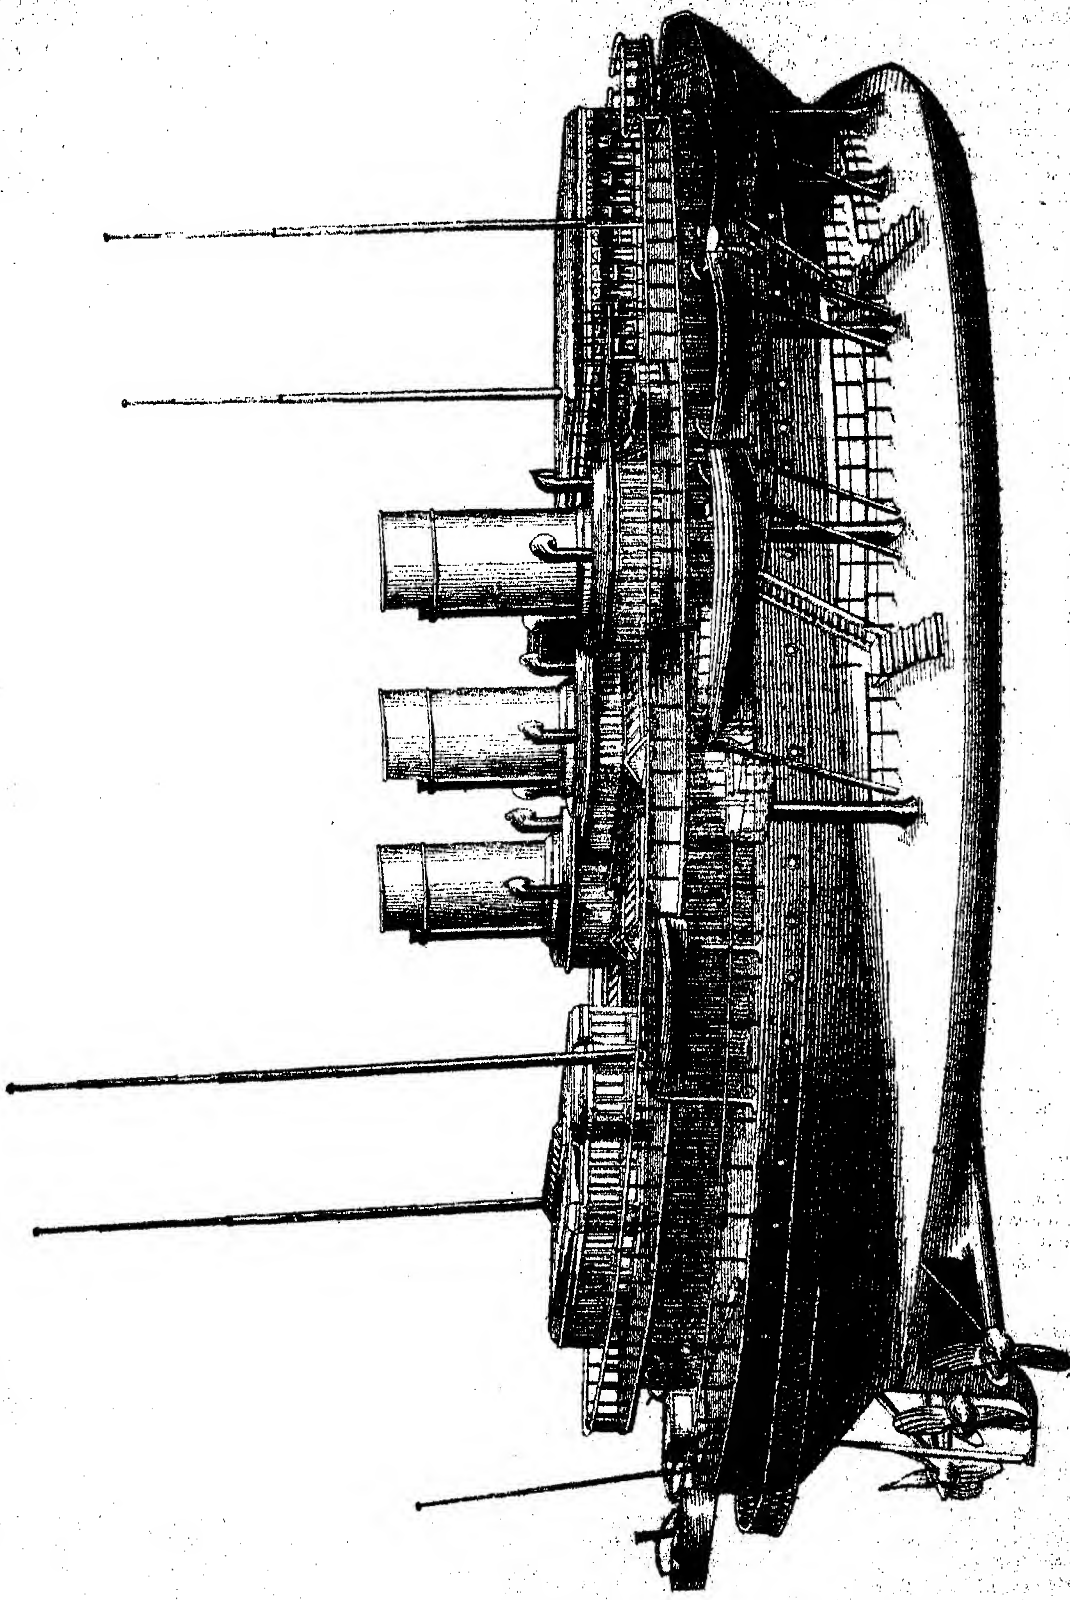

Fig. 1

officer. The formulæ give the following results for the *Livadia*:—

	Speed 14 knots.	Speed 17 knots.
Displacement constants ...	65 ...	116
Midship sec. „	234 ...	419

These figures illustrate the margins within which the performances of the *Livadia* may range when steaming at above 17 knots and 14 knots respectively. It cannot be expected that her constants will fall so low as the former of the pair just given, and therefore it cannot be doubted that her speed will surpass 14 knots.

We have intimated that Capt. Goulaeff, in his paper on

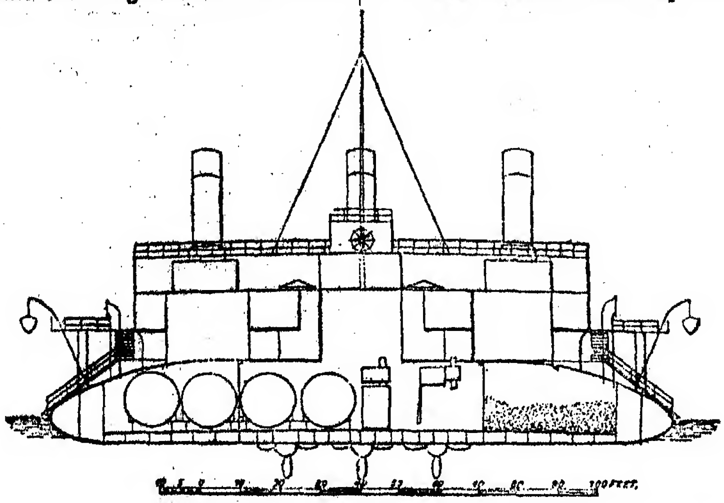

FIG. 2.

"the *Fairfield* yacht of the Czar," has written with great confidence on the favourableness of this vessel's form to speed. He says that an addition of 25 or even 50 feet of length would not have reduced the resistance, the increase of friction being more than the improved form of the water-lines would have compensated for. But it is to her shallowness that he looks for her facility of propulsion, contending that experiments on both a small and a large scale have shown that it is better for speed to have great breadth rather than great depth. He even says that "at certain speeds a very much broader vessel requires only half as much power compared with another vessel of similar form whose draught is double." It is on this ground that he chiefly bases his anticipation that great

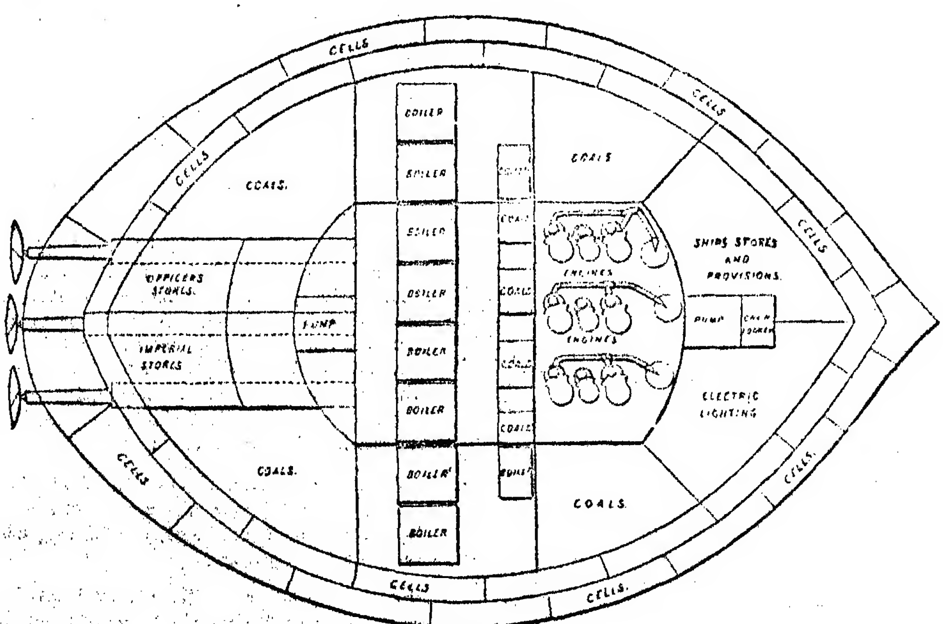

FIG. 3.

speeds are not incompatible with the form given to the *Livadia*. The form of the vessel below water has been very carefully considered. Capt. Goulaeff says:—

"The form of underwater portion was made a subject of very careful study. Besides the great experience of the designer of the ship, Admiral Popoff—experience which he derived by spending the greater portion of his lifetime either on the ocean or in constructing novel ships and trying them at sea—Dr. Tideman, member of the Academy of Amsterdam, was invited to assist in the determination of questions connected with the resistance of the yacht. In the case of this shallow-draughted

vessel, the fine lines must be the vertical sections, whereas the fine lines of the ordinary steamer are the water lines or horizontal sections. Such change has been brought about by passing from long, narrow, and deep forms of ordinary vessels to the proportions of short, broad, and shallow ones; and, as has been demonstrated by experiments with paraffin models, the sharpening of buttock lines is more essential in this case than sharpening of water lines. In other words, if the motion of an ordinary vessel may be compared with that of a wedge propelled vertically, the motion of the yacht ought to be compared with the same wedge propelled through the water horizontally. On looking at the stern of the actual vessel you will observe that the whole motion of the water between the stern tubes will be effected solely in the direction of the vertical sections, or the buttock lines."

It is needless for our purpose to consider the minor details of a vessel so fraught with features of extraordinary interest. It may be well to point to the fact that the ship is to be steered, not by rudders, but by her screw propellers only, of which she has three of equal diameter (16 feet), as illustrated in our engravings. These screws are spaced 18½ feet apart, the central one being in the line of keel. Each screw has its own engine of 3,500 I.H.P.

We need hardly say we shall watch the trials of this ship when her machinery is completed, and report the results to our readers. Meanwhile we join in the tribute of praise which is being freely accorded in this country alike to her bold and adventurous designers, and to His Imperial Highness the Grand Duke Constantine of Russia, a highly scientific and accomplished naval officer, by whose influence, and under whose personal care, some of the greatest problems in steam navigation are being developed.

NOTES

The ceremonies at Manchester in connection with the Victoria University last week were as successful as the momentous event deserved. The *conversazione* on Tuesday evening was brilliant and crowded. The meeting on Wednesday for the transaction of the business of the University was harmonious and satisfactory, while the banquet that succeeded was quite worthy of the Corporation, who acted as hosts. The address of that body to the Duke of Devonshire seemed to us to breathe the proper spirit, and to show that Manchester is quite alive to the importance of the great event which has been celebrated. But indeed we did not require any such evidence of the importance attributed to high education in Manchester; as Earl Spencer pointed out, the Manchester grammar and other schools are among the best in the kingdom, and the existence of Owens College itself is proof enough that Manchester thinks of something else besides the most effective way of loading cotton goods. The speeches were all good and appropriate; the Bishop of Manchester was as liberal and fair as he always is, and his claim for freedom of research and belief in his own line was heartily endorsed by Prof. Huxley, who replied to the toast proposed by the Bishop. Prof. Huxley hoped the time would come when such an institution as Owens would be found in every important centre—a hope we heartily echo. Mr. Freeman was forcible and sensible, and of course took occasion to correct the historical inaccuracy of some one who cherishes the belief that the University of Oxford was "inaugurated" in a desert instead of what was at the time a busy industrial centre.

It is comforting to receive the assurance given by Mr. Mundella at the opening of the Central Schools of Sheffield last week, that as long as he has the honour to occupy the place he does in her Majesty's Government the quality of education and the standard of education should not be lowered. The State, he maintains, having decided that the children of the country should receive education according to their needs and capacities and prospects in life, ought to give that education not only thoroughly, but generously and with an unstinting hand. With such a sentiment actuating the Vice-President of the Council, we feel that elementary education is safe from the raids of Lord Norton and his friends.

A somewhat laboured and diffuse article on "Scientific Arrogance" in Monday's *Pall Mall Gazette* comes to the following very sensible conclusion:—"It would appear that scientific arrogance, in so far as it has any reality, is but the obverse of popular ignorance. Let the ignorance be dispelled, and the mystery bred of it will vanish. Let some rudiments of exact knowledge, some grounding in the methods of scientific reasoning, and some notions of the nature and ends of scientific work, be made part of our general scheme of instruction, and scientific dogmatism will be impossible. Let the mind be trained betimes to walk modestly and warily, as all true leaders of knowledge have walked, by the light of diligent and patient inquiry, and the spectre of scientific arrogance will disappear." One more argument for the retention of the Fourth Schedule. Perhaps even Lord Norton might put himself to school to some advantage after this recipe.

The new Matriculation list of the London University bears ample evidence to the success of the step recently taken by the Council in admitting women to its degrees. In the Honours Division the third place is occupied by Edith Sophia Callet, from the North London Collegiate School. Altogether about one-sixth of the names on this Division are those of girls, and the proportion on the other Divisions is quite as great.

The New South Wales Government have done a creditable thing in erecting an obelisk on the spot occupied by the Transit instrument in the old observatory at Parramatta, established by Sir Thomas MakDougall Brisbane in 1822. The building has long been swept away; many valuable observations were made in it by Mr. Charles Rümker and Mr. James Dunlop, and it was only right that the exact position of the Transit instrument should be permanently marked, so that, if necessary, future verification might be made. The first suggestion of the obelisk was made by Mr. Tebbutt so long ago as 1870, and it is gratifying that the New South Wales Government has so much regard for science as to act on Mr. Tebbutt's suggestion.

We have a note from General Myer, dated July 1, stating that at the request of Prof. Wild, of St. Petersburg, the date fixed in his letter of May 4 changing the time of taking the International Simultaneous Meteorological Observations to a time thirty-five minutes earlier than at present, or to 0h. 8m. p.m., Greenwich time, is changed from September 1, 1880, to January 1, 1881, a change with which the numerous observers over the world who make the observations from which the U.S. Weather Maps are constructed will doubtless concur.

We regret to announce the death of Mr. W. A. Lloyd, who has done so much for the improvement of marine aquaria. Mr. Lloyd, it will be remembered, was for long connected with the Crystal Palace Aquarium.

From the *Gardeners' Chronicle* we learn that a committee, comprising some of the leading botanists and horticulturists of Berlin, has set on foot a project to erect a memorial stone on the grave of the late Karl Koch, and appeals through the press to his friends and admirers for subscriptions wherewith to carry out the project in a manner worthy of him whose memory it is desired to perpetuate. Subscriptions may be sent to Herrn Späth, Baumschulbesitzer, 154, Köpenickerstrasse, Berlin, S.O., and will be publicly acknowledged.

PROF. McK. HUGHES, of Trinity College, Cambridge, writes to us as follows:—"I am writing the life of Prof. Sedgwick, but I want much which I fail to find in the mass of MS. placed in my hands, especially letters from himself giving an account of contemporary persons and events. Can any of your readers help me in this matter?"

WE take the following from the New York *Nation*:—"For the English-speaking race, wherever planted, we should have supposed NATURE to be a sufficient scientific medium, and entitled to universal support. We are partly confirmed in this view by the quotations from NATURE in the first number of *Science*, a quarto weekly journal, edited by Mr. John Michels, and published at 229 Broadway, in this city. Nevertheless, the editor's statement that the enterprise has been begun 'after consultation with many of the leading scientists in this country,' and his list of co-labourers seem to point to a real want, and to entitle this new 'record of scientific progress' to a friendly welcome. Its present size is sixteen pages, including the advertising sheet. The opening article, on the United States Naval Observatory, is from the pen of Prof. E. S. Holden." We wish our new contemporary every success, and trust that it may be the means of spreading a wide interest in science on the other side of the water.

THE half-yearly general meeting of the Scottish Meteorological Society was held yesterday. The business was: (1) Report from the Council of the Society; (2) Proposed Inquiry by the Society into the Relation of Climates in Scotland to the Growth of Trees, by Sir Robert Christison; (3) Relations of Weather to Deaths from Scarlet Fever and Whooping Cough, in Thirty-one British Large Towns, by Dr. Arthur Mitchell and Alexander Buchan, secretary; (4) Anemometer for ascertaining the Direction of the Wind with reference to a horizontal Plane, by Alexander Frazer, M.A., optician.

PROF. A. H. CHURCH, late of the Royal Agricultural College, Cirencester, has begun a course of lectures on Agricultural Chemistry at the Wilts and Hants Agricultural College, Downton, near Salisbury. There are many characteristic features in the farming of the district, well illustrated on the extensive farm of the new college. These afford both valuable illustrations and important subjects of investigation to the agricultural chemist as well as to the botanist and geologists. We hope that this new institution, over which Prof. Wrightson presides, will occupy itself not only in agricultural teaching, but in agricultural research, and develop, after a time, into a "Versuch-Station" of no little value.

THE continued wet weather at Carlisle, which lasted without intermission from Monday evening to Thursday at noon, rendered it extremely difficult to do justice to one of the finest exhibitions ever held by the Royal Agricultural Society. Among the most important of the novelties was Mr. Darby's steam digger. This instrument is intended to supersede the steam-plough by producing at once a pulverising effect superior to that of the combined action of plough and cultivator, and equal to that produced by the spade. The idea is old, but up to the present time it has not been successfully applied. Mr. Darby's digging-machine consists of three sets of prongs of fourteen each, arranged on three cross-bars twenty-feet wide. Each cross-bar is worked independently and in succession by a separate crank-shaft. The earth is moved to the depth of six to ten inches, and by the action of the revolving crank-shafts the raised sod is pitched backwards and neatly inverted. The surface is left somewhat too flat for harrowing, but a second digging renders the work much more efficient. The greatest drawback to this ingenious machine lies in its weight. When charged with coal and water the engine and digger unitedly weigh fourteen to fifteen tons. Experiments in the trial fields showed that three-fifths of the power were absorbed in moving the implement over the ground. There were no new forage plants exhibited, and the stands devoted to manures and feeding-stuffs contained no articles save those with which we were familiar. In the live stock sheds the most interesting exhibits were the mountain-sheep peculiar to Cumberland and the adjoining counties. The Herdwick sheep are hardier than the Scotch black-faced breed. They are able to thrive on the poorest land imaginable, and manage to leave a good profit in the hands of the Dalesmen who own them. Thanks to the Herdwick race of sheep, the bad times of which we have heard so much are unknown in the Lake district. Another excellent breed, not often seen out of their own locality, which lies in West Yorkshire and East Lancashire, is the Louks. This race, unlike other kinds of sheep, is well suited to the damp and mossy lands lying between the hills of mountain limestone which form this part of England. Their faces are speckled, black and white, and both sexes are horned. They are readily distinguished from the Highland black-faced breed by the evidently better quality of their wool. A third race unfamiliar to the bulk of English farmers is the "Crag' or "Limestone" sheep, which occupies the highlands of the same district as the Louks. The crag-sheep are adapted for a dry and poor pasture, and can do without water. The louk and the crag-sheep therefore offer good instances of the adaptability of different races of animals to their environment.

THE Zoological Station established last year in connection with the University of Aberdeen, at Stonehaven, is at present in process of erection near Cromarty. The work will be carried on throughout August and September, and part of October, under the superintendence of George J. Romanes, F.R.S., and Prof. J. C. Ewart. Those desirous of taking advantage of the station are requested to communicate with Dr. Ewart, Dunskaith, Ross-shire.

THE Sydney papers state that some important gold discoveries have been made in the Bathurst district near Tuena, and that in one claim a bushel of broken quartz yielded two pounds of gold. A very rich gold-field has also been found at the Margaret River, in the Northern Territory of South Australia.

THE Executive Committee of the International Medical Congress for 1881 made their report to the General Committee of this Congress, which met at the College of Physicians on Tuesday last week. The officers of the Congress were proposed and nominated. The sections were agreed upon, and the treasurer, Mr. Bowman, announced that large subscriptions had already been received. It was agreed that the time of meeting of the Congress should be from August 3 to 9, 1881. The president of the Council of the British Medical Association stated that the Council of that body had postponed their meeting to the following week. It was also announced that the Congress would meet in rooms granted for the purpose by the University of London, the Royal Society, and the other learned societies meeting in Burlington House, so that the sections will be all practically under the same roof. The president of the Congress will be Sir James Paget, and there will be fifteen sections in all.

IT is intended to hold an International Congress of Commerce and Industry at Brussels, from September 6 to 11. M. Antoine Dansaert is to be the president, and the meeting will take place under the patronage of the King of the Belgians.

ACCORDING to the *Electrician*, a remarkable instance of telephony is exciting considerable interest throughout South Australia and among the scientific world in particular. By means of an improved telephone the Adelaide Post Office chimes have been clearly heard at Fort Augusta, a distance of 240 miles.

MR. G. F. H. MILNE, owner of the fossil forest recently discovered at Oldham, and referred to in NATURE at the time,

has offered to allow the Oldham Corporation to have care of it, and make a charge to visitors, the money to be applied towards a public museum. No doubt the Corporation will accept this handsome offer.

At the Rheims meeting of the French Association M. Gariel will give a public lecture on Radiant Matter, with Mr. Crookes' experiments, and M. Perier on the Law of Selection. The meeting of 1881 will be held at Algiers, and an excellent paper has been published in connection therewith by M. Macarthy, president of the Society of Natural Sciences of Algiers. This physicist settled in Algiers thirty years ago, and holds the position of librarian of the National Library of Algiers; in his *brochure* he reviewed all the different topics which might be submitted to the several sections of the Association.

A violent shock of earthquake occurred at Manila and throughout the Island of Luzon on July 18, which did immense damage, totally destroying several government buildings and other houses. Some of the native inhabitants were killed, but no Europeans suffered any injury. A slight shock was felt also on the 17th inst.

On July 14 the French Chamber of Deputies adopted a proposition of M. Lockroy, that a sum of 3,700,000 francs originally intended to rebuild the Palace of the Tuileries should be devoted to enlarge the national library, which will be quite isolated from other houses. The sanction of the Senate will be asked next session, but not a single representative having objected, the result is not dubious, and preparatory steps will be taken very shortly to execute this great measure of preservation and improvement.

In an interesting article on "Mistakes about Snakes," by Mr. Arthur Stradling, in the *Field* of the 17th inst., the author gives an *exposé* of the famous Indian basket trick, in which a boy is shut up in a basket and apparently put to death by sword-thrusts, but suddenly appears among the company uninjured. The narrative is too long for quotation, and we recommend our readers to obtain a perusal of the original.

The following is the title of the essay to which the "Howard Medal" of the Statistical Society will be awarded in November, 1881. The essays to be sent in on or before June 30, 1881. "On the Jail Fever, from the earliest Black Assize to the last recorded outbreak in recent times." The Council have decided to grant the sum of 20*l.* to the writer who may gain the "Howard Medal" in November, 1881. Further particulars or explanations may be obtained from the Assistant Secretary, at the office of the Society, King's College entrance, Strand, London, W.C.

M. Hervé-Mangon, the director of the Conservatoire des Arts et Métiers, has compiled a catalogue of the celebrated Vaucauson collection; it will be very shortly placed at the disposal of the public in the Portefeuille Industriel, a special library opened in the Conservatoire for the communication of designs and documents relating to industry. The course of public experiments is attracting an unprecedented number of visitors to the galleries. Every week a programme of the exhibits is posted on the walls outside the buildings.

The Manchester Scientific Students' Association is a busy society, as its Report for 1879 shows. It contains reports not only of various lectures and papers read at its meetings, but interesting accounts of the numerous excursions made by the members; these are occasionally illustrated, the illustrations being sometimes rather rude.

Supplement No. 5 to the U.S. *National Board of Health Bulletin* contains a report of the proceedings at a conference on Vital Statistics held at Washington on May 6 last. There is an interesting discussion on the subject of a Standard Nomenclature, with special reference to that adopted by the Royal College of Physicians of England; and appended is a very detailed nomenclature of ophthalmology and otology, by Dr. S. M. Burnett, of Washington.

Among the papers in the forthcoming number (vol. iii. No. 1) of the *American Journal of Mathematics* are the following:—"Regular Figures in n-Dimensional Space," by W. J. Stringham; "On the Algebra of Logic," by C. S. Peirce; "On the General Equations of Electromagnetic Action, with Application to a New Theory of Magnetic Attraction, and to the Theory of the Magnetic Rotation of the Plane of Polarisation of Light," by H. A. Rowland; "On Certain Ternary Cubic-form Equations," by Prof. Sylvester.

The additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus erythræus*) from India, presented by Mrs. C. Salvin; a Common Badger (*Meles taxus*), British, presented by Mr. Frank G. Haines; a Huanaco (*Lama huanacos*) from Bolivia, a Common Rhea (*Rhea americana*) from South America, presented by the Marquis of Queensberry; a Common Paradoxure (*Paradoxurus typus*) from India, presented by Col. Sturt; four Ring-tailed Coatis (*Nasua rufa*) from South America, presented by Lieut.-Col. J. A. Smith, 1st W.I. Regt.; a Common Hedgehog (*Erinaceus europæus*), British, a Greek Land Tortoise (*Testudo græca*), European, presented by Mr. L. C. Brook; two American Darters (*Plotus anhinga*) from Brazil, presented by Mr. Gerald Waller; a Goffin's Cockatoo (*Cacatua goffini*) from Queensland, presented by Miss Bartlett; two Red-legged Partridges (*Caccabis rufa*), two Common Buzzards (*Buteo vulgaris*), European, presented by Mr. W. H. St. Quintin; a Common Heron (*Ardea cinerea*), European, deposited; a Common Seal (*Phoca vitulina*), British Seas, two Japanese Pheasants (*Phasianus versicolor*) from Japan, a Bar-tailed Pheasant (*Phasianus reevesi*) from North China, purchased; a Burchell's Zebra (*Equus burchelli*) from South Africa, received in exchange; two Lions (*Felis leo*), an Eland (*Oreas canna*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

The Comet of 1668.—There is one point in the history of this comet which we do not remember to have seen mentioned since its supposed reappearance in 1843 revived the attention that was directed to it early in the last century, and it is one which, if accepted, bears materially upon the question of identity. Pingré has no reference to it in the account of the comet of 1668 in his "Cométographie." In the report of the observations made by the French Jesuit Valentin Estancel at San Salvador, in the *Philosophical Transactions*, No. 105 (1674, July 20), which is stated to be a translation from the *Giornale de' Letterati*, No. 9, published at Rome in September, 1673, we read after the description of the evening observations commencing March 5, 1668:—"It may be taken notice of that a month before, upon a report that a comet had been seen towards the morning in the horizon of the rising sun, and certain Carmelites that live upon a hillock of the said town having affirmed that they had observed it several times, our P. Estancel began to doubt whether the comet he saw were not the same which, more swift than the sun, according to the succession of the signs, might within that time have got clear of the solar rays; and his suspicion grew the stronger because the head was then turned towards the sun and the tail towards the west, opposite to the same." But if the comet of 1843 were in perihelion near the time which Henderson found it necessary to assume in order to satisfy the indications of his Goa chart, it would not have preceded the sun in the first week in February, but would have had considerably greater right ascension, so as to be visible only in the evening. Henderson's direct orbit, however, which upon the whole accords much better with his data, would place the comet in R.A. 311°, Decl. $-7\frac{1}{2}°$ on February 5, at 17h. San Salvador time, so that it would precede the sun, which was then in R.A. 320°.

If this circumstance is adverse to the identity of the comets of 1668 and 1843 there is another which would rather tend to support it, were it not that there appears to be an oversight in the record. Zach in an article, "Ueber einige unberechnete Cometen, deren Bahnen man vielleicht noch auffinden und berechnen könnte," in vol. xxvii of his *Monatliche Correspondenz*, refers to the comet of 1668, and, after mentioning the observations of Cassini and others, he adds that in the *Philosophical Transactions* for 1668 there is an observation of a comet, which places it on March 7 in longitude 16°, with 20° 30′ south latitude, and he asks, "Ist diess die *Cassinische Spina?*" referring to the title of the tract in which Cassini gave his observations of the phenomenon in March, 1668, viz: "Spina, Celeste meteora osservata in Bologna, il mese die Marzo 1668" (Bologna, 1668 in fol.). If we suppose the comet of 1843 to have arrived at perihelion February 24·284, Greenwich time, at 8 p.m., on March 7, its place would have been in longitude 16°·0, with 20°·4 south latitude, as observed, and the agreement gives an importance to the reputed observation, if it could only be traced. It was first remarked by Schumacher (*Astron. Nach.*, No. 484) that the observation mentioned by Zach does not occur in the *Philosophical Transactions*: his words are: "Diese Beobachtung 1668 März 7, Länge 0° 16°, südliche Breite 21½° steht nicht in dem von Herrn v. Zach angeführten Bande der *Philos. Transactions* und, wenn das Register der *Phil. Transact.* genau ist, in keinem der ersten 70 Bände." We find on a careful examination of the volumes or numbers of this work containing reference to the comet of 1668 as indicated in Maty's Index, that there is no such observation recorded. There are two articles bearing upon this comet: (1) in vol. 3 for 1668, in No. 35, May 18, 1668—which gives a translation of Cassini's description of its appearance, from the Italian, and a notice of its having been observed at Lyons, Toulouse, Toulon, &c., though not at Paris, and (2) in vol. 9 for 1674, in No. 105, July 20, 1674 (though not occurring in the list of contents to this number on the first page): this second notice chiefly refers to the observations of P. Valentin Estancel in Brazil, taken from *Giornale de' Letterati*, September 31 (*sic*) 1673—a journal printed at Rome.

Perhaps some of our readers may have opportunity of making further search in the libraries for information relating to the comet of 1668, though we are aware that much was done in this direction in 1843. It would be of interest more particularly if the observation which Zach would appear to have somewhere met with, could be traced.

VARIABLE STARS.—The following times of maxima and minima of variable stars during the ensuing two months are extracted from the ephemeris prepared by Prof. Winnecke for the first part of *Vierteljahrsschrift der astronomischen Gesellschaft* for 1880 (15. Jahrgang):—

Aug. 2.	S Ursæ maj., *min.*	Aug. 30.	R Comæ.
3.	R Leonis.	Sept. 2.	U Virginis.
4.	S Sagittarii.	3.	R Draconis.
11.	S Pegasi.	5.	W Scorpii.
12.	R Sagittarii.	8.	R Virginis.
15.	V Tauri.	9.	R Arietis, *min.*
16.	R Persei.	10.	R Vulpeculæ.
18.	R Ursæ maj.	16.	R Ophiuchi.
21.	T Herculis, *min.*	19.	R Camelopardi.
24.	S Vulpeculæ, *min.*	20.	T Virginis.
25.	S Herculis, *min.*	20.	R Aquilæ, *min.*
28.	R Aurigæ.	21.	S Cephei, *min.*
28.	R Sagittæ, *min.*	21.	S Vulpeculæ.
29.	S Aquarii.	29.	R Bootis, *min.*

Prof. Winnecke has August 2 for the date of approaching maximum of *Mira Ceti*; the formula in Prof. Schönfeld's last Catalogue gives August 10·8; perhaps some reader of NATURE may be able to say, in due course, when the maximum actually occurs. The amount of perturbation by the formula for Epoch 15 = + 37d·3.

M. Ceraski of the Moscow Observatory draws attention to an object which evidently deserves close observation. On June 23 he remarked that the *Durchmusterung* star R.A. oh. 49m. 39s., Decl. 81° 5′·6, 7·5m., increased from 9m. to about 7·5m. between 17h. 40m. and 19h. 35m. Moscow sidereal time. Carrington estimated this star 7·9. Schwerd observed it four times, and his estimates of magnitude are strongly indicative of variability; thus it is called 8 on December 11, 1827; 6·7 on March 11, 1828; 8 on the following night, and 10 on May 12 in the same year. It is No. 130 in Carrington's Catalogue, the place for 1855·0 being in R.A. oh. 49m. 38·9s., Decl. 81° 5′ 33″. The star was also observed by Lalande in March, 1790, as an eighth magnitude (Fedorenko 145).

BIOLOGICAL NOTES

THE EVOLUTION OF DIBRANCHIATE CEPHALOPODS.—Dr. J. Brock, in the last number of Gegenbaur's *Morphologisches Jahrbuch* (vol. vi. p. 185), gives his reasons for dissenting from von Ihering's conclusions on this subject. He has dissected spirit-preparations of many of the principal genera, and he discusses the evidence derived from the shell, the funnel, the muscular system, the radula, the nervous system, and the vascular excretory and reproductive systems. Three anatomically well-marked phyla or groups of genera are made out, of which the Œgopsidæ are the most ancient, and from this group the other two—the Myopsidæ and the Octopods—are derived. The Œgopsids he further divides into two groups—the Ommastrephidæ and the Loligopsidæ, the comparative antiquity of which cannot yet be determined; they are of great interest because they both show important connections with the two other phyla. The Œgopsid forms are primarily true Belemnites, and later developed into the Sepia type, from which stock also the decapods with simple horny shells sprang independently. The octopods, the most highly differentiated phylum, but with an organisation showing a very early origin, and branching from the main type, afford some evidence of relationship to the type of Loligopsis, although they cannot be regarded as having originated from them. Most probably they had a common origin from the primordial dibranchiate form with ten arms. Dr. Brock relies considerably on the oviduct being double in the Œgopsidæ, and single (by reduction) in Myopsidæ; but unless he can support his theory by more developmental facts it can hardly attain sufficient credit for practical use in classification.

ON A CASE OF APPARENT INSECTIVORISM.—Prof. Baillon, at a recent meeting (April 7) of the Linnean Society of Paris, read the following notes:—*Peperomia arifolia*, Miq., of which the variety argyreia is cultivated in so many greenhouses, has the leaves more or less deeply peltate. I have seen stalks on which the peltation on certain leaves was so exaggerated as to show on a cross-section a depth of nearly four centimetres. When the concave stalks take a suitable direction, water, principally that from sprinkling, would accumulate and rest in these receptacles, so well prepared to preserve it. Many small insects would fall into this water and be drowned. Last year, when the season was warm and when the windows of the house were often open, the number of insects was very considerable, and these, soaking in the water, gradually fell into decay, and it was remarkable that there was during this not the least sign of any putrescent odour. Those who believe in the doctrine of insect-eating plants may perhaps in this be led to find an argument favourable to such theories. They will add that the variety of colours so strikingly seen in these leaves constitutes the agent of attraction for the insects to come and be devoured. Three reflections, each of a different sort, here present themselves: 1. Is it not remarkable that the exaggerated peltation of these leaves is in this case accompanied by an apparent insectivorism, and that the leaves of the plants known up to this by botanists as carnivorous owe their sac-like, horn-like forms only to an excessive peltation of their limb, as we demonstrated in the evolution of the leaves in Sarracenia (*Comp. rend.*, lxxi. 630)? 2. How can it be considered as a proof of insectivorism, that plants such as the Urticularia grow better in a fluid containing albuminoid compounds, when other plants grow equally favourably in the same kind of fluid, which latter are never for a moment thought of as carnivorous? 3. How do the chief priests of our science reconcile the two ideas, that the surface of the leaves of plants are unable to absorb pure water in contact with them, and that the same surface daily absorbs water charged with albuminoid substances and the like?

INTESTINAL WORMS IN THE HORSE.—H. Krabbe has published in the *Oversigt over det K. Danske Videnskabernes Selskabs*, No. 1, 1880, p. 33, an interesting account of the occurrence of intestinal worms in the horse. As this animal is spread over the greater part of the habitable world, and under conditions of life very varied, it might be supposed that, like man and the dog, it would not be equally affected with these parasites, nor with the same species. For to determine with some degree of accuracy the worms which in Denmark are found in the intestinal

canal of the horse, Mr. Krabbe examined, during the last four years, the bodies of one hundred horses which were brought for anatomical purposes to the Veterinary College at Copenhagen, between the months of September and April in each session. In these horses he found *Tænia perfoliata*, 28 times; *T. mamillana*, 8 times; *Ascaris megalocephala*, 16 times; *Strongylus armatus*, 86 times; *S. tetracanthus*, 78 times (in 67 horses out of 86); and *Oxyuris curvula*, twice. Of *T. perfoliata* the number found was mostly less than 25; sometimes it was over, and twice between 100 and 200 were found, while once no less than 400 were met with. In general they were lodged in the cæcum. *T. mamillana* of Mehlis, a species overlooked by Dujardin and most French writers on the subject, was described and figured by Gurlt in 1831; generally less than 25, but sometimes up to 72, were met with, mostly in the anterior part of the small intestines (*T. plicata*, R., was never met with). The Ascaris never occurred in larger numbers than 11. *S. armatus* was never met with in the small intestine; in the cæcum it was common; much less so in the first portion of the colon, where very fine specimens of a dark bluish red colour were found; generally the number met with was below 25, but once nearly 200 were found. Of 1,409 samples, 1,029 were females and 380 males. *S. tetracanthus* was found in the cæcum and throughout the colon. The literature of this subject would appear to be very scanty, and the author hopes that the attention of veterinary surgeons in other parts of the world may be attracted to this subject. Ample opportunities of following it up exist in British India, America, and the Cape of Good Hope district.

THE DOMESTICATION OF DEER.—A very interesting correspondence is published in the *American Naturalist* for June between Mr. Brown, the superintendent of the Philadelphia Zoological Gardens, and Mr. J. D. Caton. It relates chiefly to the question of the domestication of species of deer. Of the twelve species kept in the Philadelphia Gardens the mule deer (*Cervus macrotis*) have bred during 1878 and 1879; of five fawns one died when two days old; the other four, though most carefully nursed and fed with astringent food, as well as supplied with iron water and gentian powders, &c., all died of a diarrhœa caused by malignant disease. Five specimens of moose-deer and eight of caribou died at periods varying from three months to two years and five months in the moose and not beyond nine months in the caribou from hypertrophy of the heart. The pronghorn (*A. americana*) all died speedily from diarrhœa or hypertrophy of the heart; change of food and tonics seemed to have no effect upon them. Of ten or twelve individuals none lived more than fifteen months. The wapiti and common deer (*C. virginianus*), however, have done well, and several fawns were raised of *C. campestris*, *C. aristotelis*, and *C. dama*. Of *C. leucurus* the Gardens possessed but a single specimen. In the case of the mule deer Mr. Brown is disposed to account for the mortality by the difficulty of supplying them with a sufficient amount of their proper (arboreal) food, which has to be replaced by dry food and grass. Mr. Caton, writing from Ottawa, Illinois, states that he had lost the last of his stock of mule deer and also of *C. columbianus*, and that he is satisfied that they cannot be successfully domesticated in his grounds. He concludes that they get at something which does not agree with them; indeed all his experiments with ruminants, *feræ naturæ* whose natural habitat is confined to the United States west of the Missouri River, have proved failures. Mr. Caton has succeeded well in hybridising the Virginian deer with the Ceylon deer and the Acapulco deer. The hybrids seem to be perfectly healthy and prolific, several of the hybrids from the Virginian deer and Acapulco buck having borne perfectly healthy twin fawns. On some of the hybrids the metatarsal gland is wanting, and on some it is present, while some have it on one hind leg and not on the other.

THE FIDDLER CRABS.—Mr. J. S. Kingsley, in a further contribution to the *Proceedings* of the Academy of Natural Sciences of Philadelphia, revises the genus *Gelasimus*, and as a result he makes a great reduction in the number of species. This has been done, not with any desire to overturn the work of others, but as the result of a study of the forms known all over the world. The range of many species is greatly extended. He refers the genus to the family Macrophthalmidæ of Dana; and it is characterised by its rhomboidal carapace, broad in front, elongated eye-stalks, and a great inequality of the chelipeds or nipping feet of the male. The latter is the most constant character of value. The species fall into two groups according as the front between the eyes is very narrow or wide; and the latter have males with a five-jointed or seven-jointed abdomen.

ORGANS OF DEEP-SEA ANIMALS.—During his researches on the fauna of the Caspian Sea, M. O. Grimm has studied the modifications which are undergone by the organs of sense in animals which inhabit great depths. Among them several have well-developed organs of sight, which seems to prove that even at very great depths light is not completely absorbed. Such are the Caspian *Mysis*, the *Gammaracanthus caspius*, several *Bæckiæ*, and others, but on the contrary, there are at the same depths many species whose eyes are quite atrophied, and in these species we observe that other organs of sense receive a greater development. Such is the case in *Niphargus* and *Onesimus*. But, whilst *Niphargus caspius* bears well-developed organs of smell and of touch on its antennæ, in *Onesimus*, which, as well as the former, has but rudimentary eyes, only organs of touch are to be found on its jaws. M. Grimm explains this last difference by the circumstance that the former species usually remains in water, whilst *Onesimus* likes to remain in the mud at the bottom, where it searches for its food very much like a mole.

CHEMICAL NOTES

IN the *Journal* of the American Chemical Society, vol. ii., Mr. P. Collier describes a new mineral from the Champlain iron region, which resembles thorite in its physical properties, but differs therefrom in containing a relatively large quantity of uranium. Analysis showed 9·96 per cent. of uranic oxide, and 52·07 per cent. of thoric oxide, with 19·38 per cent. of silica, the remainder consisting of oxides of lead, aluminium, iron, calcium, magnesium, and sodium, with moisture and combined water.

MR. COLLIER gives an account, in the same journal, of experiments he has made, which seem to point to a new possible source of crystallisable sugar. He finds that the juice of various varieties of fully ripe sorghums contains from 13 to 15 per cent. of sucrose, with 1 or 2 per cent. of glucose.

SPECIAL attention has been recently given to the liquids included in the microscopical pores of certain minerals, and it has been shown by Zimmler that these pores contain not only water, but also sometimes carbonic acid. Prof. Karpinsky publishes now in the *Memoirs* of the St. Petersburg Society of Naturalists the results of his experiments on the liquid contained in the pores of the Uralian amethyst. The mineral having been broken in a tube filled with mercury, the fluid immediately evaporated, and being brought in contact with a solution of oxide of barium, proved to be carbonic acid (1·07 cubic millimetres at 30°). The pressure under which the carbonic acid was liquefied may be estimated as seventy-three atmospheres, which would correspond to a pressure of a column of water 2,336 feet high.

AT the meeting of the French Academy of May 17, 24, and 31, notes were read by MM. Ditte and Berthelot, on the cold produced by the action of acids on hydrated salts, *e.g.*, hydrochloric acid on hydrated sodium sulphate. The action is regarded as complex: an exothermal chemical reaction occurs in accordance with Berthelot's "law of maximum work," but unless the products of this action are totally insoluble, secondary changes take place; these changes are chiefly conditioned by the amount of heat evolved in the primary action. In the special cases in question the heat disengaged in the chemical change is less than the heat absorbed in the liquefaction of the water of crystallisation which separates from the hydrated salt, hence the sum of the heat changes is negative.

THE densities of chlorine, bromine, and iodine at high temperatures cannot yet be regarded as determined. Victor Meyer, in a recent paper in the *Berliner Berichte*, admits the justice of Crafts' criticism of his determinations of temperature (see NATURE, vol. xxi. p. 561, letter by Dr. Armstrong); his latest results give for iodine at about 1,050°, a density equal to I_2, and at an extremely high temperature (exact numbers not yet given), a density of 4·55, which nearly corresponds with that calculated on the supposition that at this temperature the iodine molecules are entirely dissociated into atoms (calculated number = 4·39). Meyer and Crafts, working by Dumas' method, and using an iodine thermometer, find the density at 1,468° to be 5·05 (calculated for I_2, 5·83; for I, 4·39). The density for free chlorine seems to be normal (Cl_2), even at extremely high temperatures; but if the chlorine be produced in the vapour-density

apparatus—by heating platinous chloride—the density at about 1,400° agrees with that calculated for $\frac{3}{2}Cl_2$. Bromine produced by heating platinic bromide in the apparatus gave a density equal to $\frac{3}{2}Br_2$ at about 1,400°. Meyer and Crafts published numbers in *Comptes Rendus*, which gave for free bromine at about 1,400°, a density between that calculated for Br_2 and that for $\frac{3}{2}Br_2$, viz., 4·43 (Br_2 = 5·52, $\frac{3}{2}Br_2$ = 3·64). Meyer's vapour-density method is somewhat adversely criticised in the last number of the *Berliner Berichte* by Pettersson and Ekstrand, who give numbers which they regard as proving that the method does not give good results at high temperatures when the substance under examination is a solid. Solids, they say, condense on their surfaces considerable quantities of air, and when the solid is thrown into the highly-heated apparatus this air is evolved, is measured with the air representing the volume of the gasified substance, and so vitiates the result. It is certainly worthy of note that both Crafts and Meyer obtained a normal density for chlorine—the only halogen element gaseous before being brought into the apparatus—at the highest temperature at which they experimented. Pettersson and Ekstrand regard Dumas' method as the only altogether satisfactory one; they describe a modification of this process. It is to be remarked that the density of mercury vapour—which chemists generally regard as consisting of atoms—is shown by Meyer's results to be remarkably constant through a large range of temperature.

ALEXR. NAUMANN has arranged Meyer and Crafts' results on the density of iodine vapour in a table (in the *Berichte* for June 14) showing the percentage dissociation of iodine molecules at various temperatures; the results are in keeping with the deduction made by Naumann from the kinetic theory of gases, viz., that equal temperature-intervals correspond to a regularly increasing amount of dissociation up to 50 per cent. but after this to a decreasing amount of dissociation. Naumann regards this agreement between the theoretically-deduced, and the actual results as affording evidence in favour of the correctness of Meyer and Crafts' measurements of high temperatures. This subject is likely to receive a considerable amount of attention, as it has an all-important bearing on the question of the elementary nature of the so-called elements. Deville and Troost, in a recent number of *Compt. Rend.*, estimate the boiling-point of zinc as 940°, which is 100° lower than the number generally accepted on the evidence of older determinations by the same authors.

CHEMICO-PHYSICAL investigation has lately led to some important results. Schneider, in a recent number of the *Berliner Berichte*, has shown that any solution of malic acid containing more than 34·24 per cent. of the acid rotates the polarised ray to the right, whilst a solution containing less than this amount is lævorotatory. Solutions of sodium malate are dextrorotatory when of greater strength than 47·43 per cent., but lævorotatory when containing less than this quantity of the salt.

SOME little time since Brühl published—also in the *Berichte*—an important paper on the connection between the refraction equivalents and the chemical structure of carbon compounds; he showed that if the refraction equivalents are calculated for a number of carbon compounds, by the help of Cauchy's formula, for a ray of infinite wave-length, a distinct connection can be seen to exist between the numbers thus obtained and the number of "doubly-linked" carbon atoms in the compound. A further communication by the same author appears in a recent number of the same journal. The refraction equivalent of a carbon compound is equal to the sum of the atomic refractions of its constituent elements; the value of the atomic refraction of carbon varies according to the "linking" of the carbon atom—for every pair of doubly-linked carbon atoms present in a compound, the refraction equivalent of the compound is greater by 2 than that calculated by the use of the number expressing the ordinary atomic refraction of carbon. The atomic refraction of oxygen when doubly linked to carbon is 3·29, when in the group OH, or when linked to two atoms, it is 2·71. The atomic refraction of the halogen elements is constant. Brühl concludes that the atomic refraction of a monovalent element is independent of the atom-linking of its compounds, but that this statement does not hold good for polyvalent elements.

IN connection with this work of Brühl, the recent experiments of Prof. Janovsky (*Wien. Akad. Anz.*, June 3) are of interest. According to Janovsky the linking of carbon atoms is of subordinate influence in determining the refraction equivalents of carbon compounds, for isomers with similar linking have unequal refractive indices. In homologous series a similar difference of refractive indices corresponds to an equal difference o groups only where the series belong to similarly saturated hydrocarbons (alike in position). The refractive power of unsaturated hydrocarbons is greater than that of saturated. Lastly, the author shows that the determination of refraction-coefficients of solid bodies from their solutions is unreliable, as the refractive power depends on the state of aggregation.

IN the *Annales Chim. Phys.* Long shows that a connection exists between the velocities of diffusion and other physical constants, and the composition of various salts; thus the values of the velocity of diffusion, molecular volumes, and electric conductivity, are in the same order for the chlorides, bromides, and iodides of the alkali metals.

STÆDEL publishes in the *Berichte* the first part of an investigation on the vapour-tensions of substituted halogen derivatives of ethane; his researches, which are not however yet completed, seem to show that the increase of vapour-tension for 1° (between 400 mm. and 1,060 mm.) is equal for a bromo-derivative and that chloro-derivative which contains, in place of one bromine atom, two chlorine atoms linked to one carbon atom: *e.g.* $CH_3 - CH_2Br$ and $CH_3 - CHCl_2$: $CH_2Cl - CH_2Br$ and $CH_3 - CCl_3$, &c.

J. VARENNE continues in *Compt. rend.* his researches on the passivity of iron, which have been already noticed in NATURE. He finds that if a piece of iron be immersed in nitric acid of sp. gr. 1·325, oxides of nitrogen are evolved for a few moments; the escape of gas, however, suddenly ceases; after a time it begins again at one point of the metallic surface, spreads over the entire surface, again ceases, once more recommences, and so on intermittently. If an iron tube be very partially immersed in strong nitric acid, and after passivity is established, the passive part be placed in weaker acid for a time, it is found that by then slowly immersing the tube further in the acid the whole becomes passive, but that this passivity is very easily destroyed, *e.g.*, by shaking the tube. The passivity is less the more dilute the weaker acid, the rougher the metallic surface, and the greater the diameter of the iron tube.

IN the *Berliner Berichte* experiments are detailed by Reinitzer and Goldschmidt, whereby these chemists have succeeded in preparing the compound P_4O, about the existence of which there has been much difference of opinion. P_4O is a reddish-coloured amorphous substance produced by the action of phosphorus, or of zinc, on $POCl_3$.

HOPPE-SEYLER publishes in the *Zeitschrift f. physiol. Chem.* a continuation of his work on chlorophyllan, a crystalline substance closely resembling chlorophyll, obtained from green grass. By treatment with alcoholic potash, chlorophyllan yields, amongst other products, an acid characterised by giving a splendid purple-coloured ethereal solution, which exhibits very marked rose-red fluorescence. For this compound—$C_{20}H_{34}O_3$—Hoppe-Seyler proposes the name of *dichromatic acid*. The absorption spectrum of the acid in ethereal solution is marked by two bands between C and D, whilst the spectrum of the fluorescent light from the same solution exhibits two bright bands in exactly the same positions.

ACCORDING to Adolf Mayer's experiments described in the *Berliner Berichte*, oxygen has no direct influence on fermentation. The addition of potassium-hydrogen tartrate to a strong syrup containing yeast causes the yeast cells to grow rapidly, and fermentation to proceed with ease.

THE meeting of the French Academy of Sciences, held on July 5, presented some interesting incidents which are not likely to appear in the *Comptes rendus*. A very interesting discussion took place between M. Wurtz and MM. Dumas and St. Claire Deville on the occasion of the presentation of a memoir on the density of vapour of iodine by M. Troost. M. Dumas and M. St. Claire-Deville asserted that it was impossible to accept the idea of a dissociation of vaporised iodine at a high temperature, as no permanent alteration resulted from this alleged change in the composition of this substance. M. St. Claire Deville said he was opposed to all theories of molecules and atoms, as science had only to deal with facts, and not with mere assumptions or speculations. It might be supposed that the coefficient of expansion of iodine increased rapidly with increase of temperature. M. Wurtz argued that the diminution of the density was too considerable to be accounted for otherwise than by a *dedoublement* of molecules. All the speakers agreed that these phenomena, which are very curious, should be carefully investigated with

increased attention and care. M. Wurtz having resumed his seat, M. Dumas presented a letter from Mr. Crookes, in which he summarises his theories of radiant matter, and submits them for discussion before the French Academy. After having explained the Crookesian view of the fourth state of matter, M. Dumas added that he felt confident these assumptions would be the occasion of discussions of the same character as that which the Academy had just witnessed.

PHYSICAL NOTES

HERR DORN of Breslau has published a fresh series of experiments on the propagation of electricity by current water in tubes, and allied phenomena (*Wied. Ann.*, Nos. 4 and 5). In agreement with Helmholtz's theory, he finds the electromotive force from current water in capillary tubes independent of the cross section and the length of these. The value of the "electric moment" of water and glass (3·936 Daniell) deduced from this electromotive force corresponds nearly to that deduced by Helmholtz from Quincke's observations on the propagation of water in glass tubes by the electric current. Observations of the electric current produced by water flowing in capillary tubes lead to a somewhat smaller value. For wider tubes (within pretty wide limits) the current strength, with a given mean velocity of the streaming water, proves empirically to be nearly proportional to the radius of the tube. Traces of a sliding of the water on the glass-wall may perhaps co-operate in producing the variations of electromotive force observed in course of time. Through motion of material particles in a liquid, therefore, an electric current arises.

THE diffusion of salts in aqueous solution has been investigated by Herr Long (*Wied. Ann.*, No. 4), by a method similar in principle to that of Schuhmeister (though different in detail), viz., making a continuous water-current flow over the salt solution and measuring the amount of diffusion by the quantities of salt that pass over in given times. Various interesting relations were found, *e.g.*, the chlorides, bromides, and iodides of the alkali metals form a series, in which NH_4 stands between K (the higher) and Na; and KCl, KBr, KI, and KCy have nearly the same velocity of diffusion. Such is the case also with the corresponding NH_4 and Na salts and with the chlorides of the bivalent metals Ba, Sr, Ca, and Mg, the nitrates, and the sulphates. It seems generally that those salts which diffuse most quickly also conduct best in aqueous solution. Salts with large molecular weight and volume seem to diffuse most easily, while among the waterless salts those which absorb most heat in dissolving or (the same thing) whose molecules, through the work done, finally reach the finest state of division, have the greatest velocity of diffusion. The chlorides of the alkalies stand in the same series with regard to molecular volumes, velocities of diffusion, conductivity, and absorption of heat. This is the case, too, with the corresponding bromides and iodides. Cyanide of potassium behaves as to diffusion and conductivity exactly like the chloride, bromide, and iodide of the metal. In the second group (nitrates) the order is the same as to conductivity and diffusion; but with regard to molecular volumes and heat-absorption the salts form a special series. In the group of sulphates the individual salts have the same order as to diffusion and conductivity, but the values for molecular volume and heat of solution are quite irregular; indeed as regards velocity of diffusion and absorption of heat the waterless salts seem to stand in inverse order. These results are fully discussed by Herr Long.

A CURIOUS physical phenomenon has been lately described by Dr. Grassi (*Reale Ist. Lomb. Rend.*, f. viii. and ix.). An apparatus is formed of three concentric vessels with an annular space of about two centimetres between the first and the second, and the second and the third. The outer space is filled with oil, the next with water. The oil is heated by a gas furnace to a little over 100°, and the water boils. Then hot oil, at *e.g.*, 150° is poured into the central space. This quickly cools to a temperature close on 100°. Dr. Grassi found that the central oil cooled more rapidly the higher the temperature of the outer oil; and with more delicate apparatus (in which the vaporised water was conducted and returned, and the outer oil kept at any required constant temperature) he arrived at definite numerical results, which he tabulates. With the outer oil at a mean temperature of 129°·9, *e.g.*, the time of cooling of the inner oil from 130° to 110° was 49s.; when the former was 105°·1, the latter was 57s. Alcohol and ether gave more decided results. The maximum difference was got with ether; the outer oil being at 57·5°, the inner took 25s. to cool from 57° to 50° (7 degrees); whereas the former being 39·3°, the latter became 39·5s. In all the experiments the cooling of the inner oil commenced at a temperature little above the maximum of the external oil. When the outer oil is at a higher temperature, at a certain point the heat begins to prevail which is transmitted directly from the outer to the inner oil. An analogous phenomenon (to which Dr. Grassi refers) was that of some members of the Accademia del Cimento, who found that water in a vessel surrounded by ice cools more rapidly if the ice be heated to accelerate fusion.

DR. J. PULUJ lately communicated a paper to the Scientific Club of Vienna on "Radiant Electrode-matter," in which he traverses the researches of Crookes, Hittorf, Goldstein, and others upon the phenomena of electric discharges in high vacua. He maintains at the outset that the discharges of "radiant matter" observed by Crookes at the negative pole are not residual gas at all, but are particles of metal torn off from the surface of the pole. He thinks this proved by the mirror-like deposits of metal that are formed on objects interposed in the path of the discharge. That aluminium in this way forms no mirror is a difficulty in the way of this theory; but Dr. Puluj gets over this by remarking that the cause of this lies in the chemical constitution of the metal, and that the particles of an aluminium electrode fly round so far that they deposit themselves on the electrode! All the magnetic effects of these discharges Dr. Puluj regards as explainable by ordinary electro-magnetic laws, assuming that a stream of electrified matter acts as an electric current; but he apparently is not acquainted with the theory put forward by Maxwell on this point. Dr. Puluj has also constructed what he calls an *electrode-lamp*, which gives a bright light when worked by an induction-coil capable of affording a spark of 10 cm. length. In this lamp the radiant discharges of electrode-matter are concentrated upon a piece of carbon which glows with a white heat, but remains unchanged and unconsumed.

DR. CUSCO, ophthalmic surgeon in one of the hospitals of Paris, has invented a lens of variable focus, in which the pressure of a column of water or other transparent liquid is made to alter the curvature of the flat faces of a cylindrical cell of brass closed with thin glass disks. The pressure can be regulated by a manometer gauge to any required degree within the limits of working. It is said that the lens gives a sharp, well-defined focus. It is constructed for Dr. Cusco by M. Laurent.

M. HENRI BECQUEREL continues his researches on the magneto-optic properties of gases. He has recently examined the gases oxygen, nitrogen, carbonic dioxide, nitrous oxide, and olefiant gas, and finds that, except in the case of oxygen, the magnetic rotation of the plane of polarisation due to a field of given intensity varies inversely as the square of the wave-length of the ray, as is the case with solids and liquids. In an older research of Becquerel's it was shown that for non-magnetic solids and liquids the rotation R was proportional to a function of the refractive index n, very nearly represented by the expression $n^2(n^2 - 1)$; or, in other words, the quantity $\frac{R}{n^2(n^2 - 1)} = c$. For all non-magnetic solids and liquids the value of c lay between 0·26 and 0·59. In the case of gases in which the rotation is but a ten-thousandth part of that of most solids or liquids the same result holds good, and the values of c for gases fall between 0·26 and 0·59. The above law, that the magnetic rotation is *inversely* proportional to the square of the wave-length, implies that violet rays are more rotated than the red; or, in other words, that there is a positive dispersion. In the case of oxygen it is found that the red rays are rotated more than the green, affording an inverse or *negative* dispersion. This is the more curious as oxygen gives a positive rotation as if it were a diamagnetic body. In fact, Becquerel remarks, oxygen behaves as if it were a mixture of a magnetic and a diamagnetic body, the magnetic having small negative rotation and great negative dispersion, the diamagnetic having great positive rotation and small positive dispersion.

GEOGRAPHICAL NOTES

IN a private letter addressed to Herr von Hesse-Wartegg, the well-known explorer, Dr. Nachtigall, writes from Berlin:—"The German African Society (Deutsche Afrikanische Gesellschaft) has at the present moment not less than six different expeditions travelling through Central Africa. The large funds necessary for the outfitting of these numerous travellers are raised partly

through private subscription, partly through subsidies of the German Government. Among the travellers I may name (1) Dr. M. Buchner, who, starting from San Paolo de Loanda in an easterly direction, may have already reached the large lakes of the Upper Nile or the Upper Congo; (2) Dr. Oscar Lenz, who is on the way from Marocco to Timbuctoo, whence he will proceed to Senegambia; (3) a large expedition, comprising Dr. Böhm, von Schöler, De Kayser, &c., which will establish a station near the Tanganyika lake, in connection with the stations of the International Association; (4) Gerhard Rohlfs and Dr. Stecker will soon proceed to Abyssinia, and thence the latter through the Gallas country to the sea-coast; (5) Dr. Pogge, together with several other travellers, will shortly start from San Paolo de Loanda for the interior, to establish a German station in the neighbourhood of the Muate Janvo, about in the middle of the Continent; finally (6) Herr Flegel will follow the course of the Binué upwards, and explore the sources of that river." The German African Society has certainly developed under the presidency of Dr. Nachtigall a very unusual activity, and it is only to be hoped that these great efforts in the interest of the exploration of Africa may have good results.

THE French journal *L'Exploration* has much improved recently; its reports of geographical societies in all parts of the world are specially valuable. Its value would be still greater if it would aim at greater originality, and display more enterprise in the collection of news. It rarely gives any authorities for its numerous notes, thus minimising their value; and too much space is devoted to the translation of long articles from the *Times* and other popular sources. This may perhaps render it interesting to the general French public, but greatly detracts from its scientific and international value. However, if it goes on improving in the future as it has done during the last few months, it will ultimately become a really valuable geographical organ.

THE new number of *Le Globe* contains a useful account of geographical work in Central Asia, in 1878–1879, contributed by M. Vennikof.

IN view of the present importance of Asterabad, Her Majesty's Consul opportunely gives a brief geographical description of the province. It is situated in the south-east corner of the Caspian Sea; its inhabitants do not exceed 45,000, and the town can only boast of 8,000 souls. It is bounded on the south by the high range of mountains which separate the Caspian provinces from the other parts of Persia; on the north it is bounded by the Atrek as far as Chat, at the confluence of that river and the Sombar, while beyond that point the position of the boundary is doubtful. The west is bounded by the Caspian Sea and the province of Mazanderan, and in the east it adjoins the province of Meshed. Gez, Molla Kellé and Gumush Teppé are the only ports in use. The province is well-wooded, and is watered by numerous mountain streams. Its inhabitants belong to the Kajar tribe, of which the Shah is the personal head. The fertility of the soil is great, and the timber in the forests is magnificent, but unfortunately there are no roads worthy of the name.

M. BOUTHILLIER DE BEAUMONT, the President of the Geneva Geographical Society, has just published a pamphlet entitled *Choix d'un Méridien Initial Unique*.

THE *Colonies and India* publishes an interesting summary of a plan which Mr. G. J. Morrison, the engineer of the short-lived Woosung railway, has sketched for the restoration of the Grand Canal, which at present is usually impassable in places. The essential point in his scheme is the substitution of proper locks for the wasteful sluices now in use, with of course more extensive works at the crossing of the Yellow River.

THE same paper states that the Legislative Assembly of the Transvaal has before it a measure providing for a trigonometrical and geological survey of the country, in the course of which it is expected that abundant mineral wealth will be proved to exist in the colony.

ON July 13, at the end of the French legislative session, the Minister of Marine and the Colonies presented to the Lower House a credit of 1,300,000 francs for establishing fortified posts from Medina on the Senegal to Bafoulabe on the Niger, on the route which will be followed by the projected railway for connecting these two large rivers. It includes also several other items connected with the same scheme. It was adopted on the same day and voted by the Senate on the 15th, so that the first step may be said to have been taken for the establishment of the connecting link between Algiers and St. Louis, *viâ* Timbuctoo.

PLANTS OF THE COAL-MEASURES[1]

M. RENAULT has recently published a memoir, in which he reproduces the views of M. Brongniart respecting the relations which the Lepidodendra bear to the Sigillariæ, still insisting that the former are cryptogamic Lycopods, whilst the latter are exogenous Gymnosperms. In endeavouring to establish this position, the French palæo-botanist concludes that if the exogenous Diploxyloid stems (*i.e.*, Sigillarian ones) are but matured states of some Lepidodendra, every Sigillarian type of organisation ought to be found in a young or Lepidodendroid form, because, he contends, the type of the central organisation, once established, undergoes no further change with advancing age. In support of his position he affirms that there are three such Sigillarian types, viz. (1) *Sigillaria vascularis*, (2) Diploxyloid stems, (3) *Favularia* and *Leiodermaria*. At present he contends that only the second of these forms has been discovered in *Lepidodendron Harcourtii*. He further believes that there are three types of Lepidodendron known, represented by (1) *L. rhodumense*, with a solid central vascular axis, in which the vessels are not intermingled with medullary cells; (2) by *L. Harcourtii*, in which the vascular axis is a cylinder surrounding a cellular medulla; and (3) an undescribed plant, which he names *L. Jutieri*, in which the vascular cylinder is broken up into detached bundles of vessels.

The author of the present paper considers that the above conclusions are not in accordance with the facts, and he proceeds to give his reasons for this conclusion by demonstrating that we certainly have *two* of the three supposed Sigillarian types represented in a young or Lepidodendroid state: the first by *Lepidodendron vasculare* of Binney, and the second by *L. Harcourtii*, whilst, judging from M. Renault's own description, the *L. Jutieri* represents the third type. On the other hand, the author believes that of M. Renault's three Lepidodendroid types the first is only a young state of the second, as illustrated by the development of the Burntisland and Arran Lepidodendra described in previous memoirs, whilst the able Frenchman appears not to have been acquainted with the existence of the very characteristic type of the *L. vasculare* of Binney.

The author gives the series of facts upon which his opinions are based by tracing the history of the development, first, of *Lepidodendron Selaginoides*, the *L. vasculare* of Binney, and second, of *L. Harcourtii*.

Commencing with the declaration that the *Lepidodendron vasculare* of Mr. Binney is but the young state of the *Sigillaria vascularis* of the same author, he proceeds to show the successive stages by which the vasculo-cellular medullary axis of the former becomes not only inclosed within the exogenous cylinder of the latter, but that this cylinder ultimately develops into a very conspicuous example of the Diploxyloid form of stem. The growth of the exogenous cylinder begins at one point of the periphery of the vasculo-medullary axis, from which point it extends both laterally and radially. The exogenous growth thus first appears in the transverse section of the Lepidodendroid twig as a small crescent, thickest at its centre, but whose two horns creep gradually round the medullary axis, its constituent vascular wedges also growing radially as the lateral growth advances, until at length the exogenous zone forms a complete ring, inclosing the vasculo-medullary axis, in which state it becomes the *Sigillaria vascularis* of Mr. Binney and M. Renault. The various stages of this growth are represented in the plates, in addition to which a section is described and figured of a branch about to dichotomise, in which process the vasculo-medullary axis has divided into two equal halves, one being destined for each branch. One of these halves of the vasculo-medullary axis displays, with the utmost distinctness, the characteristic crescentic commencement of an exogenous zone, whilst the other half retains its primary non-exogenous state. The latter condition thus belongs to the *Lepidodendron vasculare* of Binney, whilst the former as clearly represents the *Sigillaria vascularis* of the same author, and the Sigillarian character of which is recognised by M. Renault. We thus have in one stem two branches, one of which, according to the views of the French savant, is a Crypto-

[1] "On the Organisation of the Fossil Plants of the Coal-measures. Part XI." Paper read at the Royal Society by W. C. Williamson, F.R.S., Professor of Botany in the Owens College, Manchester. Revised by the Author.

gamic Lycopod, and the other a Gymnospermous Sigillaria. The remarkable peculiarities characterising the central axis of these specimens make it absolutely certain that they all belong to one species of plant.

The typical *Lepidodendron Harcourtii* is then examined in a similar manner. In the details of its organisation it differs materially from *L. Selaginoides*; nevertheless, as its growth progresses, it displays typically similar changes. It attains to much larger dimensions than the latter plant does before developing its exogenous zone, corresponding in this respect with the Arran plant. Its earlier changes are chiefly seen in the rapid development of the bast or prosenchymatous layer of the outer bark and in the increase in the size and number of the vessels constituting its vasculo-medullary cylinder or medullary sheath—the "*étui medullaire*" of Brongniart; but in more advanced specimens a cylindrical zone of centrifugally developed vascular wedges begins to make its appearance in a quasi-cambian zone of the cells of the inner bark, these cells being arranged in more or less regular radiating lines. In this state the rudimentary vascular zone corresponds very closely to what is seen in young stems and roots of Cycads.

The author shows that, contrary to the views of M. Renault, very marked changes take place in the development of the vascular bundles destined for the secondary branches of the plant. In the first instance, each of these is but a concavo-convex segment of the entire vasculo-medullary cylinder, whose detachment leaves a large gap in the continuity of that cylinder, which, however, soon becomes closed again by the convergence of the disconnected ends of the broken vascular circle. The concavo-convex detached segment undergoes a similar change. Its two extremities meet, and before it escapes from the outermost bark it has assumed the cylindrical form of its parent stem.

The rootlets of *Stigmaria ficoides*, now well known to belong alike to Lepidodendron and to Sigillaria, present some peculiarities of structure which are only found in the Lycopodiaceæ and the Ophioglossæ, amongst living plants.

The vascular bundle in the interior of each Stigmarian rootlet is inclosed within a very regularly circular cylinder, composed of the cells of the innermost bark; but the position of the bundle in relation to the cylinder is always, unless accidentally disturbed, an eccentric one. This position has not escaped notice, but it was regarded as accidental; it now, however, proves to be a normal one. The bundle begins to appear in very young roots, as one or two very small vessels developed in close union with the innermost cells of one side of the cylinder within which it is located; newer and larger vessels are gradually added centripetally, until the bundle occupies a considerable portion of the area inclosed by the inner bark cylinder. The remaining space is usually empty, but occasionally specimens are found in which it is filled with small delicate cells that have escaped destruction. These represent what in the living Lycopods are liber-cells. The outer cortical layer of the root, composed of well-preserved and rather thick-walled cells, is usually separated from the inner cylinder by a similar lacuna; but in a few specimens the cells of this usually destroyed middle bark are retained in good preservation. They consist of very delicate thin-walled parenchyma, separated by a sharp line of demarcation equally from the innermost and outermost cortical cylinders. The number of the vessels in each of the vascular bundles given off from any one section of a Stigmarian root is found to vary but little, but they steadily increase, both in number and size, with the size and age of the root. Young specimens of Stigmarian roots are described, the smallest of which is not more than one-fifth of an inch in diameter, and the vascular bundles of its small rootlets consist each of from three to five minute vessels. In the largest rootlets from old roots they number about forty, most of the additional ones being of larger size; intermediate examples exhibit a regular gradation on all these points.

The only living plants which possess rootlets with this structure being Lycopodiaceæ and Ophioglossæ, and it being sufficiently clear that the Lepidodendra belong to the former and not to the latter order of cryptogams, the existence of this Lycopodiaceous feature in the rootlets of Sigillaria is another indication of the Lycopodaceous affinities of these plants.

Many of the Diploxyloid forms of the Lycopodiaceous stems of the coal-measures have an abundant development of spiral or barred cells in their numerous medullary rays. Amongst living plants this characteristic seems to be almost, if not wholly, confined to the Gymnosperms.

Two important additional observations have been made in reference to the structure of the curious strobilus, *Calamostachys Binneyana*. The exact mode of the attachment of its sporangia to the Equisetiform sporangiophores has been ascertained; but what is still more important, it has also been discovered that it is provided with both micro- and macro-spores—an additional indication of its probable Lycopodiaceous affinities, already suggested by other features of the fruit.

The recently discovered Fungi of the coal-measures are investigated, especially the *Peronosporites antiquiorum* of Mr. Worthington Smith. The author finds, in the specimens he has examined, including that described by Mr. Smith, no traces of septa in the hyphæ or of zoospores in the Oogonia. He concludes that its affinities are probably with the Saprolegniæ, and not with the Peronosporeæ.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE Professorship of Zoology in the Royal College of Science, Dublin, is vacant by the resignation of Prof. Bridge. The salary is 200*l*. a year, and at present the professor is only required to lecture during one term, commencing in February and ending in June.

THE University Court of St. Andrews have elected Mr. Arthur Stanley Butler, B.A., of Exeter College, Oxford, to the Chair of Natural Philosophy in the United College, St. Andrews, in the room of Dr. William Swan, resigned.

THE Calendar of the University College of Wales for 1879-80 shows that that institution is fairly well equipped in its various departments, science occupying a prominent place in its curriculum.

AT the end of the Legislative Session the French Chamber of Deputies voted a law establishing free primary education. It must go through the Upper House before becoming a definitive Law of the State.

SCIENTIFIC SERIALS

THE *American Naturalist*, June.—A. E. Brown and J. D. Caton, the domestication of certain ruminants and aquatic birds. J. S. Lippincott, the critics of evolution (concluded).—C. E. Bessey, the supposed dimorphism of *Lithospermum longiflorum* (the large flowers appear from April to May, the cleistogamous flowers from then until the autumn frosts).—Dr. J. Leidy, on some aquatic worms of the family Naides (describes and figures *Dero limosa*, perhaps = *D. digitata*, Oken; *Aulophorus vagus*, this forms a tube of the statoblasts of a species of Plumatella, and *Pristina flagellum*).—W. H. Dall, American work in the department of recent mollusca during 1879.

July.—G. Brown Goode, the use of agricultural fertilisers by the American Indians and the early English colonists (contains some interesting facts about fish manures).—C. S. Minot, sketch of comparative embryology (The Sponges).—O. B. Johnson, the birds of the Willamette Valley, Oregon.—J. F. James, a botanist in Southern California.—J. S. Kingsley, American carcinology in 1879.—A. S. Packard, jun., the structure of the eye of trilobites, with figures; concludes that the hard parts of the eye of the trilobites and of Limulus are throughout identical, while the nature of the soft parts of the former must ever remain problematical. There is good evidence that the retinal mass was like that of the king-crab; if so these forms as to their eye-structure will stand near each other and far apart from all other arthropods.

THE *Journal of the Royal Microscopical Society*, June, contains: Prof. Duncan, on a parasitic sponge of the order Calcarea (Plate 10), *Mobiusispongia parasitica*, growing within *Carpenteria raphidodendron*, from the reefs of Mauritius.—Dr. Cooke, on the genus Ravenelia (Plate 11).—Dr. H. Gibbes, on double and treble staining. An excellent suggestion is incidentally made by Dr. Gibbes, that the covering glasses used by microscopists should be of a known thickness. We would even go further, and advise that a fixed scale of thickness might be adopted. Dr. Gibbes uses two thicknesses, ·006 and ·004.—Dr. A. Grunow, on some new species of Nitzschia (Plates 12 and 13).—James Smith, on the illumination of objects under the higher powers of the microscope.—The most useful record of current

researches relating to invertebrates, cryptogams, &c., is continued as usual.

THE *Revue des Sciences Naturelles*, June 15, contains: M. Hesse, description of two new crustacea, male and female, of the genus Dinemoura (*D. mustela lævis*) (Plate 1). The figures are coloured from living specimens; the species lives not in the interior of the shark, but on its skin, and its mode of fixation is minutely described.—M. Duval-Jouve, on the species of Vulpia to be found in France.—D. A. Godren, on the giant maize (*Zea caragua*).—M. Rietsch, on Bobretzki's studies on the formation of the blastoderm and germinal lamellæ in insects.—A. Villot, the synchronism of the marls and clays with lignite of Hauterives with the group of St. Ariès.—M. S. Jourdain, on a very simple form of the group of worms *Prothelminthus hessi* (S. J.) = ? *Inthosia leptolanæ*, Giard (Plate 2).—Scientific review of recent French writings on zoology, botany, and geology.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, June 17.—"On the Spectrum of the Flame of Hydrogen," by William Huggins, D.C.L., F.R.S.

Messrs. Liveing and Dewar state, in a paper read before the Royal Society on June 10, that they have obtained a photograph of the ultra-violet part of the spectrum of coal gas burning in oxygen, and in a note dated June 8 they add that they have reason to believe that this remarkable spectrum is not due to any carbon compound but to water.

Under these circumstances I think that it is desirable that I should give an account of some experiments which I made on this subject some months since without waiting until the investigation is more complete.

On December 27, 1879, I took a photograph of the flame of hydrogen burning in air. As is well known, the flame of hydrogen possesses but little luminosity, and shows no lines or bands in the visible part of the spectrum, except that due to sodium as an impurity.

Prof. Stokes, in his paper "On the Change of Refrangibility of Light,"[1] had stated that "the flame of hydrogen produces a very strong effect. The invisible rays in which it so much abounds, taken as a whole, appear to be even more refrangible than those which come from the flame of a spirit lamp." I was not, however, prepared for the strong group of lines in the ultra-violet which, after an exposure of one minute and a half, came out upon the plate.

Two or three weeks later, about the middle of January, 1880, I showed this spectrum to Prof. Stokes, and we considered it probable that this remarkable group was the spectrum of water. Prof. Stokes permits me to mention that, in a letter addressed to me on January 30, he speaks of "this novel and interesting result," and makes some suggestions as to the disputed question of the carbon spectrum.

I have since that date taken a large number of photographs of the spectra of different flames, in the hope of being able to present the results to the Royal Society, when the research was more complete. I think now that it is desirable that I should describe the spectrum of the flame of hydrogen, but I shall reserve for the present the experiments which relate to the presence of carbon and its compounds.

The spectrum of the flame of hydrogen burning in air is represented in the diagram. It consists of a group of lines which terminates at the more refrangible limit in a pair of strong lines, λ 3062 and λ 3068. At a short distance in the less refrangible direction, what may perhaps be regarded as the group proper commences with a strong line, λ 3090. Between the strong line λ 3068 and the line λ 3090 there is a line less bright, λ 3080. Less refrangible than the line λ 3090 are finer lines at about equal distances. The lines are then fine and near each other, and appear to be arranged in very close pairs. There is a pair of fine, but very distinct lines, λ 3171 and λ 3167. In this photograph the group can be traced to about λ 3290. This group constitutes the whole spectrum, which is due probably to the vapour of water.

I then introduced oxygen into the flame, leaving a small excess of hydrogen. A spectrum in all respects similar came out upon the plate. I repeated the experiment, taking both spectra on the same plate. Through one-half of the slit the spectrum of the oxyhydrogen flame was taken. This flame was about 7 inches long, and the spectrum taken of a part of the flame 2 inches from the jet. The oxygen was then turned off, and the quantity of hydrogen allowed to remain unaltered. A second spectrum with an exposure of the same duration was then taken through the second half of the slit. On the plate the two spectra are in every respect similar, and have so exactly the same intensity that they appear as one broad spectrum.

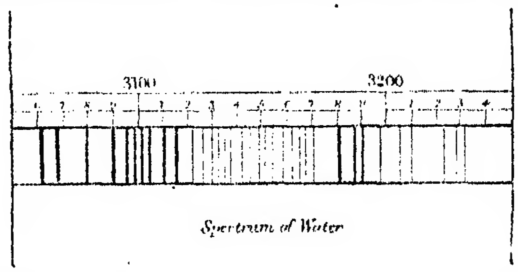
In all these experiments a platinum jet which had been carefully cleaned was used.

In these experiments the two gases met within the blowpipe and issued in a mixed state.

The jet was removed, and a flame of hydrogen was surrounded with oxygen. This spectrum shows some additional lines. In this case the jet was brass, and in this or some other way impurities may have been introduced; and I should at present incline to the view that the additional lines about λ 3429 and λ 3473, and the groups more refrangible than λ 3062, do not belong to the water spectrum, but to impurities.

Coal-gas was substituted for hydrogen in the oxyhydrogen blowpipe, and oxygen admitted in as large a proportion as possible. The inner blue flame rising about 2 inches above the jet showed in the visible part of the spectrum the usual "five-fingered spectrum." The light from this part of the flame was projected upon the slit. The spectrum contains the water group already described, and in addition a very strong line close to G, and two lines, λ 3872 and λ 3890; this latter line is seen to be the more refrangible limit of a group of fine lines shading off towards K.

The ultra-violet group, when carefully compared with the group in the spectrum of pure hydrogen, shows several small



differences. I am inclined to believe that there is the supposition of a second fainter group. There is strong evidence of this in some spectra of hydrogen taken under other conditions. There is also a broad band less refrangible than the strong line at G, and the light extends from this line on its more refrangible side.

A double Bunsen burner (Fletcher's form) with a strong blast of air was then fitted up. The spectrum was taken of the intense blue flame. It resembles the one last described. All the distinctive features are intensified, and a continuous spectrum and groupings of very fine lines fill up all the intervals between the groups already described, so that there is an unbroken strong spectrum throughout the whole region which falls upon the plate.

A spirit lamp was arranged before the slit. The spectrum is essentially the same as when coal-gas is burned, but as it is less intense only the strongest lines are seen. The water group, the strong line at G, and the pair of lines rather more refrangible than K, are seen. Probably with a longer exposure the finer lines would also show themselves.

The distinctive features of the spectra of coal-gas and of alcohol appear to be connected with the presence of carbon.

EDINBURGH

Royal Society, June 7.—Prof. Fleeming Jenkin, vice-president, in the chair.—The Council having awarded the Keith prize for the biennial period 1877-79 to Prof. Fleeming Jenkin for his paper on the application of graphic methods to the determination of the efficiency of machinery, the medal was presented to him by Prof. Balfour.—At the request of the Council Prof. Chrystal gave an address on non-Euclidian geometry, and discussed in a most masterly and lucid manner the consequences which the non-acceptance of Euclid's axiom of parallels involved. Defining a straight line as the curve completely determined by two points, the lecturer pointed out that there were three simple cases that called for discussion: first, the case where two straight lines cut in one point only and are infinite in extent; second, the case where two lines still cut in but one point, but each line is finite in length returning into itself: and third, the case where two straight lines cut in two points. Some of the peculiar properties of these three kinds of space, which might be called hyperbolic, single elliptic, and double elliptic space, were demonstrated, and many others pointed out, while Euclidian or homoloidal space was shown to be a limiting case of either hyperbolic or elliptic space.—Prof. Tait communicated a note on the theory of the 15 puzzle, in which he gave a rule for determining whether or no a particular arrangement could be solved.—Mr. de Burgh Birch, M.B., C.M., read a detailed paper on the constitution of adult bone matrix and the functions of osteoblasts.—Mr. Robert Gray exhibited two eggs of the Great Auk (*Alca impennis*), and read a short graphic account of the extinction of that bird within the present century.—Prof. Chrystal exhibited a new form of telephone receiver which was simply a fine wire, whose extension and contraction under the influence of the heating and cooling caused by the varying intensity of the current through the microphone transmitter were sufficient to communicate musical notes to a vibrating membrane. Mr. Blyth's recent communication to the Society, together with certain observations of his own on the rapid cooling and heating of thin wires which he had made several years before, had suggested the arrangement as one likely to succeed.

PARIS

Academy of Sciences, July 12.—M. Edm. Becquerel in the chair.—The following papers were read:—Observations of the comet *b* 1880 (Schäberle) made at Paris Observatory, by MM. Tisserand and Bigourdan.—On the pendulum, by M. Faye. He announces a new apparatus with which M. Govi's system (see below) and others may be studied. The reductions are limited almost exclusively to temperature.—Observations on the density of iodine vapour, by M. Berthelot. The increase of total energy of the halogen gases with the temperature, as also that of the *vis viva* of translation, exceed those of the three other simple gases hitherto studied (nitrogen, oxygen, and hydrogen); the two orders of effects seem correlative.—On the heat of formation of hydrocyanic acid, and of cyanides, by M. Berthelot.—Densities of vapour of selenium and tellurium, by MM. Sainte-Claire Deville and Troost. This gives details of operations in 1863.—On the etiology of anthrax, by M. Pasteur. Putrefaction of the animal's body destroys the parasite, but some infected blood and other liquid matter escapes into the ground about the body, and there germs may be produced and remain with latent life for years, ready to communicate anthrax on opportunity. Curiously, the bacteridium-germs may be found in the surface-earth over the body, and they appear to come thither by agency of earth-worms, carrying them in their alimentary canal. The dust of this earth, with the worms' excrement, gets blown about the plants, which the cattle eat, and are thus infected. Germs of other diseases may perhaps be conveyed similarly.—Ammonia of the air and of water, by M. Lévy. *Inter alia*, contrary to what is observed in meteoric waters, it is in the hot season that ammoniacal nitrogen seems to be most abundant in the air. The annual averages in the case of meteoric waters are nearly identical.—Alternance of generations in some Uredineæ, by M. Cornu.—New theorems on the indeterminate equation $ax^4 + by^4 = z^2$, by M. Pepin.—On some remarks relative to the equation of Lamé.—New method for determining the length of the simple pendulum, by M. Govi. A pretty long, light, and rigid rod is suspended by one end from a horizontal axis, and a heavy runner, with centre of gravity in the axis of the rod, is fixed at different points, and the pendulum set oscillating in vacuo on solid supports.—Rapid synthetic method of establishing the fundamental formulæ relative to change of state, by M. Viry.—On the constitution of matter and the ultra-gaseous state, by Mr. Crookes.—On monochromatic lamps, by M. Laurent. *Apropos* of M. Terquem's note, he recalls his modifications of gas-burners and his æolipyle.—Telephonic effects resulting from the shock of magnetic bodies, by M. Ader. Any mechanical action which disturbs the state of molecular equilibrium of a magnetic core has the effect of developing, when this core suddenly regains its equilibrium, an electric current capable of affecting the telephone.—On the fluorised compounds of uranium, by M. Ditte.—On the atomic weight and on some characteristic salts of scandium, by M. Nilson. Atomic weight, 44.—Ultimate action of bromine on malonic acid; bromoform, by M. Bourgoin.—On the etherification of sulphuric acid, by M. Villiers.—On the reproduction of *Pleurodeles waltlii*, by M. Vaillant.—Salivary glands in the Odonates (Neuroptera), by M. Poletaieu. These glands exist in all the species (though they are denied by entomologists).—Action of high and moist temperatures and of some chemical substances (benzoate of soda, benzoic acid, sulphurous acid) on germination, by M. Heckel. Seeds of *Brassica nigra* sown in a wet sponge and kept at 48° showed numerous radicles in less than twelve hours (while seeds kept in water at 48° never germinated). After emitting their radicles the seeds stopped, but they developed quickly when the temperature was brought down to 20° or 17°·5. The three chemical agents suspended the germination of various seeds.—Action of strychnine in very strong dose on mammalia, by M. Richet. It acts somewhat like curare and somewhat like chloral.—Alterations of the nerve-tubes of the anterior and posterior nerve-roots and of the cutaneous nerves in a case of generalised congenital ichthyosis, by M. Leloir.—On immunity against anthrax, acquired through preventive inoculations, by M. Toussaint.

CHEMICAL DYNAMICS

Essai de Mécanique Chimique fondée sur la Thermochemie. Par M. Berthelot. Two Vols. (Paris: Dunod, Editeur, 1879.)

THE problems which the chemist attempts to solve may be broadly divided into two groups. In studying the heterogeneous distribution of molecules, the chemist finds that new relations of molecules, in other words, new substances, are produced; he must study the composition and properties of these substances. He also finds that these changes involve a consideration of the relative positions of the changing body and of other bodies, that is to say, he recognises the action of force. He must endeavour to determine the laws of action of this force. The study of the properties and composition of substances has received more attention than that of the general laws of chemical force; both methods of investigation must, however, be applied to chemical phenomena, before these can be fully explained.

The general properties of a compound may be regarded as depending chiefly on the composition of that compound, or chiefly on the function or "power of doing" of the compound. There have always been schools of chemistry which paid most attention to composition, as there have been schools which made function pre-eminent. Modern chemistry is attempting to connect both in a general scheme of classification; whilst at the same time she endeavours to learn the conditions under which chemical force is exerted, and hopes thus to elucidate general laws.

The atomic theory, which is one great outcome of the study of the composition and function of chemical substances, has of late years been merged in the wider molecular theory of matter.

This theory, assuming the existence of a grained structure in matter, proceeds to deduce, by dynamical reasoning, the amount of motion existing among these little parts of which matter is built up. The laws of Boyle and Charles are among the primary results of this deduction. But under certain conditions gases do not exactly obey these laws; hence the theory asserts that under certain conditions the molecules exert mutual action.

Another deduction from the theory is the statement usually known as Avogadro's law—"Equal volumes of gases at the same temperature and pressure contain equal numbers of molecules." This statement provides the chemist with a means for determining molecular weights. But the chemist in applying Avogadro's law is obliged to admit that in many reactions the parts of molecules really part company. He attempts to picture to himself this molecular splitting.

Let the molecule A consist of two parts, a and b, the molecule B of two parts, c and d; let these parts be in motion. Under certain conditions the stress between a and c and the stress between b and d may be greater than that between a and b, and c and d; the original molecules are decomposed, and new molecules, C and D, are formed. The stress between a and c considered from the point of view of a or c alone is a force exerted by a on c or by c on a. This force is the force of chemical affinity.

The result of the action of this force is a new configuration of the system A B; the energy of the new system, C D, will be different from that of the original system.

Chemical action, thus regarded, is a re-arrangement of parts of molecules under the influence of the force called affinity. Chemical energy is thus regarded as potential energy.

Now a chemical action between A and B will take place under certain definite conditions only, hence although the absolute value of the affinity of A for B may be a constant, the course of the change and the entire result of the change will nevertheless be largely dependent on physical conditions. No force may be exerted except at high temperatures; the change of momentum of A will depend on its position relative to B; the relative positions at which this change occurs may only be gained at high temperatures. The force exerted may be small; still if a chemical change occur at all, there must be an action between the parts of A and the parts of B.

Now let this mutual action begin, let no energy be added to the system from without, but let the system as a whole lose energy; the energy so lost may be measured in the form of heat. But more than one re-arrangement of the parts of two molecules may frequently be possible; which will be produced? A system is in equilibrium when its entropy (using the term in the Clausian sense) has reached a maximum. Hence that system whose entropy is the greatest of the entropies of the possible systems will be produced.

This is substantially Berthelot's "law of maximum work," a law which lies at the foundation of his system of thermal chemistry. But a system not marked by possessing the largest amount of entropy of all the possible systems, may nevertheless be the most stable under the experimental conditions; the stability will depend on pressure, temperature, relative masses, &c. Hence in order to determine the actual result of a chemical action, the conditions of stability, in other words, the relations to temperature, pressure, &c., of the various possible products of the reaction must be known. The necessity of this knowledge is insisted on by Berthelot. To determine, therefore, the product of a given chemical action one must measure the quantities of heat evolved in the passage of the system from the standard state to each of the possible new states, and one must know the conditions of existence and stability of each of these states This problem therefore presents both a chemical and a physical question for solution. The solution of the chemical question is much aided by a knowledge of the laws of atom-linking; but these cannot be here considered.

A measurement of the heat evolved in a chemical change evidently enables us to find the difference between the energy of the original and final chemical systems; the total heat change being independent of intermediate states through which the system may pass. So if work is done on a chemical system whereby it is caused to assume a new configuration, this work measures the energy transferred from the initial to the final system; in this case heat will be absorbed during the chemical change.

But in actual chemical reactions the action of the chemical force proper will be interfered with and complicated by physical, or secondary forces. So much is this the case, that for many years these actions were not distinguished.

One school simply measured the quantity of a substance A, which was needed to act on B to produce C; the greater the quantity of A required to act on a given weight of B, the greater was the affinity of A for B. With this school all was chemical. With Berthollet, on the contrary, all was physical; but facts have been discovered since the publication of the "Statique Chimique" which have necessitated a reconsideration of his laws.

Gradually the meaning of affinity has been made clear. The greatest contribution towards this end is undoubtedly the papers of Guldberg and Waage, whose work has been sketched by the present writer in this journal (vol. xx. p. 530). The Swedish naturalists disregard the action of secondary forces in their method of determining the ratios between the affinity coefficients of various substances.

The importance of a measurement of the change of energy accompanying the passage of a chemical system from one specified state to another; the importance, in other words, of a measurement of the heat evolved or absorbed in such a passage, is at once apparent. But this measurement—even taken along with a general knowledge of the conditions of existence of the various possible systems—does not enable us certainly to predict the result of the chemical action. If we had a complete knowledge of the mode of variation of the potential energy of a system with changes in the configuration of the system, then it *might* be possible for mathematicians to predict all possible arrangements of the system under the action of specified external forces. But having made heat measurements only, we are very far indeed from this point.

Indeed the fundamental assumption that chemical energy is wholly potential, and depends on the arrangement of the parts of a system, may be false; and even if this assumption be true we know nothing as yet of the relation between this energy and the configuration of the system.

The heat absorbed or evolved in a chemical change measures the total work done by the system in its passage from one specified state to another, but it is evident that it does not directly measure the true force of affinity. The stress between the parts of two molecules may be small, yet under certain conditions a chemical change may occur; the loss of energy in the formation of the new system may be considerable, and hence the heat evolved, considerable. Chemical affinity thus regarded is a kind of liberating force.

For the measurement of the ratios of the affinities of various systems, Guldberg and Waage's method is to be preferred to the thermal method of Berthelot. For a full consideration of chemical equilibrium Berthelot's method is altogether insufficient, although it has *largely* advanced the solution of this problem.

The method of Willard Gibbs seems the only feasible one in the present state of the chemical and mathematical sciences. In this method (see NATURE, vol. xxi. p. 516) the energy and entropy of a system are considered—the stability of a system depends on the component masses, volume, and entropy (the *magnitudes* of the system); and on the temperature, pressure, and *potential* (the *intensities* of the system).

The stability of a system is chiefly dependent, according to Berthelot, on the amount of heat evolved in the passage to the given state from an initial state, and on the general properties of the given system as compared with other possible systems. This is evidently a much cruder statement than that of Gibbs. Berthelot's principle of maximum work is indeed one among many deductions made by the method of the American professor.

Both methods lead to a recognition of chemical equilibrium as an outcome of chemical action; the conditions of the latter are considered before those of the former; chemical kinetics precedes chemical statics. The usual method of the text-books is to make chemical equilibrium all-important, and barely to mention the subject of chemical kinetics.

It is evident that the time when it will be possible to treat chemical problems by a purely dynamical method is yet distant. The method of Gibbs leads the way in bringing chemical generalisations under the domain of the principles of energy, and it does this without assumptions about the action of the parts of molecules; the method is a thermo-dynamical one.

Berthelot's method, on the other hand, is thermo-chemical; but a thermo-chemical method seems to promise the largest development in the present state of the science.

Berthelot perhaps claims too much for his method: in his great work he is not always definite in his use of such terms as "force," "affinity," "energy," "work;" nevertheless the "Essai de Mécanique chimique" is undoubtedly a great work. To Berthelot (and to Thomsen) is due the honour of having steadily pursued the thermo-chemical method for many years, and of having collected masses of most important facts; and he has now enriched chemical science by the publication of these results in a collected and systematic form, in a treatise full of original ideas and suggestive of almost unlimited topics for future work and discussion. What a field of work is opened before one in this book! To determine that this body is produced by the action of these bodies is not enough; indeed it is scarce a beginning. Chemical science has higher aims. The changes of energy which accompany changes of configuration of matter must be measured; the physical and chemical constants of all the products of a chemical change must be determined with care, the velocity of the change must be measured, and an attempt must be made to apply dynamical reasoning to the results thus obtained.

The first volume of the "Essai," entitled "Calorimétrie," begins with general remarks on thermo-chemical work, and on affinity; after laying down certain general theorems concerning chemical reactions, and illustrating the application of these in the formation of insoluble and soluble salts, the formation of series of carbon compounds, &c., a detailed account is given of experimental calorimetric methods; this is accompanied by numerous tables of specific heats, heats of combination, heats of solution, heats of formation of salts in solution, heats accompanying isomeric changes, &c. The second volume—entitled "Mécanique"—is concerned with a

study of the conditions which determine chemical changes. This general study divides itself into two branches: chemical decompositions and recompositions—included under the title of "Dynamique Chimique"; and secondly those final distributions of matter which result from reciprocal actions between simple or compound bodies, grouped together as "Statique Chimique." Would it not have been better to have entitled the general subject "Chemical Dynamics," and the branches "Chemical Kinetics" and "Chemical Statics" respectively?

It would obviously be impossible to give here even an outline of Berthelot's treatment of this immense field of work; one or two instances must suffice.

The two fundamental generalisations of the French chemist have already been mentioned. Let us turn to his treatment of the specific heats of elementary bodies and of chemical equilibrium.

Berthelot refuses to accept the law of Dulong and Petit as applied to solid elements. He says that the actually-determined specific heats of the elements vary much with temperature, and that the products of these numbers into so-called atomic weights are of very different values. He gives a list of 11 elements, the specific heats of whose *equivalents* is about 6·4; and a list of 31 for which the product of specific heat into equivalent weight is about 3·2.

This result well illustrates what will probably be regarded by most chemists as a fundamental error on the part of the author of the "Essai"; Berthelot is still to be classed among the staunch supporters of the system of notation founded on equivalents. In this country we have no such phenomenon as a great chemist who writes the formula of nitric acid AzO_6. Nevertheless Berthelot's thermal chemistry is founded on a molecular theory. He constantly speaks of molecules and of action between the parts of molecules; he also speaks of the architecture of atoms, and seems to regard the modern atomic theory as utterly opposed to such an idea.

"The kinetic energy of the molecule may be regarded as made up of two parts—that of the mass of the molecule supposed to be concentrated at its centre of mass, and that of the motions of the parts relative to the centre of mass. The first part is called the energy of translation, the second that of rotation and vibration. The sum of these is the whole energy of motion of the molecule. The pressure of the gas depends on the energy of translation alone. The specific heat depends on the rate at which the whole energy, kinetic and potential, increases as the temperature rises." (Clerk Maxwell, *Chem. Soc. Journ.*, 13, 502.)

In the present state of our knowledge of the internal motion of the parts of a molecule it is impossible to determine satisfactorily the ratio of the two parts of the energy of the molecule, and it is extremely difficult to reconcile the observed with the calculated ratios of specific heats.

Nevertheless, if we adopt the mean numbers found for the specific heats of the solid elements and multiply these into the maximum atomic weights as determined by the aid of Avogadro's law, we get a result which is too constant to be merely accidental. Taking Kopp's numbers, calculated from specific heats of compounds, for those elements which have not yet been obtained in the solid form, we find that the product of specific heat into atomic weight (*not equivalent weight*) is about 6·4 for forty-four elements, about 5·5 for ten elements, less than 5 for two elements, and is yet unknown for eight elements. Furthermore we find that the specific heats of the elements are fairly constant, provided they be determined for a temperature-interval known to be considerably below the temperature of fusion of the elements.

We seem, therefore, fully justified in accepting the law of Dulong and Petit as an empirical statement of very considerable value, although not as a final statement of the connection subsisting between the ratio of the two parts of the energy of the elementary molecules, and the relative weights of the parts of the same molecules.

In treating the subject of chemical equilibrium Berthelot first of all examines processes of chemical combinations in general, and contrasts these with processes of decomposition; he then studies those changes which are made up of two parts—a direct and reverse—and which are characterised by the attainment of a limit dependent on conditions of temperature, pressure, relative masses, &c. The chemical equilibrium thus established he divides into two kinds: equilibrium of homogeneous bodies, *i.e.*, when the original and final substances are all liquid or gaseous and capable of complete admixture during the course of the change; and equilibrium of heterogeneous bodies, *i.e.*, when some of the substances are solid and some liquid, or some liquid and some gaseous, or when all are liquid or gaseous, but are nevertheless incapable of complete admixture. Examples are given of each kind of equilibrium, and of the conditioning influence of temperature, pressure, mass of solvent, contact with other substances, relative masses of reacting bodies, chemical functions of reacting bodies, velocity of the change, &c. The phenomena of equilibrium of heterogeneous systems lead to a discussion of dissociation; this to a consideration of precipitation, and thence to an instructive chapter on the state of salts in solution, and the meaning of the terms "feeble" and "strong" as applied to acids and bases.

Although, in considering Berthelot's treatment of chemical equilibrium, one misses the bold and fascinating results obtained by Gibbs in his great paper on the "Equilibrium of Heterogeneous Substances," and the exactitude and simplicity of the beautiful theory of Guldberg and Waage, and although one cannot but much regret that he should not have written his formulæ and equations in a language more easily understood by the chemist of to-day, one must nevertheless admire the breadth of view, the felicity of illustration, and the suggestiveness of the work of the French chemist.

The publication of the "Essai" marks an important point in the advance of modern chemistry: it comes to the chemist with the message, amongst others, that his science demands more than the stereotyped so-called original investigation, in which are detailed a few properties of a number of new compounds produced by methods long ago marked out and defined; it tells him that he must revise and advance his methods, that he must try to explain his facts by appeal to principles, that he must not be afraid to strike off the beaten path into the by-ways of research, and that there is more to be hoped

for in a bold impatience than in the "Smooth diffused tranquillity of heartless pains."

M. M. PATTISON MUIR

A JAPANESE ROMANCE

Chiushingura, or the Loyal League; a Japanese Romance. Translated by F. V. Dickins, B.Sc., of the Middle Temple, Barrister-at-Law. (London: Allen and Co., 1880.)

THIS book is one of great value and interest, both from a purely literary and from an anthropological point of view, and further as yielding a most instructive lesson in the meaning of Japanese pictorial art. Mr. Dickins is well qualified for the task which he has performed, being not only a practised Japanese and Chinese scholar, but a man of very wide attainments in various branches of natural science, and he has been able to supply a series of most valuable explanatory notes in the appendix of his work. It may be mentioned that he commenced his career by graduating in science and medicine at the University of London, and that after having served for some years as a surgeon in the navy he was called to the bar, and practised his profession for many years at Yokohama, where, by constant study, he became deeply versed in all that pertains to Japanese life and customs.

The present work is illustrated by the actual Japanese woodcuts with which the Japanese edition of the historical novel of which it is a translation is embellished. The woodcuts were printed in Japan by native workmen, and are now bound up with the English text. The reader is therefore able to form an exact conception of the ideas which the Japanese artist has intended to convey in the twenty-nine pictures which the work contains. It is most interesting to all who are in any way attracted by Japanese art to realise the mode in which the emotions, such as rage and despair, laughter and pain, are depicted, and to join as it were in a Japanese game of blind-man's-buff. The "Chiushingura, or Loyal League," is an historical romance which embodies the history of the forty-seven Ronin so well known from Mr. Mitford's account of it in his fascinating "Tales of Old Japan." The present romance is one of the most popular and best known in Japan, or rather was so, for its main object is to glorify "Chiushin," or loyal-heartedness, the supreme virtue of the Bushi class under the old order of things that passed away with the year 1868. Disloyalty was considered to be the meanest of crimes, rendering the person guilty of it unworthy of existence, and the Japanese self-despatch, seppuku, which occurs abundantly in the romance, was a self-inflicted atonement for this crime, and in no sense a mere ignoble suicide.

The action of the romance is laid in the fourteenth century, although the events on which it is founded really occurred at the beginning of the eighteenth, the author having been compelled to disguise barely the reality by diluting the history with a certain amount of fiction, and altering names and dates so as to evade the law which, under the Shogunate, attached severe penalties to the publication of recent or current events of a public character.

We cannot detail the plot of the story, but will give a few extracts. A highway robber after murdering an old man soliloquises thus as he kicks the body aside: "Wretched piece of work. Well, I am sorry for it. I did not do it out of any malice, but you see you had money, that killed you. No money, and you'd be alive now. Your money was your enemy. I can't help pitying you. Which prayer are you for? Namu amida butsu, or Namu miyôhô renge-kiyô? Choose one, and let all end." The prayers are Buddhist, the words being Sanskrit ones which have undergone much Japanese alteration.

The story closes with the account of the attack of the forty-seven Ronin on the castle of Maronhao, the murderer of their lord Yenya (by "murderers" being meant the persons who compelled Yenya to perform seppuku). Their mode of proceeding is very quaint. In the very heat of the attack, just as they burst into the dwelling of their victim, the leader of the expedition, in true style of a Japanese general, calmly seats himself on a camp-stool and gives his orders. The neighbours on either side are roused by the noise and send their retainers to see what is going on. "Ya ya," they cry, "what means all this uproar and confusion, clashing of weapons and hurtling of arrows? Are you attacked by rioters or by robbers, or has a fire broken out somewhere? We have been commanded to find out what is going on, and inform our masters of the cause of disturbance." The Ronin answer, "We are liegemen of Yenya Hanguwan; some forty of us banded together to revenge our lord's death upon his enemy, and are now struggling to get at him. We are not rising against the Government, still less have we any quarrel with your lords. *As to fire, strict orders have been given to be very careful*, and we beg you not to be under any apprehension on that score. We only ask you to leave us alone and not to interfere with us. If as neighbours you should think yourselves bound to assist our enemy, we shall be obliged, despite our inclination, to turn our weapons against you."

To these bold words the retainers of the noblemen shout back approvingly, "Right, well done, right well done; in your place we should feel ourselves bound to act as you are acting; pray command our services." So they desert the roofs and put out their lights.

When Maronhao is at last caught he is treated with ceremonious respect, and afforded the opportunity of performing suicide in the usual manner. "We pray you pardon our violence, and beg of you that you will *present us with your head* according to the usage of our country." But Maronhao is a vile, ungentlemanly ruffian, and drawing his sword under pretence of ripping himself up, he makes a treacherous lunge at the leader of the Ronin So he is at once despatched without more ado. The head is cut off with the dagger with which Yenya committed "seppuku," and is struck at in frenzy, gnashed at, and cried over in grief and fury by the Ronin. Then it is washed, and presented on a small stand before the "ihai" (a tablet inscribed with the posthumous name of the deceased) of Yenya placed opposite to it on a similar stand. Incense is burnt before the "ihai," and a prayer is offered up to the dead Yenya "resting amid the shadows of the tall grass" (in the grave), that he will look with favour on the offering. Then all the Ronin betake themselves to his grave and perform "seppuku" themselves.

The Appendix contains an interesting account of a Japanese orchestra, many historical notes, and various information of great ethnological value. The notes throughout the book are very interesting, and some of them amusing. Thus, when the Ronin are crowding round the body of their victim they shout, "Happy are we as the Môki when he found his waif." In the note we learn that "the Môki, according to a Chinese fable, was a species of sea-tortoise with one eye in its belly. For three thousand years the monster had longed to see the light, but in vain. One day, while swimming about the surface of the sea, it came into contact with a piece of drift-wood, to which it immediately clung in such a manner that the belly was uppermost under the wood, a ragged hole in which fortunately allowed the tortoise the opportunity of at last satisfying its long-cherished desire. There is a curious note on p. 120 on an allusion in the text as follows:—"Allusion is here made to the practice of hacking at the dead bodies of criminals, by which the young Samurahi was wont to perfect himself in swordsmanship under the old order of things. Treatises exist upon this repulsive art—for an art it seems to have been considered—and one of the commonest of picture-rolls used to represent the various cuts, distinguished by special names, by practising which the aspirant could best learn on the dead subject to qualify himself for mangling the living one."

The Appendix contains a translation in verse of a popular Japanese ballad which is often sung as a kind of epithalamium, and which gives a pleasing conception of Japanese poetry. We commend the book to all our readers.

H. N. MOSELEY

OUR BOOK SHELF

Loch Etive and the Sons of Uisnach. With Illustrations. (London: Macmillan and Co.)

ALL sorts of epithets have recently been applied to Oban—the Brighton of Scotland, by those whose highest ideal of heaven is "London by the Sea"; the future Liverpool of the North, according to one of its most constant wooers, that enthusiastic Celt, Prof. Blackie; the "Charing Cross of the Highlands," a picturesque placard of one of the railway companies informs the public. But to those who have been there and know from impressive experience all the romantic beauties of island and loch and rugged coast to which the modern Argyllshire coast town is the key, no epithet however ingenious is half so expressive and beautiful as simple "Oban" itself, especially since the "Princess of Thule" has shed a glory over all the Western Islands from Stornoway southwards. But there is the glamour of a story much older than that which William Black has told so well hovering around some of the lochs and headlands in the neighbourhood of Oban. It is this old old story which is told in the anonymous volume before us, the author of which, were we at liberty to reveal his name, our readers would recognise as one occupying a very high rank in a certain department of physical science. The story is that of the early migrations of the Irish Scots to the land which for the last 800 years has borne their name. By the help of a somewhat clumsy dialogue the author takes the reader to some of the localities in and around Loch Etive mentioned in the half-legendary record which remains of these early migrations. He seeks to reproduce the stirring life of the time and localities, takes us to the spots where the Irish emigrants and their distant kinsmen came in contact, unearths the ruins of their houses and forts, and the remains of their household utensils and warlike weapons. The work has, however, wider bearings than its immediate subject, and several important points connected with the early "Aryan" migrations are discussed in a style much more in accordance with the canons of scientific investigation, and therefore of common sense, than is usual with those who are in the habit of handling such subjects. The chapter on the Celts is specially interesting; its breadth of view is admirable. The author's discussion of the question of Celt and Saxon, Aryan and non-Aryan, and in connection therewith the subject of mixture of race, is an excellent specimen of close reasoning, and we strongly commend it to the study of "Saxon" and "Celtic" enthusiasts. To those who read this work with care and with the help of a good map a new interest will be added to Oban and its vicinity, which is now rendered so accessible by the opening of the Oban Railway. The numerous illustrations will be found really helpful; and grand and musical as the names of many of the places illustrated are in themselves, they will be clothed with a lively significance to those who take the trouble to study the legends of the Sons of Uisnach.

The Birds, Fishes, and Cetacea commonly frequenting Belfast Lough. By Robert Lloyd Patterson. (London: David Bogue, 1880.)

THIS work does not purport to be a scientific treatise, but to be a record of many years' observations on the cetacea, birds, and fishes found commonly frequenting Belfast Lough. This lough is, in its way, almost classic ground to the naturalist, and in connection with the treasures to be found around its shores or in its waters, the names of Thompson, Hyndman, Templeton, Haliday, and that of the father of the author of this volume, will ever be associated. The lough is favourably situated for receiving the visits of birds, though the great and still increasing traffic through it must to some extent frighten away many a species; and in grandeur of beauty and variety of life it will not favourably compare with the fine fjord-like bays of Western Ireland. Mr. Patterson tells us that the greater portion of the matter in this volume was originally brought together in the form of papers, which were read at different times before the Belfast Natural History and Philosophical Society, which will account in great measure for their style and for their being somewhat discursive; still the volume is for the most part pleasant reading, and every now and then we come across very interesting and novel facts. In the chapter about gannets we read a good deal about their great feeding powers, and the following estimate of how many herrings the Scotch gannets eat in a year is noteworthy; it is given on the authority of Commander M'Donald, of H.M. cruiser *Vigilant*. Of the five Scotch stations where the gannet breeds, the number of birds frequenting each is put down as follows:—Ailsa Craig, 12,000; the Bass Rock, 12,000; St. Kilda, 50,000; the Stack, 50,000; Gula Sgeir, 300,000, or a total of 424,000. Each of these birds would consume at least a dozen herrings in the day if it could get them; but estimating the daily average as six to each gannet produces 928,560,000 as the quantity consumed in one year, and reckoning 800 herrings to a barrel gives us 1,160,700 barrels captured by the gannets, as against 750,000 barrels, the total take by fishermen on the west coast of Scotland for 1872. Many more such extracts might we give, but our space is limited, and our desire is to send the reader to the volume itself. Almost everywhere throughout the work the author spells the specific names with capital letters, in this overlooking both the rules and practice of men of science. Sometimes, indeed, a specific name, if after a person or place, may be thus spelled without offence, but these exceptional cases should not be made the rule. The volume is dedicated to the memory of the author's father, Robert Patterson, F.R.S.

Key to the Universe; or, a New Theory of its Mechanism. Founded upon a (1) *Continuous Orbital Propulsion, arising from the Velocity of Gravity and its Consequent Aberrations;* (2) *Resisting Ethereal Medium of Variable Density, with Mathematical Demonstrations and Tables.* By Orson Pratt, Senior. Second Edition. (Salt Lake City, Utah Territory, 1879.)

MR. ORSON PRATT'S work is not a text-book for students, but an application of dynamical principles to the system of the Universe. "The aim of the author is to vindicate the UNIVERSALITY of the law (*i.e.*, of gravitation); to rescue it from the environed limits sought to be thrown around it, and to give it that unlimited freedom of action which the distinguished name 'UNIVERSAL' so appropriately and definitely imports." Mr. Pratt states that astronomical science needs a theory which will answer as far as possible nine questions, which he propounds; the second is, "Why do planetary bodies rotate upon their respective axes? Why do they rotate from west to east, instead of the contrary direction? Is there any law governing their diurnal periods?" The ninth, "Will cometary orbits ever be converted into those of a planetary form?" "Unaided and alone, he launches his humble barque upon this great unexplored ocean, with a compass of his own invention." The discussion occupies thirteen chapters, and his investigations result "in the development of the following beautiful law: *The cube roots of the densities of the planets are as the square roots of their periods of rotation.*" Without making any long comments of our own we can say that Mr. Pratt's book gives evidence of much hard work and, it may be, of ingenious speculation, and we quote as appropriate to the work before us the following remarks of Prof. Newcomb ("Popular Astronomy," p. 233): "It is true that many ingenious people employ themselves from time to time in working out numerical relations between the distances of the planets, their masses, their times of rotation, and so on, and will probably continue to do so; because the number of such relations which can be made to come somewhere near the exact numbers is very great. This, however, does not indicate any law of nature."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Recent Gas Explosion

THE explosion of the gas main in the neighbourhood of the Tottenham Court Road appears to be an example on a large scale of the phenomenon which occurs on the bursting of a eudiometer.

It is known (although I do not speak from experience) that when such an accident happens the glass gives way at the surface of the mercury in the tube, for at this point the explosion is most violent, in consequence of the gas being compressed by the explosion of that above it. When no accident takes place the flash of light is more brilliant at the surface of the mercury than in the upper part of the tube. In order to see if this fact would throw any light on the explosion of the gas main I tried a few experiments about a fortnight ago, an account of which may possess some interest. A piece of combustion tube 1·93 m. long and 13·5 mm. in diameter was closed at one end, and at 100 mm. from the open end of the tube a pair of platinum wires was sealed into the glass. The tube was filled over water with a mixture of hydrogen and oxygen obtained by the electrolysis of dilute sulphuric acid, and the mouth of the tube closed with a plug of wet cotton wool. The tube was placed on the lawn and secured to a heavy weight by a piece of string tied near the open end; a spark from an induction-coil was then passed between the wires. The explosion of the gas blew out the plug of cotton wool and bent the platinum wires against the sides of the tube, but the glass was not broken. The tube was again filled with the mixed gases and closed with a cork, which was not forced tightly into the mouth of the tube. This time the tube burst in the middle, leaving ·78 m. of the closed end and ·59 m. of the open end without damage. The cork was projected some distance, but the wires were not bent by the rush of gas; the closed end of the tube was only slightly moved from its original position by the explosion.

Another piece of similar tube, but only about ·88 m. in length, was next filled with gas and exploded in the same manner. The closed end was burst, and ·475 m. of the open end remained. In this case the cork was also projected, but the wires were not bent. The experiment being made at night, it was noticed that the flash was much more brilliant at the closed than at the open end of the tube. A third tube of the same length as the first was next tried; the cork was blown out, but the tube did not burst. It was again filled and the cork forced in tightly, but it was again projected. The third time a block of stone was placed a few millimetres in front of the cork; this prevented its projection, but the tube did not burst, being apparently of thicker glass than the previous tubes. In the last three cases the flash was brilliant in the half of the tube towards the closed end.

The explanation of the experiments seems to be, that in the two tubes that burst the pressure produced by the explosion at a distance of about three quarters of a metre from the point at which the gas was fired was sufficient to overcome the resistance of the glass; and in the case of the long tube, which burst in the middle, the release of the pressure prevented the closed end from being destroyed. If the tube had been much longer there would probably have been another place where the violence of the explosion produced by the compression of the gas would have burst the tube.

The press of work at the end of the term has prevented my carrying the experiments farther, but I intend to try the effect of an explosion in a long lead or composition pipe, when I expect to find several swellings or burstings of the metal at the points where the pressure is greatest. When the experiments have been made I hope to be allowed to communicate them to you.

HERBERT MCLEOD

Cooper's Hill, July 24

The Freshwater Medusa

IN NATURE, vol. xxii. p. 241, Prof. Lankester asserts that I had in a previous number (vol. xxii. p. 218) incorrectly represented him as holding that in Limnocodium the radial canals terminate blindly, and as denying the presence of a marginal canal. In proof of my inaccuracy he makes the following statement:—

"A reference to NATURE, vol. xxii. p. 147, will show that in my first publication on the subject I gave as a character of the new genus, 'Radiating canals 4, opening into the marginal canal. Marginal or ring canal voluminous.' I made the same statement in my communication to the Royal Society on June 17, and have not since deviated from it."

I have read the article to which Prof. Lankester here refers, and which was published on the date of the reading of his paper at the Royal Society. The only allusions in it to this subject are the following:—

"RADIATING CANALS 4, terminating blindly at the margin of the disk."

"MARGINAL or RING CANAL obliterated (or, if present, of very minute size)."

GEO. J. ALLMAN

Storm Effects

THE storms about this part of Surrey have been lately local and violent, and the effects produced in some instances curious. Visiting a neighbour's farm on Wednesday evening (21st), we found a field of standing wheat considerably knocked about, not as an entirety, but in patches forming, as viewed from a distance, circular spots.

Examined more closely, these all presented much the same character, viz., a few standing stalks as a centre, some prostrate stalks with their heads arranged pretty evenly in a direction forming a circle round the centre, and outside these a circular wall of stalks which had not suffered.

I send a sketch made on the spot, giving an idea of the most

perfect of these patches. The soil is a sandy loam upon the greensand, and the crop is vigorous, with strong stems, and I could not trace locally any circumstances accounting for the peculiar forms of the patches in the field, nor indicating whether it was wind or rain, or both combined, which had caused them, beyond the general evidence everywhere of heavy rainfall. They were to me suggestive of some cyclonic wind action, and may perhaps have been noticed elsewhere by some of your readers.

Guildown, Guildford, July 23 J. RAND CAPRON

The Inevitable Test for Aurora

I HAVE not long returned from abroad, and have only recently had the opportunity of perusing in NATURE (vol. xxii. pp. 76, 96, 145) the correspondence of Messrs. De La Rue and Müller, Prof. Piazzi Smyth, and Mr. Backhouse on this subject.

I do not understand Messrs. De La Rue and Müller as claiming their electric discharges to be in the nature of an actual auroral discharge, but rather that their experiments inform us inductively at what heights auroræ are to be found. This, however, doubtless assumes that the discharges in question and auroræ must have something very much in common; and Prof. Piazzi Smyth is quite to the point in remarking that unless the citron line (and, I would add, the red line) are present in the spectrum, the identity of the discharges with the aurora has not even a foundation.

The fact is, that many of the electric discharges in air and the air gases, and the circumstances attending them—we may instance the ordinary tube glow, its change from rose-tint to violet under magnetic influence, the aura-arc accompanying the spark discharge under similar conditions, the dark space between the terminal and the glow, the change of colours in a hydrogen tube, and other appearances which I have not time to capitulate—so closely resemble auroral incidents, that one is quite disappointed to find on examination no concordance in the spectra. At the most, in a vague and unsatisfactory way one or two of the blue and violet lines in the aurora spectrum have been assigned to one or other of the atmospheric gases; but as Prof. Smyth points out, the red and green giant lines of the spectrum have up to the present time found no terrestrial analogues. I have examined the air spectrum and the spectra of the component gases of air under many various conditions, but always without success so far as these lines are concerned.

I have not, however, had the opportunity of doing this in the case of direct discharges from large secondary batteries; and it would undoubtedly be a valuable addition to our knowledge of facts relating to auroræ if Messrs. De La Rue and Müller would undertake this examination, and clear up matters in that respect. With regard to the heights at which auroræ obtain, the evidence is very conflicting. Certainly they have been seen very near the earth ("Auroræ, their Characters and Spectra," pp. 37 to 40. Height of the Aurora). It is unfortunate that simultaneous observations of the auroral corona are almost entirely wanting. I think I once saw one in print, but missed it subsequently, and would be glad if any particulars could now be furnished me. Prof. Newton, by calculations based on observations of auroral arches in 28 auroræ, has assigned a height of from 33 to 281 miles, with a mean of 130 miles.

Messrs. De la Rue and Müller, I notice, deduce experimentally that at 124 miles no discharge could occur. As to whether the red or the white aurora is the nearest to the earth, my impression certainly is that the apparently low-lying auroræ have generally been the white. I may instance the aurora seen by Mr. Ladd a Margate, "a white ray," and that seen by me in the Isle of Skye in September, 1874. In Lapland, too, the auroræ seem almost universally yellow, but it can hardly be assumed that they are all thirty-seven miles high. The apparently lower position of the red tint is by no means universal, and can hardly be relied upon as evidence on the point, especially when so many auroræ are seen in which it is wanting. I have great hopes, with a spectrocope specially prepared for the purpose, of getting the photographed spectrum of an aurora.

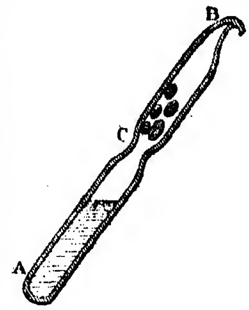
The red line is of course out of the question, but judging from experiments on gas tubes I think the green might be got, and the blue and violet I make in anticipation pretty sure of in the event of an aurora lasting some hours. The principle of the instrument is a long collimator, a single fluid prism, and a short focus-projecting lens, used with rapid dry plates.

Guildown, Guildford, July 23 J. RAND CAPRON

Experiment with Glass Tubes

I HAVE just been repeating a very beautiful experiment of Prof. Quincke's which he showed me some weeks ago in his laboratory at Heidelberg. The experiment was, I believe, described in *Poggendorff* about two years ago, but I have not seen it noticed in English papers, and a few words about it may interest your readers.

Prof. Quincke, with a view to test the porosity of glass for gases, sealed up tubes in which hydrogen and carbonic acid were generated in great quantity, and weighed them from time to time. Up to the present time, as I learned from him, no loss of weight has been detected. He obtained, however, a very curious result. As I do not know precisely how Prof. Quincke filled his tubes, let me describe what I did myself three weeks ago, remarking that I have done nothing but attempt to repeat what he showed me in Heidelberg.



I took a glass tube, A B, about 5 inches long and $\frac{3}{4}$ inch in external diameter, with good stout walls. I closed the end A, and let the glass fall in at C, keeping it still very strong, and annealing very carefully at A and C. I introduced some sulphuric acid into the part C A, carefully keeping the neck C dry, and dropped into the part B C some fragments of marble, previously washed, in order that no little particles should tumble down through the neck, C, and commence effervescing before I was ready. I then drew out the tube at B, making a small hook, by which the tube can be suspended if necessary, closed it very strongly, and annealed the extremity carefully, wrapped the tube in cotton wool, and inverted it. The sulphuric acid attacked the marble, and carbonic acid was given off no doubt in great quantity.

For the first few days there was nothing particular to be noticed. The tube was filled with a bubbling mass of liquid and white mud. Latterly, however, it has begun to show the phenomena which Prof. Quincke observed. The liquid now no longer wets the glass as it did at first, but creeps away from it, giving very much the appearance of the "tears of strong wine." Day by day this is getting more marked, and I expect that soon, as was the case in the Heidelberg tubes, the acid will roll about in the tube like so much quicksilver. Meantime it is most interesting to watch.

I believe Prof. Quincke considers that a thick layer of gas is condensed over the surface of the glass, and that it is this which gives rise to the very peculiar capillary phenomena that present themselves.

I feel bound to remark that the experiment is one that ought not to be attempted without great care and caution.

J. T. BOTTOMLEY

Physical Laboratory, University of Glasgow, July 15

On the Colours of Double Stars

IF any light whatever has its intensity increased the effect on the eye is to add to the sensation a certain yellow element which I have accurately defined by experiment (*Am. Jour. Sci.*, April, 1877, vol. xiii. p. 247). A red light brightened becomes yellower, a green light yellower, a yellowish white less white, a blue or violet light whiter. The phenomena are described at length in Prof. Rood's "Modern Chromatics." The fact that an incandescent body becomes less red and more yellow when it is heated is probably due to this physiological principle. That the incandescent body ultimately becomes white is probably owing to some not understood modification of the principle for excessively bright lights.

It follows that if two stars are of unequal brightness they will appear of different colours unless the qualities of the two lights have a peculiar relation to one another; and the brighter star will usually be the yellower. Accordingly, if we refer to Mr. Burnham's lists of binaries recently published by Prof. Holden (*Am. Jour. Sci.*, June, 1880, vol. xix. p. 467) we find that although differences of colour are so little distinguished that three-quarters of all the pairs are considered to be of the same colour, yet of the twenty-four pairs which differ in brightness by two magnitudes

or over, not one is considered to have components of the same colour. And of the forty-two pairs which are said to be of different colour all but two have more yellow in the brighter, so much so indeed that it is possible to suppose that the difference of brightness is the chief cause of the difference of colour. The two exceptions are:—

No. 23.	ε *Boötis*	A. eq. Cærulea	B. eq. Cærulea
No. 42.	O Σ 507	A. Blanche	B. Cendriolivatre

There is evidently some error about No. 23. Either the colours are wrong, or it is wrongly stated to have differently coloured components. In No. 42 it is difficult to say which component is more yellow. Although, then, it is certain that other causes largely affect the colours of stars, yet differences of brightness seem to have the greatest effect in producing the apparent differences in the colours of double-stars.

Prof. Holden compares the colours of bright and faint stars to those of a more or less hot incandescent body. But in the latter case the dimmer light is accompanied with redness. We know that this is not the case with the light of our own sun; for of a white surface, upon part of which the sun shines, while the rest is in shadow, the darker part is bluer. In the same way, of the forty binaries of which the brighter component is the yellower, there are thirty-seven in which the fainter is bluer, and only three in which it is distinctly redder. It appears, therefore, that most double-stars do not differ greatly in colour from our sun, and do not shine with the strongly red light of an incandescent solid.

C. S. Peirce

Paris, July 20

Coffee-Disease in New Granada

The following information about what appears to be a new disease of the coffee-tree is taken from an official letter written on April 29 last by Mr. C. Michelsen, Commissioner of Agriculture at Bogotá, to Mr. José Herrera, Vice-consul of New Granada in this city, who sent me a copy of it, requesting me to give him my opinion about the disease.

At first there appear on the leaves small spots of a light-greenish colour, which in two or three days turn brownish, and then appears on each of them a fungus *divided in three or more greenish-yellow branches*. This fungus is said to be phosphorescent at night, and *in places where it is very common a phosphoric smell is noted* (!) After some days the diseased leaves fall off; the fruits, which also are attacked by the parasite, follow very soon, and the trees are left quite bare. They form, however, new leaves after some months, but these are again attacked by the fungus.

The disease is reported to be more frequent in damp places than in dry ones, its ravages being greatest in plantations where the trees are planted rather close. The fungus has also attacked the shade trees, especially the *guamos* (*Inga* sp.).

Though the description is far from being satisfactory, I think it is pretty clear that the fungus is not the *Hemileia vastatrix* of Ceylonese celebrity. However it bears a great resemblance to it, so that I recommended to employ fumigations with sulphur under the kind of large umbrella proposed by Mr. George Wall (Nature, vol. xix. p. 423). The unusually rainy weather in the last year has very likely much to do with the spread of the disease, which at the same time is a new proof of the eminently fatal consequences resulting from close planting.

I have asked for dried specimens of diseased leaves, in order to submit them for examination to a competent mycologist.

Carácas, June 26 A. Ernst

Toughened Glass

Probably the accident mentioned by Mr. Noble Taylor is not exceptional, as a similar one happened to a member of my own family. She was about to take a seidlitz-powder, and had poured the contents of the blue paper into a tumbler of toughened glass half filled with cold water, and was stirring it gently to make the powder dissolve, when the tumbler flew into pieces with a sharp report. There was no fire or lamp in the room at the time. Some of the fragments flew to a distance of three or four feet. The bottom of the tumbler was not altogether fractured, but cracked into a number of little squares, which could be separated readily.

T. B. Sprague

Edinburgh, July 20

The same accident occurred to me a few nights ago as happened to your correspondent, and I cannot help thinking that the spoon had most to do with the phenomenon.

In a hot room I had just finished what is usually called a "lemon squash," *i.e.*, the juice of a lemon and a little white sugar, with a bottle of soda-water, a lump of ice being put into the mixture. I was talking at the time, and so held the empty glass with a spoon in it in my hand for a second or two, when suddenly it went off in my hand into thousands of pieces, none larger than an inch or so.

I picked up one of the largest and thickest pieces, and found it to be so thoroughly disintegrated that I broke it up with my fingers into about a hundred small pieces, and might have done more. This disintegration seems to be a natural property of toughened glass when broken, but I never before saw a case of its breaking up without being struck. I do not think that usually such occurrences are dangerous, on account of the entire destruction of the fabric.

J. C. J.

Large Hailstones

On Tuesday, July 13, at 2.30 p.m., hail began to fall heavily in this neighbourhood. A thunderstorm was at the time approaching rapidly from the north-east. I was struck with the extraordinary size of the stones, and going into the open air I collected six—the first that came to hand—in an accurately-tared glass, and weighed rapidly. The six stones weighed 5·766 grams. The average weight for each stone was therefore ·961 gram. or 14·8 grains. A pane of glass in a skylight window had a hole driven through it by one hail-stone.

PAUL BROCA

The sudden death of the eminent French anthropologist, Dr. Paul Broca, which we announced a fortnight since, is an irreparable loss to science, and for the French medical and anthropological schools particularly.

Prof. Broca, born in 1824 at Ste. Foy la Grande (Gironde), was a senator, vice-president of the Academy of Medicine, officer of the Legion of Honour, and member of several learned societies. Since 1846, the year in which he was promoted Aide d'anatomie, till 1880, when he died as a professor of surgery, during nearly thirty-four years the life of Dr. Broca has been an uninterrupted consecration to science. A rapid review of his scientific work, especially of what he did for anthropology, will show how indefatigable was his zeal, how well his life has been spent.

Broca's publications on various subjects in anatomy, surgery, and anthropology are innumerable, especially his contributions to the last-mentioned subject. One has only to open the numerous volumes of the *Bulletins* of the Paris Anthropological Society, of the *Mémoires* and the *Revue d'Anthropologie* and other scientific journals, to get an idea of Broca's immense activity. In 1856 he published his famous "Traité des Anéurismes," which, with his "Traité des Tumeurs," published in 1866, constitute his principal medical works. The former opened a new era in the treatment of these affections; in the latter Broca expounded the historical evolution of the knowledge of tumours and their treatment in so able a manner that it has hitherto not been surpassed.

In 1861 Broca made his remarkable discovery of the seat of articulate language at the third frontal convolution of the left side of the brain. Moreover in later years Broca devoted himself to the study of the brains of man and animals, greatly contributing to our knowledge on that subject. The *Revue d'Anthropologie* contains many of the results of these studies; for instance, "Sur la Topographie cranio-cérébrale," "Étude sur le Cerveau du Gorille," "Anatomie comparée des Circonvolutions cérébrales," "Localisations cérébrales," &c.

His treatise "Des Phenomènes d'Hybridité dans le Genre humain" appeared in 1858 and 1859, and in 1864 was translated into English.

Among the great number of memoirs may further be mentioned: "L'Intelligence des Animaux et le Règne humain," "La prétendue Degénerescence de la Population française," a brilliant plea for the French nation, "L'Ordre des Primates: Parallele anatomique de l'Homme et des Singes," "Recherches sur l'Indice Nasal," "Étude sur la Constitution des Vertèbres caudales chez les Primates sans Queue," "Les Troglodytes de la Vézère," "La Race Celtique ancienne et moderne," "Étude sur les Propriétés hygrométriques des Crânes," "Sur l'Origine et la Répartition de la Langue basque," "Recherches sur l'Indice orbitaire," "Sur l'Angle orbito-occipital."

The practical results of a good deal of Dr. Broca's anthropological researches are found in his "Instructions," forming two separate volumes; one, for the anthropological study of the living, appeared for the first time in 1864, and has been re-edited several times since; the other, particularly on craniology and craniometry, was published in 1875. Another valuable memoir is that on the "Indices de Largeur de l'Omoplate chez l'Homme, les Singes et dans la Série des Mammifères," in which he opened up new views on the comparative anatomy of races and mammals. One of Dr. Broca's last works was his important study on the "Variations craniométriques et de leur Influence sur les Moyennes," &c.

The greatest glory of Broca is perhaps the foundation of the Anthropological Society of Paris in 1859. The perseverance and talent of the founder surmounted all the difficulties and troubles of every kind which threatened in the beginning the existence of the society, which now, after nearly one-and-twenty years, is flourishing as one of the first learned societies in Europe. During these long years Broca was the soul of the anthropological movement in France; nay, we may say that his influence extended far beyond his own country, and that the study of man in other civilised countries has been followed after his method. In reality Broca was at the same time the founder of a new and excellent anthropological school: his method of anthropometry, &c., as expounded in the "Instructions" above-mentioned, is now followed by the great majority of anthropologists. But this was not enough for the indefatigable zeal of the eminent scholar; in 1872 he commenced to publish the *Revue d'Anthropologie*, one of the best organs on the science of man. Many of his own works have been published in it.

Broca's last and greatest work was the foundation in 1876 of the now celebrated École d'Anthropologie in Paris, with a first-rate museum, laboratories, library, and a complete course of anthropological lessons given by more than half-a-dozen professors, among whom are de Mortillet, Bertillon, and Topinard. Broca himself taught the comparative anatomy of the Primates.

The laboratories above-mentioned belong at the same time to the École pratique des Hautes Études since 1878.

Broca, the scholar, philosopher, and statesman, died on the field of honour, in the midst of his work, in the vigour of life. Though dead, his work will never perish; man dies, but science remains. His illustrious example will continue to enlighten the path of those who follow the imperishable footprints he has left.

H. F. C. TEN KATE

THE WOOLWICH GUNS

A PETITION signed by several men well known in the field of mechanical science and presented to the House of Commons last week contains many points to which it is important that public attention should be directed. The memorialists state their belief that the system of heavy ordnance now in use and known as the Woolwich system is inefficient and dangerous, that, considering the increasing dependence of the nation for food supply upon its command of the sea, it is evidently unsafe to neglect any of the opportunities which the mechanical skill and manufacturing resources of the country afford for securing the best weapons of offence and defence for our fleet and our army; "that, having regard to the advances constantly being made by private manufacturers in this and other countries, and to the ordnance actually in use or in course of construction for the other Powers of Europe and America, your petitioners look with dismay upon the defects of the English heavy guns, and they are of opinion that these defects seriously endanger our naval supremacy and our national safety." Further the petitioners maintain that it is not right that the heads of the manufacturing department, which is in competition with outside manufacturers, should be the official advisers of her Majesty's Government as regards new inventions, and that the defects in our present system of ordnance arise and are likely to continue from the absence of independent criticism, and in consequence of the technical advisers of the Government being the same persons as those who either are or have been in charge of the manufactories responsible for these defects; that there are in existence several systems of ordnance superior to the Woolwich system, and that it is of national importance that private establishments for the production of arms of all kinds should be encouraged and should not be crushed by giving a virtual monopoly to the Government establishments, but that the private trade and the Government factories should rather serve as reserves to one another.

The principal issues thus raised may be very shortly stated. If we want the best guns, can they be obtained better from a Government manufactory carefully fenced round by official jealousy, or can a better article be procured by open competition amongst private manufacturers? Is it impossible for the technical advisers of the Government to select from the enormous mass of inventions and improvements offered to them those of real value? And further, do they, or would they make this selection if it were in their power? It has often been objected that the great quantity of suggestions and friendly advice constantly being received renders it quite impossible to treat them with adequate discrimination; but if the officials intrusted with this work were only possessed of a thorough scientific knowledge of mechanical principles, we believe that nine-tenths of the worthless schemes could be at once rejected, so inevitably does the mark of the circle-squarer appear in his work to one who knows where to look for it.

Respecting the remaining 10 per cent. of inventions and improvements, it would probably require somewhat greater practical judgment to decide which were worth further investigation; but while we do not for a moment suggest that the whole of these should be examined and tested at the expense of the tax-payer, it is at least not too much to expect that an obviously good design should not be rejected with an official reply. Inventors are probably the most persevering of all men, and, fortunately for the cause of progress, though not perhaps for their own advantage, they have a greater belief than any one else in the results they hope to obtain; but it is hardly to be expected that they will bestow their whole powers of persuasion on the authorities of their own country when they plainly see a more open field abroad.

For instance, there can be little doubt that the Whitehead torpedo might have been a secret exclusively the property of this country if the inventor had been afforded a fair investigation; again, it would be interesting to know whether the Russian Government required as much persuasion to induce them to adopt the Moncrieff hydro-pneumatic gun-carriage as has been expended in bringing it as far as the "experimental" stage in our own service.

That many inventors have had a short innings at the

hands of the War Department is to be plainly seen in the collections of what are merely regarded as useless eccentricities at Woolwich and Shoeburyness, but it is very improbable that most of the lessons to be learnt from these have ever been appreciated by those who were responsible for their rejection. Has it not taken twenty years for the system invented by Robert Mallet of building up a massive piece of ordnance capable of being taken to pieces to facilitate transport, to at length bring forth the present seven-pounder screw gun, which can be carried in halves on the backs of mules? It would be interesting to know whether any private firm in this country, if they had received the order, could have manufactured and proved a train of siege guns on similar principles, and capable of as easy transport as the modern field gun, and which would have considerably facilitated Gen. Stewart's advance to Cabul.

It can of course be urged with some show of reason that, considering the enormous supply of most patterns of guns and the vast quantity of ammunition required throughout the Empire, great inconvenience would result from too great a multiplicity of designs; but to continue the manufacture of an inferior pattern for this reason when a better one is procurable appears to us only to make the evil greater when the former has to be finally abandoned as obsolete. Thus we suppose it must have been obvious to a great many persons for the last five years that the days of heavy muzzle-loading guns for the navy were numbered, from the difficulty or impossibility of giving sufficient length of bore for the consumption of large charges of powder while still enabling the gun to be fought in a turret. All possible ingenuity was then expended on shortening the recoil and on mechanical systems of loading in a confined space, with results that might have been incalculably disastrous had this country been involved in war previous to the terrible accident on board the *Thunderer;* all this too while we believe a suitable pattern of breech-loader was in the hands of a private firm and had been tendered by them for adoption by the War Department. If it could be shown that a Government factory could alone turn out guns of the best manufacture, superior to anything that could be produced by private establishments, the logical sequence would be that armour plates and marine engines and the ships themselves should all be provided in the same way.

The effect of a Government monopoly on the foreign trade of a manufacturer is too well known to require demonstration; but if the encouragement of private establishments for the production of all kinds of arms and warlike stores should result, as it doubtless would, in a larger trade with foreign powers in these manufactures, while we should profit by their custom in time of peace, they would not only find themselves in the event of war with this country cut off from their supply of fresh arms and ammunition, but the whole of our own increased production would be available for national defence.

If such an inquiry as is sought for in this petition be instituted by the present Government, conducted not only by officers of the army and navy, but also under independent scientific advice, we believe that numerous articles of belief and revered principles of construction will be shown to have been long exploded and will have to be at once abandoned. We shall then probably find the Woolwich system of rifling with increasing pitch and studded projectiles giving place to the poly-groove of uniform pitch with rotation by gas-check which has been under consideration for years, and is yet scarcely recognised; we may even take a hint from the Chinese Government, who, by applying to Sir William Armstrong's firm, have for more than a year been in possession of four more powerful guns than any afloat in our most recent ironclads; we should perhaps find that a system of breech-loading is ready for adoption solving most of the difficulties of turret and casemate defence, and that a trustworthy type of hammered steel is ready at hand to be substituted for the welded coils of wrought iron at present in use.

If it should be found that our Government establishments have been suffering from a slow process of crystallisation, they might be resuscitated by being placed in keen competition with private firms whose very existence depends on their unceasing activity, or at the least it would be ascertained whether in a critical time the country would have to depend entirely on the Royal Gun Factory, or whether some of the old firms who in former years fought so hard for a share in the work have not forgotten their skill.

LIVING ON WATER

HOW long a man can live on water alone is now the subject of an experiment in New York. A Dr. Tanner from Minnesota is devoting himself to this trial. Tanner declares that he can live for forty days without food, and is proving, or trying to prove, the truth of the hypothesis on his own unfortunate person. He is reported to have got through twenty-eight days of his endeavour, and still to be alive and comparatively well. On the twentieth day his pulse was 76, his temperature 98·405, and his actual weight 132 lbs. On the twenty-eighth day his weight was 130 lbs. He lost 27½ lbs. in the first nineteen days during which he fasted, and then ceased to waste at the same rate. The latest report we have of him states that he is cheerful, active, and, notwithstanding abundant medical opinion to the contrary, confident that he should continue to the end of the time named for the experiment. Of food of the solid kind he touches none; of drink he partakes of water and nothing else; water and air will, he maintains, sustain him, and that notwithstanding exertions from riding and other exercises. Dr. Tanner is not original in this mode of attempt upon his own life. In the *Transactions* of the Albany Institute for 1830 Dr. McNaughton reported the history of a man named Reuben Kelsey, who on July 2, 1829, declined eating altogether, assigning as a reason "that when it was the will of the Almighty that he should eat he would be furnished with an appetite." McNaughton's account of this man is singularly interesting. We have not room for all the details, but it may be told in brief that Kelsey continued to live for *fifty-three* days; that he went out of doors and walked about during the greater part of the time, and that he was able to sit up in bed until the last day of his life. During the first three weeks of his abstinence he fell away very fast, but afterwards did not seem to waste so sensibly. Towards the close of his days the colour of his flesh was blue, and at last blackish. His skin was cold, and he complained of chilliness. His general appearance was so ghastly that children were afraid of him. Of this he himself seemed to be aware, for it was not uncommon to observe him covering his face when strangers were passing by. At the time of his death Mr. Kelsey was twenty-seven years of age. The writer of this notice once attended a gentleman, who, for a nearly similar reason as that assigned by Mr. Kelsey, abstained from all food, except water, for even a longer period, viz., fifty-five days. In this instance the wasting was most observed in the first three weeks of the fasting. From this it will be gathered that Dr. Tanner may live to the full extent of forty days on water without being suspected of having been the subject of a miracle. It is against the success of his experiment that he should be exposed to an amount of excitement and vexation that must reduce greatly the vital power, but for all that he may possibly survive the ordeal. The grand question is how he will cry back again. The facts of these examples, painful as they are, are not without their use. They indicate that water being admitted into the body, life may go on for periods

far beyond any that might be expected, and they expose altogether the fallacy about the value of alcohol when with large quantities of water it has been administered as a supposed life-sustaining food.

B. W. R.

WATERFOWL[1]

ONE of the principal objects of these lectures being the illustration of the animals exhibited in the Society's Gardens, I have selected for my address to you this day the subject of "Waterfowl," by which I mean the *Anseres*, or family *Anatidæ*, of naturalists, commonly known as ducks, geese, and swans. Three familiar species of domestic birds, the names of which I have just cited, belong to this family, and have been known to us since the times of the Romans, and a fourth, the Muscovy duck, has been added to the series since the discovery of America. Besides these four domestic species nearly all waterfowl show great aptitude for semi-domestication. When pinioned and put in small ponds, and supplied with food and shelter, most of them will thrive, and many of them will breed in captivity.

The acquisition of waterfowl has long been a subject of special interest to this Society. In 1830, in the first list of our animals ever published, I find thirty species of waterfowl included, amongst which are the Orinoco goose, Mandarin duck, and the Cercopsis goose. In 1844 I find twenty-six species included in the catalogue of the animals then living in the Gardens. About that time the thirteenth Earl of Derby, then president of this Society, was the great patron of waterfowl, and, by means of collectors and agents in all parts of the world, brought together in his celebrated menagerie at Knowsley one of the finest collection of these birds ever made. At the disposal of the Knowsley menagerie by auction in 1851, examples of 51 different species of waterfowl were sold, many of which had been bred in the Knowsley Gardens.

Since that period the Zoological Society, having become the possessor of some of the choicest specimens sold at Knowsley, has taken up the subject of waterfowl with increased vigour, and has succeeded in adding considerably to the list of introduced species. During the past twenty years there have been exhibited in the Society's Gardens examples of 86 species of this group of birds, and at the present time the collection consists of not less than 270 individuals, referable to 53 different species, forming, as we believe, the finest living series of these birds now in existence. The zoological gardens of Amsterdam, Antwerp, and Berlin, and the Jardin d'Acclimatation of Paris have also excellent collections of waterfowl, and have succeeded in breeding some species which have obstinately refused to avail themselves of the inducements we have offered them in these Gardens. But in extent and variety I believe our series remains pre-eminent.

The total number of species of the family Anatidæ at present recognised by naturalists is about 175; of these some 94, or more than half, have been at various times represented by specimens held in captivity either in our Gardens or elsewhere, and of the species thus exhibited no less than 50 have paired and produced young.

Of the nine groups or sub-families into which, as will be seen by the Table, the Anatidæ are divisible, the *Anatinæ* or geese, swans, and river-ducks show the greatest aptitude for this kind of semi-domestication. The sea-ducks, lake-ducks, torrent-ducks, and mergansers are much more wild in their nature, and do not thrive nearly so well in confinement. Of the 31 known species of sea-ducks (*Fuligulinæ*) but 13 are known to have been exhibited in zoological gardens, and of these only 5 have reproduced in captivity. None of the lake-ducks (*Erismaturinæ*) or torrent-ducks (*Merganettinæ*) have ever been introduced alive, and none of the Mergansers (*Merginæ*) have been bred in captivity,

Table of Water-fowl

	Species		
	Known.	Exhibited.	Bred.
1. Anseranatinæ	1	1	—
2. Cercopsinæ	1	1	1
3. Anserinæ	38	25	14
4. Cygninæ	10	8	5
5. Anatinæ	75	43	25
6. Fuligulinæ	31	13	5
7. Erismaturinæ	9	—	—
8. Merganettinæ	3	—	—
9. Merginæ	6	3	—
	174	94	50

although examples of three species of the last-named group have been occasionally exhibited.

Of the geese (*Anserinæ*), on the other hand, which number some 38 known species, no less than 25 have been introduced at various times, and of these 14 have reproduced in captivity. Amongst these one of the best introductions effected by the Society is that of the Magellanic or upland goose, of which examples were first received in 1857, presented by Capt. Thomas Moore, at that time Governor of the Falkland Islands, in which settlement, as we know from no less an authority than that of Mr. Darwin, the upland goose is a familiar species. The upland goose commenced to breed with us in 1863, and has continued to do so with tolerable regularity ever since; it has also hybridised in this country with the closely-allied form from Chili, which has been called *Bernicla dispar*, and of which many examples have been received by the Society in recent years.

Besides the upland goose, the allied ruddy-headed and ashy-headed geese of Antarctic America have been acquired and successfully bred. The ruddy-headed goose has unfortunately been lost, and requires reintroduction, but its ashy-headed brother remains a denizen both of these Gardens and also of similar establishments on the Continent.

Passing on to the swans, we find that a still greater degree of success has been obtained in the acclimatisation of these birds. Ten species of swans are recognised by naturalists, of which eight have been introduced into zoological gardens and five have been bred in captivity. Besides the common tame swan which is upon every piece of water, the ponds of our Gardens contain at the present time examples of the hooper, Bewick's swan, trumpeter swan, black swan, and black-necked swan, and but a short time ago we had also examples of the beautiful Coscoroba swan of Antarctic America, remarkable for its coral-red bill. Of all these the most engaging is perhaps the black-necked swan, originally obtained by the late Lord Derby from Chili, and first acquired by this Society at the dispersal of the Knowsley collection in 1851. A pair of these birds first bred with us in 1857, and the species has continued to do so with more or less regularity ever since that date.

The river-ducks (*Anatinæ*), which succeed the swans in the natural series, are the most numerous group of the family. Of the seventy-five known species of river ducks forty-three have been introduced into captivity, and twenty-five have been successfully bred. Of these I will call particular attention to two which have been recently added to the list of introduced species, and are charming representatives of the group.

The rosy-billed duck of South America was first introduced by this Society from Chili in 1867, but only, unfortunately, in the shape of a single male. In 1870, however, we obtained examples of both sexes from the same locality, which began to breed with us in 1873. Since then young ones have been hatched nearly every

[1] Abstract of a "Davis Lecture" given before the Zoological Society of London, July 8, 1880, by P. L. Sclater, F.R.S., Secretary to the Society.

year in the Society's Gardens, and we have been able to supply many of the gardens and collections on the Continent with pairs of this fine species.

Another successful introduction, from a very different quarter of the globe, has been the paradise duck of New Zealand. The so-called paradise duck belongs to the genus *Tadorna*, or shield-drake, and is remarkable, as I believe we were first certainly able to ascertain from our living specimens, for the black head of the male being replaced by a brilliant white in the female. What is still more remarkable however is that in this bird the young in both sexes, contrary to what usually obtains amongst the whole class of birds, have the plumage of the male parent, the female birds putting on the white head only after the first moult. The paradise duck was first obtained by the Society in 1863, when specimens of both sexes were presented to us by Mr. J. G. Tetley; the species first bred in the Gardens in May, 1865, and, assisted by the arrival of subsequent specimens, has continued to do so ever since, so that we have been able to supply many of our friends and correspondents on the Continent with examples of this duck, which may now be considered as firmly established in the gardens of Europe. Amongst other fresh-water ducks which have been successfully acclimatised in the same way within recent years I should also notice the Chiloe widgeon and the Chilian pintail, of Antarctic America, the spotted-billed duck of India, and the Brazilian teal, all of which have of late years bred freely in the Society's Gardens.

I will conclude with a few remarks upon the geographical distribution of the Anatidæ.

In treating of this part of the subject I find it impossible to separate conveniently the Palæarctic and Nearctic species, or those of the northern parts of the Old and New World. So many of the high northern species are circumpolar or common to both continents, and so many other of the Palæarctic species have closely allied (in some cases barely separable) representatives in the Nearctic area, that it is much more natural to unite these categories into one group as "Arctic Anatidæ." Adding to this the other four generally recognised divisions, we shall find the Anatidæ come out, somewhat as follows, in five great geographical groups:—

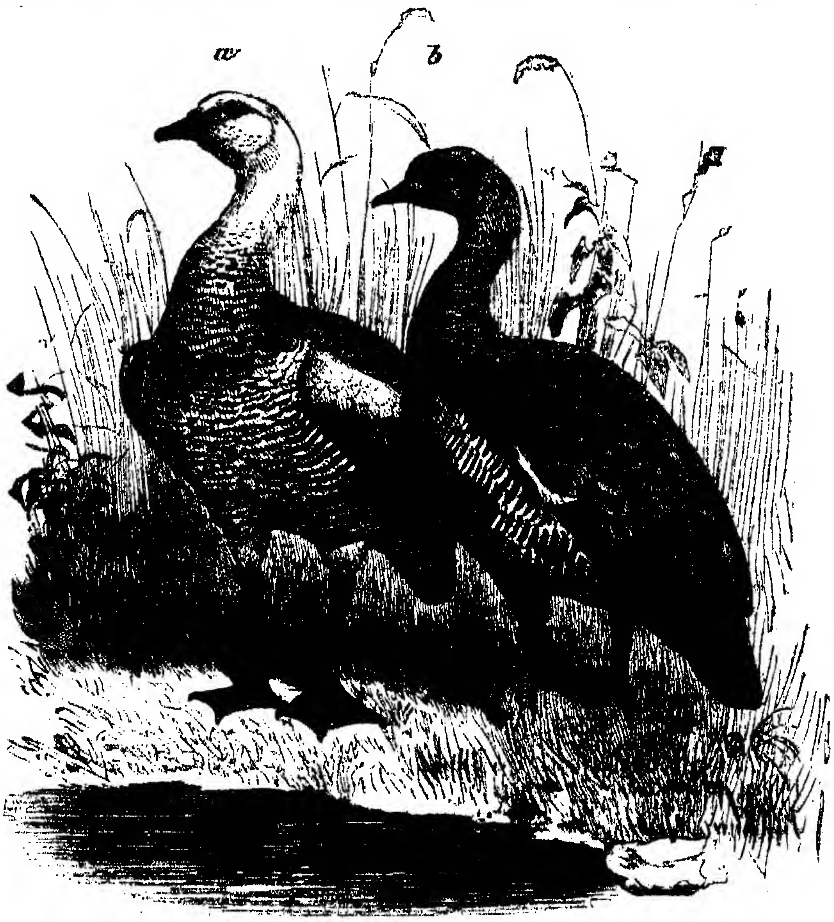

FIG. 1.—Upland Goose.

I. ARCTIC ANATIDÆ.—The Arctic Anatidæ are by far the most numerous of all the five groups, these birds with their thick covering of feathers, and aquatic habits, being naturally adapted to cold and wintry climates. Out of the 38 known species of geese 20, out of the 10 known swans 7, and of the 31 known sea-ducks not less than 26 belong to this category. Of the whole number of 174 generally recognised species of Anatidæ, 77 may, I think, be best set down as Arctic, although some of them, such as *Tadorna rutila*, *Fuligula rufina*, and *Marmaronetta angustirostris*, cannot be strictly so termed, as they inhabit only the temperate portions of the Palæarctic region. Very many of the Palæarctic species also, as will be noted below, go far south in winter and intrude far into the Æthiopian, Indian, and Neotropical regions.

II. ÆTHIOPIAN ANATIDÆ.—Under this head I place only those species that live all the year round, and breed within the Æthiopian region. These are about twenty-two in number.

Amongst these are two generic forms not found elsewhere, *Plectropterus* and *Thalassornis*. Of the nine Anatidæ hitherto registered as met with in Madagascar two species only are peculiar to the island, *Anas melleri* and *A. bernieri*, the remaining seven being also found in Africa.

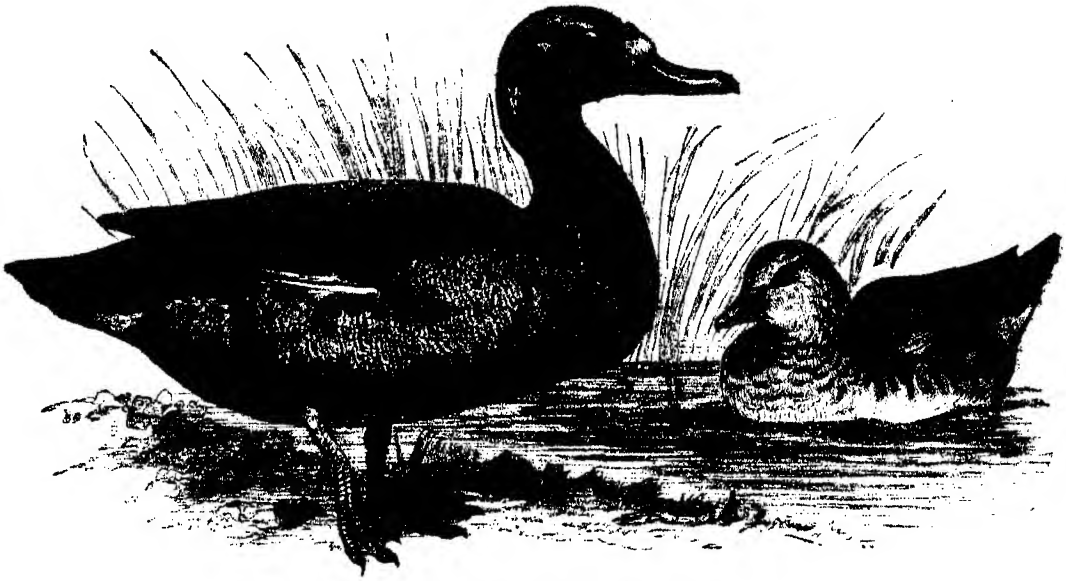

Fig. 2.—Rosy-billed Duck.

In winter, as will be seen by Heuglin's recent works, many of the Palearctic Anatidæ penetrate into Eastern Africa.

III. Indian Anatidæ.—In this category again I include only species that are permanent inhabitants of some parts of the region. They are not numerous, consisting only of twelve species.

Amongst these there is only one peculiar generic form, *Rhodonessa*.

In winter, however, a host of immigrants from the north invade the Indian region. Jerdon gives us accounts of upwards of twenty northern ducks and geese which are found in various parts of the Indian peninsula in the cold weather.

IV.—Australian Anatidæ.—As we advance farther south the Anatidæ commence to increase again. Instead of only twelve native species we find the number in the Australian region running up to twenty-nine. The greater number of these are found in Australia itself, that great continent, although so dry and arid, being well supplied with waterfowl.

Fig. 3.—Paradise Duck.

Among these there are no less than five generic monotypic types peculiar to Australia, namely, *Anseranas*, *Cereopsis*, *Stictonetta*, *Malacorhynchus*, and *Biziura*.

Proceeding to the outlying parts of the Australian region, we find New Zealand also well provided with Anatidæ, nine species being comprehended by Dr. Buller in his lately-published work on the birds of New Zealand, while the adjacent Auckland Islands are tenanted by two very peculiar ducks, quite unknown elsewhere, namely *Nesonetta aucklandica* and *Mergus australis*.

In Polynesia Anatidæ are scarce, *Dendrocygna vagans* and *Anas superciliosa* being the only species known until we come to the Fanning group, where the peculiar *Chaulelasmus couesi* has lately been discovered.

In the Sandwich Islands two peculiar species occur, *Bernicla sandvicensis* and *Anas wyvilliana*.

V. NEOTROPICAL ANATIDÆ.—The Neotropical region is better supplied with Anatidæ than any other of the divisions here adopted except the Arctic, thirty-nine species being specially attributable to it. Besides these, as Mr. Salvin and I have shown in our articles on the Neotropical Anatidæ published in the Society's *Proceedings* for 1876,[1] twenty-three of the Arctic Anatidæ are more or less regular visitants to it during the winter season.

The generic types of Anatidæ restricted to the Neotropical area are four, namely, *Heteronetta*, *Cairina*, *Tachyeres*, and *Merganetta*. There are, however, only six species belonging to these peculiar genera, so that the mass of the Neotropical Anatidæ belong to Arctic forms.

On the whole the Neotropical Anatifauna (if such an expression be allowable) is not so peculiar, as that of Australia, where there are five generic types not found elsewhere. In true Anatidæ the Neotropical region is specially rich, possessing twenty-three species against the Arctic eighteen.

In *Fuligulinæ*, on the other hand, it is very poor, having only one species against the Arctic twenty-six.

In concluding my lecture I would venture to urge those who have friends and correspondents abroad, or who are so fortunate as to travel themselves, not to let any opportunity pass of adding to the Society's living collection of Waterfowl. In a paper recently read before the Zoological Society I have given a complete list of the known species of these beautiful birds, and an exact account of the introduction of each species that has been obtained alive, and if not, where it is to be found. I shall be happy to supply any one interested in the subject with a copy of this paper when in type, as it will shortly be. Meanwhile I may venture to specify some of our principal desiderata in different parts of the world.

1. Freshly-imported examples of the *Cereopsis* goose of Australia to cross with the present European stock.
2. Examples of the *Bernicla cyanoptera* of the highlands of Abyssinia, never yet obtained alive.
3. Examples of David's swan (*Cygnus davidi*) from Pekin. Even skins of this little known bird would be very desirable for our museums.
4. Specimens of the canvas-backed duck and smaller white swan (*Cygnus americanus*) of North America.
5. The pink-headed duck of India, of which we have only yet received a single pair in 1874.
6. The Radjah shieldrake of Queensland (*Tadorna radjah*), a most beautiful species allied to our *Tadorna vulpanser*.

Any examples of these species would be most gratefully received by the Society for their living collection.

NOTES

As we have already intimated, the German Association of Naturalists and Physicians meets at Danzig from September 18 to 24. Contributions from non-German workers in science are earnestly asked for, and we are sure that any foreigners who desire to be present at the meeting will receive a hearty welcome. Applications for quarters should be made before September 10 to Herr L. Biber, Brodbänkengasse 13, Danzig. Besides the usual excursions, concerts, and other social gatherings which the Germans know how to manage so well, there will be plenty of work in the twenty-three sections. Among the public lectures to be given are the following:—On September 8, "On Writing, Printing, and the Prevailing Shortsightedness," by Dr. Hermann Cohn of Breslau; "On some Characteristics of Cell-life," by Dr. Strasburger of Jena. September 21—"The Food of Marine Animals," by Dr. Moebius of Kiel; "The Statics of Continents and the alleged decrease of the Water of the Ocean," by Dr. Jentzsch, of Königsberg; "The Scientific Standpoint of Psychiatry," by Dr. Wernecke of Berlin. September 24—"Polar Expeditions or Polar Observatories," by Dr. Neumayer of Hamburg; "Foreign Domestic Birds, with special reference to the scientific results of their Breeding," by Dr. Carl Russ of Steglitz.

MUCH capital is being made out of the reports of some of the inspectors in the new Education Report, who attempt to enliven their pages by giving some of the results of the recent attempts at higher education in elementary schools. The answers are certainly ludicrous enough sometimes, almost as ludicrous as those said to be given occasionally by the undergraduates of Oxford and Cambridge. But the rational conclusion to be drawn from this state of things is not that which finds favour with Lord Norton and his friends, that the attempt to improve elementary education should be abandoned. As the *Times* well puts it:—"They are firstfruits of the attempt to put to a higher and more exacting work instruments fashioned for a lower and a simpler one. All such results are at first necessarily imperfect, and nothing is easier than to make them appear ridiculous. The true remedy, however, is not to reject the instruments, but to adapt them, or give them the means of adapting themselves, to the higher function." If science is to be taught in elementary schools, let it be taught in a proper manner by properly trained men.

EVIDENTLY the Government of New Zealand have no fear of over-educating the people. From the *Colonies* we learn that the New Zealand system of education has been characterised by the Governor, Sir H. Robinson, as "the most ambitious yet adopted in any country in the world." To quote the words of Sir Hercules:—"It is proposed in New Zealand to provide the whole juvenile population with instruction free of charge in the following subjects:—Reading, writing, arithmetic, English grammar and composition, geography, history, elementary science, drawing, object lessons, vocal music, drill, and, in case of girls, needlework and the principles of domestic economy. The scheme includes also provision at the public expense for a system of scholarships, for the maintenance of normal schools for training teachers, for the efficient inspection of public schools, and for the erection of suitable school buildings. As soon as sufficient school accommodation has been provided the Education Act contemplates that attendance at public schools shall be made compulsory on all children between the ages of seven and thirteen who may not be otherwise under efficient or regular instruction." While Sir Hercules thinks the programme may be too varied and too costly, he attaches little weight to the objection that there is a risk of over-educating the masses above their occupations and so making them discontented with their lot in life. While he criticises the scheme in some of its details, still he says:—"I think that your scheme of national education is one of which any country might well feel proud, and that it is being administered with an earnestness and an ability which is deserving of all praise. I have been much struck, in travelling about the country, with the deep interest which is universally taken in this most important question, and with the determination which pervades the whole community that the blessings of education shall for the future be placed within the reach of all.

[1] Revision of the Neotropical Anatidæ, *Proc. Zool. Soc.*, 1876, p. 358.

With such a healthy, vigorous motive power, supervised and directed with so much intelligence, any defects in the driving gear of the machinery will soon be detected and corrected, until the object which all have equally at heart is fully attained, and New Zealand is placed in the front rank amongst the educated communities of the world."

THE Trustees of the British Museum appear to be determined to earn the reputation of hopeless incapacity for appreciating science. Everybody knows how completely successful has been the experiment of furnishing the reading-room of the British Museum with the electric light, and what an impetus this has given to the use of the British Museum Library. A few days ago a question was asked in the House of Commons by Mr. D. Grant, whether the Trustees were prepared to make arrangements for lighting the building so that the scientific collections and other portions of it might remain open to the public until 10 p.m. The answer returned by Mr. Walpole on behalf of the Trustees was unsatisfactory enough. The use of gas would be deleterious to sculptures and books; and experience would not "justify" a more extended use of the electric light in the exhibition-rooms and long galleries. The body of Trustees, though they may be admirable custodians of the national library, appear to have the most limited and provincial notions with respect to the scientific collections which are committed to their charge.

THE ways of official French science are somewhat inscrutable. Some months ago we notified our readers that the *prix Volta*, instituted by Napoleon, had been awarded to Graham Bell for the articulating telephone. It appears that this award was made in accordance with the report of a commission appointed in 1876, of which M. Dumas was president and M. Becquerel secretary, the Commission being unanimous in their award. In their report they also mentioned with high approval the names of M. Gramme, the inventor of the Gramme machines, M. Gaston Planté, whose researches on secondary batteries, &c., are now so well known, and Dr. Onimus, who has done much to advance our knowledge of electro-physiology. But in passing through the hands of the Minister of Public Instruction this report was manipulated in order to please the national vanity by lifting up the claims of M. Gramme above those of MM. Planté and Onimus, and eventually a grant of 70,000 francs was voted by the Chamber, 50,000 francs being the prize awarded to Prof. Bell, and 20,000 francs to M. Gramme. No one will grudge M. Gramme his prize, though we cannot help thinking that this secondary award will give rise to invidious comparisons of claims, for M. Gramme is not the first nor yet the last in the field amongst electrical engineers and inventors.

THE fund established by the Birmingham Philosophical Society for the endowment of scientific research now amounts to 820*l*., which will be invested, the interest only to be used. The subscription list amounts to over 80*l*. a year. A donation of 25*l*. has been received from Mr. Charles Darwin, who, in a letter received from him by Mr. Lawson Tait, a member of the council of the Society, says:—"I saw something in the newspapers about the fund, and admire greatly the noble spirit of Birmingham."

WE have often referred to the enterprise of the Midland Union of Natural History Societies, and now they have gone in for the encouragement, if not the endowment, of original research. The Council, at the last annual meeting at Northampton, submitted for consideration a proposal to the effect that an annual prize should be provided for the purpose of recognising and encouraging original research by members of the societies in the Union. After careful consideration by the committee at a meeting held at Birmingham on July 15, the following scheme was adopted:—1. That a prize (by permission of Mr. Ch. Darwin, F.R.S., to be called "The Darwin Prize") of the value of 10*l*., to include a gold or bronze "Darwin Medal," at the option of the successful candidate, be given annually for a paper indicating original research upon a subject within the scope of the societies in the Union, contributed by a member for publication in the journal of the Union. 2. That the subjects for "The Darwin Prize" for the three years ensuing be limited as under:—In 1881 to Geology, in 1882 to Biology, in 1883 to Archæology. 3. That a committee of five, annually elected for the purpose by the Committee of Management, adjudicate the prize to such paper, of sufficient merit, on the subject of the year, contributed as aforesaid to the journal of the Union (the *Midland Naturalist*), either actually published or sent in for publication during the twelve months preceding March 31 of that year, and declare the adjudication at the annual meeting. 4. That right be reserved for the adjudicators to withhold the prize if in their opinion no contribution has been sent in of sufficient merit. The scheme is a happy one, and might with great advantage be adopted by other groups of societies all over the kingdom. Mr. Darwin, in giving permission for the use of his name in connection with the medal, says: "It is particularly pleasing to me to have my name connected, in however indirect a manner, with a scheme for advancing science—the study of which has been my chief source of happiness throughout life."

THE death is announced of M. Lissajous, the discoverer of the well-known Lissajous figures, and author of a number of elegant and valuable scientific memoirs. M. Lissajous, who was Professor of Physics at Toulouse, was one of the founders of the Société Française de Physique.

A COMMITTEE has been formed to erect a statue to the late Dr. Broca by public subscription.

WE have received the following details with reference to the career of the late Mr. W. A. Lloyd:—Born in Wales, he early developed a taste for study, and in his early years went deeply into such subjects as archæology, numismatics, and heraldry. In 1852 he turned his mind to natural history, especially as regards marine life. The first really successful marine aquarium was that at Hamburg, which was wholly devised by him, and in which the circulating principle was the great element of success. In 1870 he was engaged by the Crystal Palace Company to construct and superintend the fine aquarium there, which, although not large, is probably one of the best existing. His reputation spread, and he was consulted for almost every new aquarium that was projected. Besides his practical knowledge of the aquarium, he was a man of very considerable culture, and contributed largely to the literature of the subject. At the time of his death he was engaged on a work comprising all his life-long experience, which unfortunately he has not completed. His death, at the age of fifty-six (July 13), was the result of effusion of blood on the brain, and took place at his study table, where he was at work. Mr. Lloyd was connected with aquaria at Paris, Vienna, Dresden, Frankfort, Naples, New York, San Francisco, Melbourne, Adelaide, Calcutta, Rhyl, Yarmouth, Tynemouth, Nottingham, Morecambe, Edinburgh, Westminster, Southport, Rothesay, Aston, and possessed the only medals (gold, silver, and bronze) ever awarded for aquaria.

THE Committee of Council of the British Medical Association have awarded the gold medal of the Association to William Farr, C.B., M.D., F.R.S., D.C.L., "as an expression of their high appreciation of his long, unwearied, and successful labours in behalf of statistical and sanitary science; as a recognition of the light he has thrown upon many physiological and pathological problems; and on account of the extraordinary services

his work has rendered to the advancement of the health of the nation." The presentation will be made in the Senate House, Cambridge, on Thursday, August 12, at half-past twelve in the afternoon.

THE French Parliament has voted a sum of 300,000 francs for purchasing from the City of Paris the grounds which had been rented for a nominal sum to M. Leverrier by the Municipal Council, and had been already annexed by the great astronomer to the Observatory. The reason for this resolution is the impending erection of a new monument, which, according to the provision of the French law, cannot be built except on ground the freehold of which belongs to the Government.

THE first of the great annual Congresses, that of the Archæological Institute, commenced proceedings at Lincoln on Tuesday.

THE summer meeting of the Institution of Mechanical Engineers will be held at Barrow-in-Furness from Tuesday to Friday next week. A number of technical papers will be read, and several interesting excursions have been arranged for.

SIR W. HARCOURT stated in the House of Commons on Thursday that the Commissioners on Explosions in Coal Mines hoped to make their report at the end of the present or beginning of next year.

THE first annual meeting in connection with the Parkes Museum of Hygiene was held at the Mansion House on Tuesday, when a number of eminent medical men were present. The Museum has so expanded that a building specially designed for it has become necessary. It has attracted a considerable number of visitors, and during the past winter a series of demonstrations have been given by members of the executive committee. The various speakers testified to the great educational value of such a museum, and the absolute necessity for all classes to know something about sanitary science.

THE Council of Public Hygiene of Paris, on the proposition of M. Pasteur, has decided to erect two establishments, one at each end of Paris, intended for the disinfection by steam of all furniture or clothing contaminated by individuals attacked by any contagious diseases.

AN official despatch from Manila of the 20th inst., giving some additional particulars of the earthquake, states that the first shock lasted seventy seconds, and that nine of the native inhabitants were killed and eleven others injured. A second shock, lasting forty seconds, occurred at four o'clock in the afternoon. At Leguno and Rabacan some of the public buildings were also thrown down. The earth opened in several places, and jets of boiling water and showers of ashes were ejected from the fissures. Another shock is stated to have occurred on the evening of the 24th. Other accounts received state that the period of seismic disturbance commenced on the 13th inst., and that repeated shocks have occurred since then, those of the 13th and 20th inst. being the most violent. The cathedral and the barracks at Manila have fallen in, and the troops are now encamped outside the city. Almost all the volcanoes of the island of Luzon are in full activity.

A SHARP shock of earthquake occurred at Naples at 3.30 on Sunday morning, preceded by lighter shocks at regular intervals, beginning at 9.30 the previous night. The principal shock was undulatory from east to west, lasting five seconds, and was sufficiently strong to awake all the inhabitants of Portici. Vesuvius shows increased activity. Several new fissures have opened, sending lava streams eastwards.

THE Epping Forest and County of Essex Naturalists' Field Club held a meeting at Ilford last Saturday for the purpose of visiting the well-known pits which have yielded such a rich harvest of Post-glacial mammals, &c. A well-preserved jaw of *Bos primigenius* was exhumed in the presence of the members. The zoology of the period and the geology of the district were respectively treated of by Sir Antonio Brady and Mr. Henry Walker, the conductors for the occasion. After spending some time in the pits the meeting adjourned for tea to the "Angel Inn." The president announced that as the result of the Field Meeting at the ancient earthworks in Epping Forest (already noticed in these columns) it was decided, in accordance with a suggestion made by Major-General Pitt-Rivers, to apply for permission to excavate in one or both of the camps, and to start a fund for this purpose. As the period of these camps was quite unknown, this would be the only method of arriving at any definite conclusion concerning them. A discussion upon the results of the afternoon's excursion then took place. Sir Antonio Brady brought for exhibition a large number of specimens from his valuable collection of Palæolithic and Neolithic remains; and remarks of great scientific interest were made by Mr. A. R. Wallace, Mr. Worthington Smith, &c. The Club appears to be in a flourishing condition, as it already numbers over 200 members.

M. GAUTHIER VILLARS is publishing, at the expense of the Laplace family, a new edition of the works of the illustrious astronomer. The reason of this republication is very singular. The widow of the Marquis de Laplace bequeathed a certain sum of money to the Academy in order to deliver every year a copy of the works of her husband to the youth who obtains the first rank in the leaving examinations at the Polytechnic School. But latterly it has become almost impossible to find these volumes in the trade. M. Gauthier Villars and executors *in perpetuo* are obliged to deliver gratis a copy every year to the Academy.

PROF. CHURCH was lecturing last week at the Cirencester Agricultural College on "Some Recent Advances in Agricultural Chemistry."

A FRENCH journal states that the first astronomical instruments intended for a great astronomical observatory, to be established at the Trocadéro, have been recently mounted on the first terrace of the east tower of the palace.

ON August 8 the pupils of all the schools of the Arts et Métiers of France meet at Liancourt to celebrate the 100th anniversary of the foundation by the Duc de la Rochefoucault-Liancourt of the first establishment of this kind at his private residence. There are four of these useful schools—Aix, Angers, Chalons, and Cluses—in existence in France, and one in Algeria, of very recent creation, at Delhys. It is said that each of the two provinces of Oran and Constantine will establish, at their own expense, a similar institution.

THE President of the Republic has conferred a knighthood in the Legion of Honour on M. Serrin, the inventor of the first regulator which could be used in lighthouses; and on M. Gariel, the general secretary of the French Association for the Advancement of Science, who will lecture on Radiant Matter at Rheims in the forthcoming session.

"TASMANIAN Friends and Foes, Feathered, Furred, and Finned," is the title of a work, illustrated by woodcuts and coloured plates, upon the Natural History of Tasmania, to be issued this autumn by Messrs. Marcus Ward and Co. The volume is from the pen of Mrs. L. A. Meredith, the author of several well-known works upon this colony, and gives in a popular style accounts of the kangaroos, bandicoots, wombats, and other marsupials, the birds and fishes. Several of the species described the author believes to be new to science, and the marvellous intelligence displayed by some of these lowly-

classified mammals when kept by the author as household pets will be both new and interesting to English readers.

THE additions to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. Fred Peake, F.Z.S.; a Great Eagle Owl (*Bubo maximus*) from Nyland, South Finland, presented by Mr. Lindsay von Julin; two Ocellated Turkeys (*Meleagris ocellata*) from Yucatan, Mexico, presented by Mr. W. E. Sibeth; a Crimson-crowned Weaver Bird (*Euplectes flammiceps*), two Red-backed Pelicans (*Pelecanus rufescens*) from West Africa, two Common Blue Birds (*Sialia wilsonii*) from North America, two Great Eagle Owls (*Bubo maximus*) from India, five Four-rayed Snakes (*Elaphis quater-radiatus*), a Black-spotted Snake (*Elaphis dione*), a Lacertine Snake (*Cœlopeltis lacertina*), four Dahl's Snakes (*Zamenis dahli*), thirteen Vivacious Snakes (*Tachymenis vivax*), a Four-lined Snake (*Coluber quadrilineatus—var. leopardinus*), South European, deposited; five Australian Wild Ducks (*Anas superciliosa*), three Garganey Teal (*Querquedula circia*), three Common Teal (*Querquedula crecca*), two Horned Tragopans (*Ceriornis satyra*), a Peacock Pheasant (*Polyplectron chinquis*) a Bronze-winged Pigeon (*Phaps chalcoptera*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

FAYE'S COMET.—The following ephemeris of this comet is for Berlin midnight, and is calculated from elements accurately perturbed to the approaching perihelion passage, which were communicated by Dr. Axel Möller to the Academy of Sciences at Stockholm in September, 1878:—

	R.A. h. m. s.	Decl. N. ° ′	Log. dist. from Earth.
Aug. 1	23 16 14	10 35·5	0·1859
3	— 16 16	10 40·3	0·1784
5	— 16 12	10 44·3	0·1709
7	— 16 3	10 47·2	0·1635
9	— 15 48	10 49·2	0·1562
11	— 15 28	10 50·2	0·1490
13	— 15 3	10 50·1	0·1419
15	— 14 33	10 48·9	0·1349
17	— 13 57	10 46·6	0·1280
19	— 13 17	10 43·2	0·1213
21	— 12 31	10 38·6	0·1147
23	— 11 42	10 32·8	0·1083
25	— 10 47	10 25·8	0·1021
27	— 9 49	10 17·5	0·0961
29	— 8 47	10 8·0	0·0903
31	23 7 41	9 57·3	0·0847

The theoretical intensity of light at the end of the month will be twice as great as at the beginning, when it somewhat exceeds that corresponding to the last observation at Pulkowa in March, 1866. At the return in 1873 the comet was observed on four nights only at Marseilles and at Clinton, New York; the admirable calculations of Dr. Axel Möller gave positions which exhibited hardly appreciable differences from the observations. In the present year it will be nearest to the earth on October 3 (distance = 1·09), and perhaps most favourably circumstanced for observation during the last ten days of the same month, though at no time does the intensity of light exceed its value on October 16, 1858, when the comet was last observed at that appearance with the 10-inch Berlin refractor. The perihelion passage does not take place until January 22, 1881, and although Dr. Axel Möller's ephemeris does not extend beyond the end of the present year, it appears possible that the comet may be observed till quite the end of next February, when its place will still be commanded on a dark sky-ground, or perhaps later; indeed, on April 26, when the comet sets three hours after the sun, its intensity of light is equal to that at the last observation at Pulkowa in 1844.

THE OBSERVATORY, CHICAGO.—The "Annual Report of the Board of Directors of the Chicago Astronomical Society, together with the Report of the Director of the Dearborn Observatory," dated May 13, 1880, is before us. During the preceding year the Observatory had been in charge of Prof. G. W. Hough, formerly of the Dudley Observatory, Albany, Prof. Colbert and Mr. S. W. Burnham taking part in the regular work with the 18½-inch Alvan-Clark refractor. Mr. Burnham's attention, as in previous years, was chiefly directed to the measurement of double stars, including the more interesting binary systems and objects beyond the scope of smaller instruments. A series of observations of the planet Jupiter was commenced on August 27, 1879, and continued on every fine night till February 11. With a magnifying power of 638 the disk was measured on eight nights by Prof. Hough, and six by Prof. Colbert, the resulting values for ellipticity being respectively 1-16·23 and 1-16·73, sensibly smaller than Struve's value, though not differing much from other more recent determinations. The measures further showed "the figure of Jupiter's disk to be a true geometrical spheroid." The belt system during the opposition of 1879 is indicated by the following numbers, the equatorial diameter at the planet's mean distance being 38″·70, and the polar diameter 36″·32.

No. 1 ...	+ 15″·10		No. 5 ... − 5″·83
„ 2 ...	+ 9·78		„ — ... − 6·94 Red spot.
„ 3 ...	+ 5·98		„ 6 ... − 9·83
„ 4 ...	+ 2·59	N. edge of equat. belt.	„ 7 ... − 13·84
„ — ...	− 3·18	S. edge of equat. belt.	

An examination of which shows that the belts were symmetrically arranged on either side of the equator, the large red spot coinciding nearly with belt (5). Prof. Hough remarks that the faint belts are not seen with small instruments, in which there is merely a darkening towards the poles. The middle of the great equatorial belt was subject to gradual change in its appearance between September 1 and November 1. At first it was made up essentially of three separate belts, approximately of equal width; gradually it formed in two nearly equal portions with a rift extending through a large part of the planet's circumference. The colour of the equatorial belt was reddish-brown—brick colour.

The red spot was studied from September 3 to February 10. Its colour was similar to that of the equatorial belt, but brighter, and appeared sensibly the same when only partially on the disk as when on the centre. The mean value of its length at the centre of the disk was 12″·73, and its breadth 3″·56, for Jupiter's mean distance; the length appeared to vary to the extent of two seconds, and the breadth about the same amount, but owing to the irregular outline of the object it was difficult to decide whether actual change took place, or whether the discordances in the measures were due to indifferent vision. By observations extending from September 25 to February 10 the time of sidereal rotation was found by Prof. Colbert to be 9h. 55m. 34·2s. The diameters of the satellites were measured on three nights with the following results for the planet's mean distance:—

I. 1″·114 ... II. 0″·980 ... III. 1″·778 ... IV. 1″·457

Prof. Hough states that the two interior satellites of Uranus reported by the Washington observers to be "the most difficult well-known objects in the heavens" can be "readily seen and measured under ordinary atmospheric conditions" with the Chicago refractor: micrometrical observations of *Ariel* were obtained on four nights, *Umbriel* appears to have been measured on one night only, but the weather was unusually adverse to this class of observations.

PHYSICAL NOTES

A SINGULAR phenomenon was seen (according to the *New York World*) recently off the coast of Florida by the officers of the brigantine *Fortunate*. Shortly after dark two columns of fire appeared, seemingly a mile away. They were fifty yards apart and about 500 feet high, arching towards one another at the top, but without meeting. They were of a dull red colour, without sparks; but the arching portions emitted tremulous rays or streamers of light like those of the aurora. They were visible all night, but faded at daybreak. The weather was fine, not a cloud being seen all night. The following day there was a gale of wind accompanied by thunder, but no rain. It is not stated in what quarter of the heavens the appearance was seen. Could it have been an *aurora?*

M. MARCEL DEPREZ, the ingenious inventor of many pieces of electrical apparatus, has just brought out a new electric motor, in which a piston of soft iron is attracted up and down in a hollow cylindrical electro-magnetic coil with a motion like that of an

ordinary steam-engine piston. This principle is not new, having been employed by Page, Bourbouze, and Du Moncel in the construction of electro-motors. The novel point however about the motor of M. Deprez is that the magnetism of the soft iron core is never either reversed or interrupted. This was the weak point of the earlier machines, but it has been obviated in the new form by the device of dividing the solenoidal coil into sections like the separate coils of the ring-armature of the Gramme machine, the current being thus transmitted first to one part of the cylindrical coil and then to another. The commutator which distributes the current successively to the various sections is worked by an excentric on the shaft of the fly-wheel in the ordinary way, but the "lead" does not require to be so much as a quarter of a revolution.

The phenomena of explosion of bombs by freezing of water (once studied by Major Williams at Quebec) have been further elucidated by Prof. Hagenbach of Bâle (*Archives des Sciences*, June 15), who exposed, last winter, two iron bombs 15 ctm. exterior diameter and 2·2 ctm. thickness, filled with water and closed by screw stoppers, at temperatures descending to $-20°$. One bomb, placed out early in the afternoon, burst next morning about 7; the other, exposed about 10 a.m., exploded about 9 p.m. In the latter case the stopper was violently projected to a distance and could nowhere be found (the spotless snow around would have soon revealed its position, if anywhere near). Some parts of the screw thread were detached; there were several fissures round the orifice, and a cylinder of striated ice was forced out, having an irregular top and a curious upward-curved filament of ice attached, narrowing from 9 mm. to 3 mm. diameter, and flattened on its upper concave surface. It is thought a little water in suspension got out by the first opening in the screw, flowed down the bomb, and froze; its freezing provoked crystallisation of the whole mass, and the stopper was expelled, the ice following and lifting the attached frozen vein. A little later some water within the expelled cylinder probably froze and burst the top of this cylinder into four pieces, which twisted like petals, causing the filament to turn upwards. The other case was perhaps even more curious. The stopper was not thrown out, but the bomb burst, a triangular piece next the stopper being raised. A round filament curving downwards was here found attached to the protruded ice, and it had some sixteen enlargements or nodes, equidistant 7 mm. The initial jet of water had probably come out with high velocity and straight course, and been solidified, afterwards curving down by the action of gravity. The nodes were doubtless due to the vibratory motion observed in liquid veins.

In a recent paper to the Vienna Academy (June 10), Prof. Reitlinger and Dr. Wächter throw some new light on the nature of "electrical ring-figures." They consider these to arise from two causes not clearly perceived before; first, a disruption of the metal, with projection of solid, fused, and vaporised particles from it by positive electric potential alone; and second, an electro-chemical decomposition of aqueous vapour present in the atmosphere in which the figures are produced, between point and plate. To the first-named cause is due the *disruption disk* (*Aufreissungscheibe*) in the centre of positive or mixed figures, and appearing oxidised in air, but metal-bright in hydrogen (it affords a new mode of distinguishing positive electricity from negative). With a strong spark (from a Ruhmkorff strengthened with a Leyden jar) the authors got *dispersion and condensation rings* round the disk, presenting various metallic colourings in dry hydrogen. To the second cause (electro-chemical decomposition of water-vapour) are attributed the various-coloured *oxide rings*, giving the ring-figures observed by Priestley, Nobili, Grove, Riess, &c., and Peterin's *bright disks*. The former occur where positive, the latter where negative, electricity passes from the plate into the air. Thus all the ring-figures observed consist of four "form-elements," viz. (1) central disruption-disks; (2) oxide rings; (3) bright disks; and (4) dispersion and condensation rings. It is further found that all these kinds can be altered in form by a magnet.

According to the dynamical theory of gases it is probable that the exponent characterising the relation of the coefficient of diffusion to the absolute temperature is higher by unity than in the case of coefficients of internal friction. This has been fully confirmed by experiments of Herr v. Obermayer (*Wien. Akad. Anz.*, May 7), which give, for permanent gases, approximately $1\frac{3}{4}$, for coercible 2 (the lower exponents being $\frac{3}{4}$ and 1). The experiments extended over too few gas-mixtures to determine how the exponent is affected when a coercible and a permanent gas diffuse into each other.

Don Eduardo Lozano of Teruel, Spain, has lately published a modest little volume of ninety pages, entitled "Estudios Fisicos," in which some of the more recent advances in physical science are explained in an easy and popular form. Amongst the topics are the blue of the sky, the mechanical equivalent of heat, atmospheric electricity, &c. It is interesting to observe such signs of a revival of interest in the physical sciences in Spain. It is somewhat of a novelty to find the names of Mayer, Hirn, Wells, Dove, and Tyndall in a Spanish treatise; and we draw a good augury from this sign that these names have already penetrated into a country where science has unfortunately been so long at a low ebb.

A Bunsen burner of modified form has been contrived by M. Terquem which promises to be well adapted for spectrum work and for producing monochromatic light. Instead of the usual two lateral apertures to admit air, the air is allowed to penetrate between the foot of the lamp and the base of the vertical tube, which is for this purpose raised 6 or 7 millims. above the solid foot. The top of the tube is divided into four by a couple of vertical partitions, so that instead of the usual central cone in the flame there are four cones. It is claimed for this flame that it is more solid, and that the temperatures throughout the different parts of the flame are more nearly equal than in the usual Bunsen burner. To procure monochromatic light it suffices to place a small fused bead of sodic chloride between the four central cones of flame.

Following out his recent discovery that the prolonged action of the actinic rays upon a sensitised photographic plate produces a reversal of effects, M. Janssen has obtained some interesting results. He has by direct exposure taken a positive photograph of the sun 10 centims. in diameter, showing the spots in their usual dusky tints. He has, after exposures varying from one hour to three hours, obtained perfect positives of landscapes. A view of the park of Meudon thus photographed shows the sun as a white round spot upon a dark sky. Moreover, from such positives other positives can be printed by prolonged exposure; and it is now possible to obtain negative prints of negatives by the same simple expedient. M. Janssen promises at an early date a complete and searching memoir on the whole subject of photography in relation to the different rays of the spectrum.

An electrical stone-breaker is the latest American invention. A dynamo-electric machine furnishes the power to an electro-magnetic chopper capable of delivering from 1,000 to 2,000 blows per minute. Stone-breaking requires the exertion of very great forces through very small distances, in fact precisely the kind of work for which electro-magnetic machines on a large scale might be expected to be successful, if only the cost of generating the electricity were not so serious.

In a recent valuable paper on the thermal and optical behaviour of gases under the influence of electric discharges (*Wied. Ann.*, No. 6), Herr E. Wiedemann first studies the thermal phenomena in the case of discharges of the influence-machine, and indicates a different behaviour of the positive and the negative electricity. He then describes an experimental attempt at numerical determination of the quantities which produce a change of the band-spectrum of hydrogen into the line-spectrum. He further investigates the nature of the discharge from the negative electrode in greatly rarefied space. Then he discusses the applicability of other electrical sources, inductoria, large galvanic batteries, and Leyden jars, to spectrum-analytical researches, also the continuous and discontinuous discharges in gases. The paper concludes with theoretical considerations as to the phenomena of discharge in gases and the nature of spectra.

The known abnormal variation of density of mixtures of acetic acid and water suggested to Herr v. Reiss (*Wied. Ann.*, No. 6) a means of ascertaining whether there were any perceptible relation between the densities and specific heats. He finds that, unlike solid bodies, those mixtures show in general, with increase of density, a proportional increase of specific heat.

An example of anomalous dispersion by a glowing vapour, viz., that of sodium, has been recently observed by Herr Kundt (*Wied. Ann.*, No. 6). He was preparing for a lecture the well-known experiment of reversal of the sodium line, and per-

ceived that when the absorbent sodium-vapour was very dense and the dark line very broad a peculiar bend outwards appeared in the spectrum at the ends, and on opposite sides, of the line. The cone of sodium vapour in the Bunsen flame acts as a prism with upward horizontal refracting edges. If glowing sodium vapour give dispersion, this cone should give, with horizontal rays passing through it, a vertical (though necessarily impure) spectrum; and if the rays have also passed through a glass prism with horizontal refracting angle, a spectrum of the form above described should be got. From the position, the refractive index of the vapour is greatest for those rays which are most deflected downwards. In agreement with the author's researches on solid bodies and liquids, the refractive index increases greatly as you approach the band from the red side, is less on the green side than on the other, and then quickly increases again. If an actual prism of glowing sodium vapour could be produced, one might observe, even with little thickness of vapour, indications of anomalous dispersion in the narrow absorption lines. Herr Kundt's attempts, however, to change the cone-shaped flame, by means of lateral plates of glass or mica, to a prismatic one, led to nothing.

IN a recent paper on the theory of inconstant galvanic elements (*Wied. Ann.*, No. 6) Herr Exner contends that the so-called galvanic polarisation in elements has no existence. The distinction between a Daniell and a Smee element is merely quantitative, not qualitative. What does he mean?

GEOGRAPHICAL NOTES

WE understand that a letter was received in London last Saturday from a member of one of the Belgian Expeditions in Central Africa, stating that he had met Mr. Thomson, with the African Exploration Fund's Expedition, on May 18, at a place some ten days' march from Simba's, so that the party had evidently found it necessary to return to the coast by the caravan route to Bagamoyo or Saadani instead of following the original plan of coming out at Kilwa. It is probable that the change of route was necessitated by civil wars among the native tribes. Mr. Thomson has thus had an opportunity, not contemplated at the outset, of passing through a considerable tract of unknown country between the south-east of Lake Tanganyika and Unyanyembe, and it is satisfactory to know that in so doing he has been able to visit Lake Hikwa and settle its proper position, which has been a puzzle to geographers for some time. In a map accompanying the account of Mr. H. B. Cotterill's journey with the late Capt. Elton northwards from the head of Lake Nyassa, this lake is placed with dotted lines in a position which is probably a good deal too much to the south and east of its true locality. The letter above referred to added that Mr. Thomson was in excellent health, and that he claimed to have traversed 2,000 miles of unknown country in the twelve months he had then been on the march. A telegram from H.M.'s Consul-General at Zanzibar, dated July 17, announces the safe return of Mr. Thomson and his party.

MR. ALFRED RABAUD, president of the Marseilles Geographical Society, has just published (Marseilles: Barlatier-Prissat) a *brochure* entitled "L'Abbé Debaise et sa Mission géographique et scientifique dans l'Afrique centrale," which is accompanied by a photograph of the deceased traveller.

PROF. R. J. VETH, president of the Dutch Geographical Society, has just issued in Italian (Turin: Guido Cora), "Notizia de Selajar et Isole Adiacenti," which is illustrated by an original map of Selajar and other islands of the Celebes group, together with a note by Signor Cora.

THE *Travailleur*, with the French Government Expedition for the exploration of the Bay of Biscay, left Bayonne on July 17, having on board MM. Milne-Edwards, father and son, Vaillant, of the Natural History Museum; Fischer, assistant naturalist; Marion of Marseilles, Fohn, Perin, and the English naturalists, Dr. Gwyn Jeffreys and the Rev. Mr. Norman. The results of the expedition may be described at the Swansea meeting of the British Association.

NEW SCHEME FOR DIRECTING BALLOONS

M. GABRIEL YON, one of the directors of the great Giffard captive balloon, and Mr. E. A. Pearse of Bristol, have each published a pamphlet on the direction of aërostats. The balloon of each inventor is to be elongated according to the principles of the experiments tried by Giffard in 1852 and by Dupuy de Lome in 1871. The propeller is to be moved by a gas-engine in the Pearse balloon, and by a steam-engine in the Yon balloon. M. Yon proposes to use the gas of the balloon as fuel, but only in proportion to loss of weight produced either by uncondensed steam or by consumption of petroleum.

Nothing can be said to be really impracticable in the Pearse scheme, although Mr. Pearse lacks the aëronautical training which distinguishes M. Yon, an aëronaut who ascended with M. Giffard in 1854, and has witnessed all his experiments. The only essential difference between M. Giffard's scheme and the new system is the place given to the fan, which M. Giffard attaches to the car. Practice will only decide whether the alteration projected is an improvement or otherwise. The reason alleged for the change is the bringing of the fan nearer to the centre of resistance. But it obliges the aëronaut to give to his fans a very small diameter, which requires an immense number of rotations in a second, and consequently represents a loss of power.

The calculations appear to have been made with care by M. Yon and Mr. Pearse. A trial would be greatly desirable, although it is impossible to suppose that the aërial carriage of Mr. Pearse or the directing balloon of M. Yon can possibly bring aëronauts to the North Pole for their inaugural trip, they may be instrumental in eliciting useful facts. We may add to the peculiarities of M. Yon's scheme that he uses a small globe inclosed in the lower part of the aërostat called a compensation sphere, and connected by a pipe with a ventilator, for keeping intact the form of his aërial machine. Mr. Pearse does not appear to be convinced of the urgent necessity of abstaining in any aërial construction from every complication which can be avoided at any cost, and he suggests the adoption of some accessory organs which, although designed to help aëronauts, would tax too much the lifting power or the attention of the aërial sailor. Mr. Pearse supposes that he will be able to navigate the air with an excess of weight, and does not pay attention to the intensity of motive power required to counteract gravitation even in a partial manner. He should certainly take advantage of the pamphlet written by his French competitor, who deals mostly with facts belonging to the public, and on which nobody can, in the present state of science, raise any claim as being his own property.

Both these pamphlets are greatly in advance of similar productions, and are creditable to their writers. Mr. Pearse's pamphlet has been only published for private publication. M. Yon's is printed with a number of plates representing many details; but a directing balloon is so complex a matter that this part of the publication can hardly be said to be complete.

Having been the builder of M. Dupuy de Lome's balloon and one of his crew, M. Yon may be said to have witnessed all the great aëronautical constructions of the age. Next to M. Henry Giffard, of whom he claims to be the pupil, he is the most completely qualified aëronaut to work out the solution of the great problem to which a recent success in photography has given unexpectedly in some respects a practical result.

W. DE FONVIELLE

EXPERIMENTS WITH THE WIRE TELEPHONE, CHIEFLY ON STRONGLY MAGNETIC METALS

BY a wire telephone is meant an instrument like that described in NATURE, vol. xxii. p. 168. In most of the experiments mentioned below, the mercury cups there figured were dispensed with, as they are unnecessary when stout wires are used. A small ear-piece with a ferrotype plate was also used instead of the drum-head, whose special purpose was to reproduce music so as to be audible at a distance. For hearing close at hand the ferrotype plate is much superior; indeed with the drum many of the sounds alluded to below could not be heard.

So far as I can see yet, the most probable cause of the sound in the wire telephone, when fine wires of ordinary weakly magnetic metals are used, seems to be variation of the longitudinal tension arising from the variation of the heating effect of the current. It is of course quite possible that there may be a lengthening of the wire due to the passage of the current over and above that arising from the heat developed, although such an effect can scarcely be said to be certainly established by experiment as yet.

Besides this cause three others were traced in the course of my experiments: Electrostatic action, external magnetic action, and internal magnetic action.

The following experiment was made with a very fine palladium silver wire, about 13 cm. long, as sounder. I connected the violin and microphone with four Bunsen's cells in circuit with the primary of a small induction coil (resistance of primary ·27, resistance of secondary 44), while the wire telephone was put in circuit with the secondary. With this arrangement the music was reproduced quite audibly, although the quality of the notes was "wiry." This small coil had a movable core, consisting of a bundle of iron wires, and the sound was louder with than without the core.

I next tried a more powerful induction-coil (resistance of primary ·3, secondary 320), all the other arrangements being unaltered. The music could then be just heard, but no more.

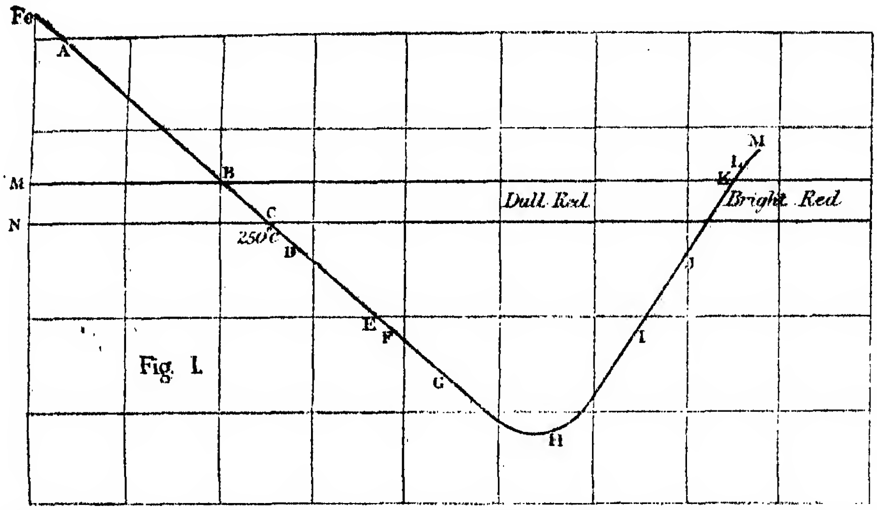

FIG. 1.—Iron.—A, sound very feeble at the temperature of the air; B, high note distinctly heard and increasing; C, feeble fizz now heard; D, fizz increased; E, quality of sound deepening; F, low note heard; G, sound very loud, low, medium, and high notes and buzz; H, no falling off; I, falling off now evident; J, marked diminution; K, fizz very soft, nearly gone; L, high note left; M, silence.

A large and very powerful induction-coil (resistance of secondary about 10,000), tried under similar circumstances, gave no result whatever.

Electrostatic Action.—As I have said, nothing was heard with the large induction coil when the secondary circuit was closed; but when it was interrupted at a mercury break, a loud hissing, rattling noise was heard. This could not have come by mechanical transmission from the induction-coil, which was several rooms off, the line wires being hung to the walls and jammed over three doors. It had its seat at the mercury pools of the break, and was doubtless due to electrostatic action. Similar sounds, only weaker, were observed with the smaller Ruhmkorf when the circuit was broken.

If two small disks separated by a small air-interval were made the terminals of an induction-coil, in the primary of which an interrupted current flows, they would form a condenser, and the difference of potential between them would vary in unison with the primary current. Consequently the electrostatic force of attraction would vary, and the disks, being set into vibration, would act as a telephone. The sounds in Thomson's singing condenser are probably due to this cause.

I have not attempted to carry this idea into practice, but I believe that telephones have been made on this principle by Edison and others.

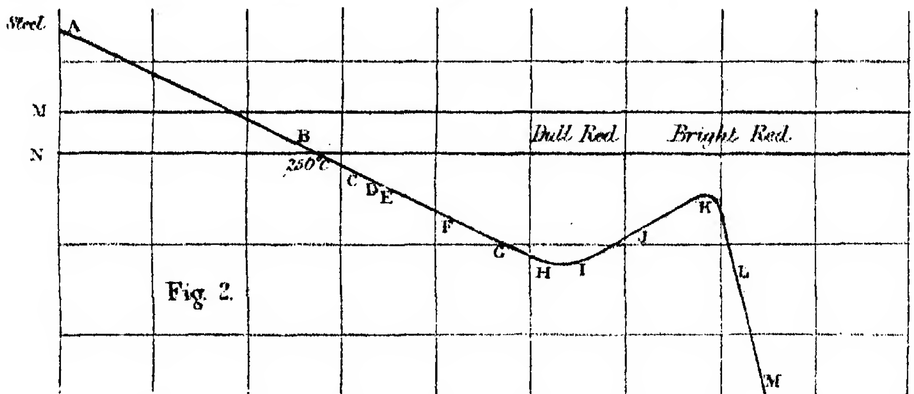

FIG. 2.—Steel.—A, fizzing sound and high note, neither loud; B, silence; C, high note comes in again; D, sharp fizz; E, buzzing sound and general increase of loudness. The other letters as with iron.

External Magnetic Action.—If the stretched wire of the telephone be brought into a magnetic field so as to cross the lines of force, and an interrupted current passed, loud sounds are heard. I used a tuning-fork interrupter with two Bunsen's cells. When a thick copper wire was put into the telephone, at first nothing whatever was heard; but when a horse-shoe magnet was brought up, and held with its plane perpendicular to the wire, the note of the fork was heard very loud (much louder than in the neighbourhood of the fork itself, in fact), and comparatively pure. Little or none of the hissing or buzzing sound of which I shall have to speak by and by can be got in this way. It makes no great difference to the sound produced in this way whether we use a wire of 2 mm. diameter or a wire ·3 mm. in diameter. With the thin wire, however, the visible amplitude

of the transversal vibrations is much greater than with the thick. Using a brass wire 15 cm. long and ·4 mm. in diameter, I obtained with a tolerably powerful horse-shoe magnet transversal vibrations of 2 mm. amplitude or more.

The wire telephone, when used in this way, is pretty sensitive to magnetic influences. The presence of the pole of a bar magnet could be detected at a distance of several inches from the wire. It might be used to explore the magnetic field in a rough way. I found, for instance, that when I brought up a north pole on one side I could neutralise its effects by bringing up a north pole to a proper distance on the other side.

To get these sounds it is by no means necessary to have any elaborate arrangement of stretched wire and so forth. If a magnet be brought up to the wire leading to the telephone, the sound will be heard quite distinctly. If the wire be grasped tightly in the fingers between the magnet and the telephone wire, the sound is stopped, showing that it is transmitted mechanically along the wire. This experiment is certainly not new, but, although I have seen the possibility of such action mentioned (*e.g.* Wiedemann, "Galvanismus," Bd. ii. p. 602), I have nowhere seen any indication that the sounds are so marked and so easy to produce. I believe that this cause has been at work along with others in many experiments on the sounds obtained in magnetisation; for instance, in De la Rive's experiments. It is impossible, however, to decide with certainty, because no sufficient indications are usually given as to the nature of the magnetic field in which the wire conveying the interrupted current was placed.

The wire telephone arranged in this way with the wire in a strong magnetic field is well suited for reproducing music. Whether it could be adapted for articulate speech, I do not know.

The above experiments of course raise at once the question whether the sounds in the ordinary wire telephone and those I shall describe presently may not be due to the earth's magnetism. To settle this point, I stretched a brass wire 15 cm. long in the telephone; the wire was fine enough to give a feeble sound of itself when the interrupted current of two Bunsen's cells was passed through it. I shifted the apparatus about, so as to bring the wire as nearly as possible into the line of dip, and then placed it perpendicular to that position; but I could not detect the slightest change in the intensity of the sound. If it be borne in mind that here the distinction between wires as to their thickness is only important in so far as it affects their stiffness, it will, I think, be clear that this experiment settles that the earth's magnetism is not an operative cause with the current strengths I generally used. Another proof of this will be given by and by.

Effects due to the Magnetism of the Telephone Wire itself.—The following experiments were made with a view to test a conjecture of Prof. Tait's, referred to in a letter to NATURE, vol. xxii. p. 168, and to settle, if possible, the cause of the exceptional behaviour of iron wires in the experiments of De la Rive and Dr. Ferguson.

Two Bunsen's cells were used throughout, and the current was interrupted by a tuning-fork driven by an auxiliary battery.

My first experiment was made with an iron wire (A, 19 cm. long, ·50 mm. diameter). It gave a moderately loud sound to begin with, a low note with a predominating fizz, not unlike the fizz heard at the mercury cup in the far room (owing, I suppose, to the volatilisation of the spirit by the heat of the spark, which passes when the dipper of the tuning-fork leaves the mercury).

When a portion of the wire was heated with a Bunsen flame the sound increased very much for a short time, and then died away again considerably after the wire got red hot. On allowing the wire to cool, the sound, after a short time, suddenly swelled out and then fell away again. The permanent sound was, however, louder than it had been at first.[1]

I soon satisfied myself, by cautiously bringing the flame up to the wire, that there is a certain temperature at which the sound is a maximum. The wire was heated up to white heat and allowed to cool pretty rapidly, and it was found that the sound was at its loudest at a dull red heat, just before the phenomenon of the re-glow occurred, along with which a peculiar crackling could be heard, due, no doubt, to the abnormal contraction and extension of the iron at that temperature.

Several causes at once suggested themselves. The alteration of the elasticity of the wire was dismissed as probably not the *principal* cause at all events; for the increase of the sound begins at comparatively low temperatures. Although I did not expect to find any such thing, I looked for a maximum of resistance at a high temperature by placing the iron wire in one circuit of a differential galvanometer, balancing it with an equal resistance in the other, and then heating. I found, as is already known, that the resistance increases with great rapidity after dull red heat, but obtained no indication of a maximum.

The most probable explanation seemed to be the magnetic properties of the wire. It is well known that the magnetic susceptibility of iron (that is, loosely speaking, its power to become inductively magnetised under the influence of a given magnetic force) is at its maximum about dull red heat; that it declines very rapidly at higher temperatures, and is almost insensible at a bright red heat. The coercitive force of iron, that is, its power to retain magnetism permanently, unaided by external magnetic forces, disappears at a much lower temperature.

The sound in the above experiment depends, therefore, upon temperature in the same way as the magnetic susceptibility of the iron wire. This is strong proof that the sound is simply due to the fact that the iron is magnetised. I convinced myself by direct experiment that the effect extends throughout the whole of the wire, for I found that two flames at different places produced, when properly applied, more effect than one, and that, as I brought more and more of the wire to the proper temperature, the sound grew louder and louder. The fact that on cooling the permanent effect was greater than before probably corresponds to the fact that, under certain circumstances, the permanent magnetism is increased by heating and subsequent cooling,

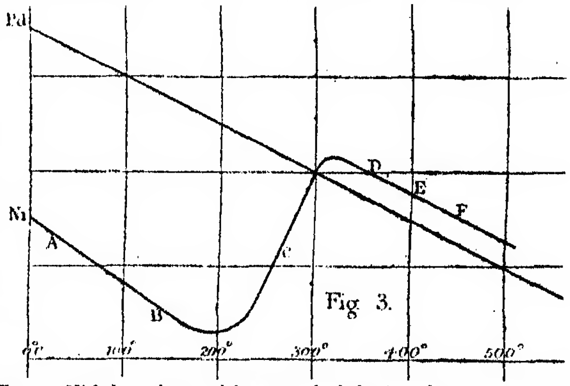

FIG. 3.—Nickel.—A, buzz and low note, both loud; B, low note, gone; C, buzz, tending to soften; D, buzz, gone; E, feeble high note; F, high note.

of which fact it was easy enough to make certain by testing the magnetism before and after heating.

I next took a piece of steel piano wire (B, 20 cm. long, ·9 mm. diameter) and mounted it in the telephone. At first no sound whatever could be heard. On magnetising it longitudinally, by stroking once or twice with a pair of magnets, a sound was heard quite distinctly, viz., a gentle fizz accompanied by a high note. On magnetising more strongly this sound became somewhat louder, but retained the same character. Gentle heating with a spirit-lamp decreased the sound; but it recovered its intensity when the wire was allowed to cool, and remained permanently a little louder than at first. Repeated gentle heating and cooling increased the permanent sound somewhat.

The wire was then strongly heated with a Bunsen flame. At first the sound died away to a minimum, then it increased, and was very loud about a dull red, then it fell off again. When the wire cooled the sound rose to a maximum, and then fell off, no minimum being perceptible. After this the permanent sound was a good deal louder, but the diminution on slightly heating could no longer be observed with certainty.

I next heated the steel wire B to white heat throughout, so as to deprive it entirely of all magnetism, and tempered it by dropping it into cold water when dull red. When put into the telephone after this treatment it gave no sound whatever. One stroke with a pair of bar magnets caused it to sound quite distinctly. It gave a gentle fizzing sound along with a very high note. Repeated gentle heating and cooling gave the same

[1] This phenomenon was observed by Dr. Ferguson independently, and exhibited to the Royal Society of Edinburgh at the meeting before that at which an abstract of the present paper was read.

results as I had got before. I then gradually raised the temperature till part of the wire was bright red, and finally allowed it to cool. As the temperature rose, the original fizzing sound died out, then the high note became inaudible, then there was a short interval of almost complete silence; after that a high note came in, then the fizzing sound again, which very quickly changed into a deep buzz, accompanied by a very low note like that of the tuning-fork, a note of medium pitch, and a high note (and possibly others), then the buzz died out, and at last the high note was left. When the wire cooled, the phenomena recurred in the corresponding order. First the buzz came back along with the low and medium notes, then it died away, and the high note alone was left; then there was silence, then the high note again, and lastly the fizzing sound.

Most of the notes heard, certainly the most prominent of them, appear to have little relation to the tuning-fork. They seemed to be affected to some extent by the tension of the wire.

When a magnet was brought up to the wire the deep note, obtained in a similar way with wires of other metals, was heard along with those peculiar to iron and steel.

These experiments with the steel wire appear to me to settle the question as to the cause of the sound in thick iron wires. The fact that the wire can be put into a condition in which no sound is produced, and then made to sound by magnetising it, shows that the action is due to the magnetism of the wire, and is also an additional proof that the earth's magnetism had *nothing* to do with it.

This view is still further confirmed by the effect of heat on the tempered steel wire. The first effect of heat is to destroy the permanent magnetism of the wire, hence the initial diminution of the sound. At a temperature of about 250° C. the permanent magnetism is much reduced.

On heating farther, the magnetic susceptibility of the steel begins to increase rapidly, until it reaches a maximum about dull red, and then it falls off again very rapidly; hence the increase of the sound to a maximum and the final falling off.

The reason why the minimum cannot be observed with iron, and not always with soft steel, is that with them the permanent magnetism is less and the magnetic susceptibility in general greater at ordinary temperatures, so that the increase of the latter begins sooner and masks the decrease of the former. At a dull red all kinds of iron or steel are much on a par as to susceptibility; hence in the case of hard steel, whose susceptibility begins to increase rapidly only at a pretty high temperature, the phenomena are much more striking, as well as more varied than in the case of soft iron.

On cooling the sound came and went again as usual, leaving, however, a permanent sound of considerable loudness, which was increased by repeated operations of this kind.

As a test of the soundness of the above conclusions I was anxious to examine the behaviour of the other strongly magnetic metals, and Prof. Tait kindly put several pieces of nickel and cobalt at my disposal.

The piece of nickel used was 3 cm. long, 2 mm. broad, and about ·6 mm. thick. It was hard soldered to platinum terminals, and mounted in the usual way, after being heated red hot and dipped in water at dull red.

At first it gave a very feeble high note, accompanied by a gentle fizzing sound. One stroke with a magnet caused it to emit a loud buzzing sound. On heating gently this sound was somewhat reduced, and on heating farther the hissing sound died away, and a high note was left, but it too was extinguished before the nickel was visibly hot.

I made some temperature determinations by means of an air-bath and a mercury-thermometer, and found that at 200° C. the buzzing noise first began to be softened down. After 250° C. the diminution appeared rather more rapid, but at 350° C. the sound was still quite loud; after that the falling off was very rapid, and somewhere (say 400° C.) beyond the range of the thermometer, the mercury in which just boiled at the end of the experiment, the sound died out rather suddenly.

The behaviour of nickel is therefore exactly what we should expect from its magnetic properties, for it loses its magnetic susceptibility, according to Faraday and others, somewhere between 350° C. and 400° C.

I found with nickel, as with iron, that the current itself at a certain high temperature could produce much the same effect as I got by magnetising. On testing a piece of nickel after being magnetised by the current I found it to be transversely magnetised. This induced me to try magnetising my nickel strip transversely, but although I got results this way they were not so good as I had got by magnetising longitudinally.

I was thus led to try the following experiment, the result of which is at least curious. Instead of passing the current through the nickel itself as before, I passed it round two flat pieces of iron electro-magnet-wise. These were placed with their ends pretty close together, and the nickel was stretched between them so that it lay in a nearly uniform field of magnetic force, whose strength varied in unison with the interrupter.

I found that with this arrangement the nickel sounded very much as it did when the current was passed directly through it. The sound was not so loud, but its quality appeared to be the same. The sound, however, was loudest when the plane of the nickel strip was parallel to the lines of force, being very feeble when the plane of the strip was perpendicular to the lines of force.

A piece of watch-spring was tried in the same way, with exactly similar results.

This experiment is of course very nearly the same as some of those by which the sounds due to the magnetisation and demagnetisation of iron are usually demonstrated. A very full account of these sounds will be found in Wiedemann's "Galvanismus," Bd. ii. p. 565 *et seqq.*

I tried a piece of cobalt 6 cm. long and 6 mm. broad, ·7 mm. thick, in the ordinary way. In its original state it gave no sound whatever. After being magnetised longitudinally by a large number of strokes it gave a sound, very feeble, however, compared with that got in the same way from iron and nickel, or even from hard steel; it was, moreover, more of a pure note and less of a hissing noise. Heating in the first place diminished this initial sound, so that there came an interval of comparative silence, then the sound rose again, and by and by the familiar buzz came in; but up to a bright red heat no maximum was reached. On cooling, the phenomena reappeared in the proper order.

Cobalt behaves, therefore, just as we should expect from its refractory magnetic nature.

I may mention one curious phenomenon that appeared once or twice with cobalt and once or twice with a piece of steel. On cooling, after the maximum was past, the buzz had died away, and a period of comparative silence had come, strong beats began to be heard, which lasted for a considerable time, and then died away as the temperature fell. Various causes for these might be assigned. It might have happened that two parts of the metal were at different temperatures, and gave notes nearly in unison. It may very well have been interference between notes due to permanent and temporary magnetism; for in cobalt generally, and with the particular piece of steel in question, the minimum was not marked by the absolute silence which probably indicates cessation of the sound due to permanent magnetism before that due to temporary magnetism begins.

Relation to Thermo-electric Properties.—As it seemed to be of some interest to connect these magnetic sounds with the curious thermo-electric peculiarities of iron and nickel brought to light by the recent researches of Prof. Tait,[1] I asked the help of his assistant, Dr. C. G. Knott, who has had great experience in work of this kind.

The sounding-wire, a short piece of which was always used in order to get the phenomenon pure, was inclosed along with a double or triple thermo-electric junction in a small tube made by rolling up a piece of sheet-copper. The tube was then heated up in the blowpipe flame. This was a rough way of setting to work, but it was sufficient for our purpose.

The diagrams (Figs. 1, 2, 3), made by Mr. Knott, with the appended notes, will show the results. I have given the observations made during heating, as being on the whole probably nearest the mark. The cooling, except in the case of nickel, which was inclosed in a wide iron box, and did not require to be raised to a very high temperature, was much more rapid than the heating, and consequently inequalities of temperature due to the different positions of the sounding-wire and the junction would have been more apparent. In point of fact the discrepancy was not great.

The abscissa in the case of nickel is the temperature in centigrade degrees, in the other cases it is the electromotive force of a junction formed of a certain pair of platinum iridium alloys (called M and N) much used by Tait in his thermoelectric researches, because their lines on his thermoelectric diagram are

[1] *Trans.* R. S. E., 1872, 3, vol. xxvii. p. 134, &c.

nearly parallel (see p. 140 of the paper above referred to). The ordinate in all these cases is the thermoelectric power.

The special feature here is the period of silence at the neutral point of N and steel, viz., about 250° C.

This observation agrees remarkably well with the theory that the initial sound in the case of steel is due to its permanent magnetism; for, according to Faraday, steel loses its coercitive force about the temperature of boiling almond oil. See also Marshall (*Proc. R.S.E.*, 1871–72, p. 605). On cooling, owing doubtless to the fact that exposure to a high temperature had softened the steel, which was very hard to begin with, no period of absolute silence appeared, and beats were heard.

It was difficult to distinguish whether the note at E and F was or was not due to the singing of the Bunsen flame. The observations, on cooling, exactly corroborated those taken during heating.

It appears to me that these experiments establish that a series of sounds are produced by the passage of a varying current through magnetised iron, nickel, and cobalt, which depend on the fact of their magnetism. They are apparently of the same nature as those observed heretofore in magnetising and demagnetising iron.

I believe that the phenomena above described explain the exceptional power of iron wires of considerable thickness, as sounders in the wire telephone. When the iron wire is very thin it is most likely that the effect obtained with thin wires of ordinary metals predominates, and it is possible that the magnetic effect may in that case be very small. I cannot say, however, that I have settled this point, which clearly involves an experimental difficulty.

At all events I hope the above observations will be of sufficient interest to attract notice to a subject which has not been much studied lately, notwithstanding its important bearings on the theory of the telephone, and what is of more scientific importance still, the theory of magnetism in strongly-magnetic bodies, a department of physics which stands in as much need of additional light as any that I know. G. CHRYSTAL

INTERNATIONAL METEOROLOGY

THE International Meteorological Committee appointed by the Congress of Rome (1879), will hold its first meeting at Berne on the 9th proximo.

The following is the programme of questions to be considered by the Committee:—

1. Report on the action of the Committee since the date of the Congress at Rome.
2. Report of the Polar Conference (Weyprecht's project) held at Hamburg in October, 1879.
3. Proposed Conference for Agricultural Meteorology, summoned for September 6 at Vienna.
4. Proposed comparison of the Standard Instruments of the chief Observatories of Europe.
5. Proposed Catalogue of Meteorological Observations and of Meteorological Works and Memoirs in all languages.
6. Proposed International Tables for the reduction of observations.
7. Proposal for an International Meteorological Dictionary.
8. Report on the Meteorological Organisation of England in 1877, being a Supplement to the Fifth Appendix to the Report of the Roman Congress.
9. Proposal by Capt. Hoffmeyer for an International Telegraphic Service for the North Atlantic.
10. Proposal respecting the exchange of Meteorological Publications by post.

The Circular concerning the meeting, which is issued by Prof. Wild and Mr. Scott, requests all persons wishing to make any communications to the Committee to address them to Mr. Scott, at 116, Victoria Street, during the current month.

A private Conference on the relations of Meteorology to Agriculture and Forestry will be held at Vienna on September 6. The following is the programme of subjects for discussion:—

1. What are the mutual relations of the meteorological elements on vegetation, not only those which are proved to exist, but those which are theoretically supposed to be probable?
2. What observations of meteorological elements are to be particularly attended to, with especial reference to their influence on vegetation?
3. How far, and in what way, can meteorological observatories and stations, without interfering with their other work, include these observations in their sphere of operation?
4. Would it not be useful with a view of establishing special systems of observations for this object, as, for instance, phenological observations, to prepare general instructions?
5. Can, at the present moment meteorological central offices issue weather forecasts for the use of agriculture, with reasonable prospects of utility, and if this question is answered in the affirmative, how can the service be organised as fully as possible?

Preliminary materials for the answers to these questions will be found in the Reports of Dr. Lorenz and Dr. Bruhns to the Roman Congress on Article 35 of the Programme. These Reports have also been published separately in German, and partially in French in the collection issued by the Central Office at Rome of all Reports presented to the Congress. In the latter volume the Report of M. Denza on the same subject is to be found.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

A TOWN'S meeting was held at Liverpool last week for the purpose of hearing a report from the committee appointed a year or two ago as to the progress of a scheme for establishing a University College in Liverpool. The report showed that in spite of bad times a very gratifying readiness had been exhibited on the part of a number of the leading residents of Liverpool to contribute to the necessary funds, several of whom had promised sums of 10,000*l.* each for the endowment of different chairs. The Earl of Derby had also promised a similar sum, the result being that 80,000*l.* was already insured. The college is to be upon the broadest basis, being non-sectarian, and offering no disabilities of any kind to intending students. A resolution was moved thanking donors to the fund, pledging the meeting to the furtherance of the scheme, and recommending that the different classes and businesses of the town should form themselves into committees for the purpose of canvassing.

IN reply to a question by Sir J. Lawrence on Monday as to the embarrassed position of the United College of St. Andrews, Sir W. Harcourt stated that the Government would consider the report during the recess, with a view to making some proposal early next session.

A COMMITTEE is to be appointed to inquire as to the existing establishments which are available for intermediate and higher education in Wales.

THE Superior Council of Instruction in France has terminated its second session. The most notable feature has been the introduction of descriptive natural history in the eighth class, that is, in the first step of classical education.

Paris

Academy of Sciences, July 19.—M. Edm. Becquerel in the chair.—The following papers were read:—Researches on the organic alkalies, by M. Berthelot. This relates to ethylamine and trimethylamine, their heat of combustion, &c.—Modifications of respiratory movements by muscular exercise, by M. Marey. The respiratory curves obtained from young soldiers with a (so-called) *pneumograph* show that after a gymnastic course they breathe about twice as much air as before; the number of respirations is reduced from twenty to twelve per minute, but their amplitude is more than quadrupled. At the outset the respiration is considerably modified by running (600 m. in about four minutes), but after from four or five months' exercise this running has no perceptible effect.—On strengthening the immunity of Algerian sheep against splenic fever by preventive inoculations; influence of inoculation of the mother on the receptivity of the fœtus, by M. Chauveau. Direct contact of the animal organism with the bacteridian elements is not necessary to its ulterior sterilisation. Preventive inoculations act on the humours proper, which are rendered sterile and sterilising, either by removal of substances necessary to bacteridian proliferation, or rather by addition of matters adverse to this proliferation.—On the construction of the dam of Gileppe, Belgium, by M. de Lesseps.—Ephemerides of comet *b* 1880 (Schäberle), by M. Bigourdan.—Reply to a remark of Mr. Sylvester's concerning the lessons on the theory of numbers of Dirichlet, by M. Dedekind.—On the cause of the fugitive spectra observed by M. Trouvelot on the solar limb, by M. Tacchini. He has often observed such spectra (attributed by M. Trouvelot to solar disturbances) on passage of swallows and other birds across the sun. In simultaneous observations on three days, by Prof. Ricco, at Palermo (where birds are very rare), no such spectra were recorded; and M. Tacchini finds, as one might expect, that they become less frequent as the sun rises in the sky.—On atmospheric electricity, by M. Mascart. His observations at the College of France are made with a Thomson quadrant electrometer, the deflections of the needle being transmitted to a pencil. The two pairs of quadrants are kept at equal potentials of contrary sign by two poles of a battery which communicates with the ground; the needle is connected with a vessel letting flow a continuous stream of water into the outer air. Generally the potential of the air, always positive, is found much higher and more uniform by night than by day. From 9 p.m. to 3 a.m. it varies little, falls at daybreak, reaches a minimum about 3 p.m., then rises rapidly to a maximum about 9 p.m. (It is commonly thought there are two maxima, morning and evening; and two minima, one in the day, the other at night. M. Mascart considers insulation has been too much neglected.)—On the alternative currents and the electromotive force of the electric arc, by M. Joubert. When the current intensity is *nil* there is no difference of potential between the carbons, but the difference quickly reaches 40 to 50 volts, which is preserved nearly constant till the current is again very weak. The final fall is very sudden. The difference of potential remains the same during the period of the current, though the mean intensity of this be largely varied.—On a new air-thermometer, by M. Witz. This is a sort of Leslie's thermometer, with one air-globe kept at constant temperature by means of a thermal regulator of special form.—On some fluorised combinations of uranium with the alkaline metals, by M. Ditte.—On the atomic weight and the principal properties of glucium, by MM. Nilson and Pettersson. The atomic weight is 13·65 if the earth is equal to Gl_2O_3.—On some combinations belonging to the group of creatines and creatinines, by M. Duvillier.—Action of chloride of ethyl on ethylamines, by MM. Duvillier and Buisine.—Action of electrolysis on benzine, by M. Renard. A new body named isobenzoglycol, $C_6H_6(OH)$, is obtained.—On a peculiar alteration of butcher-meat, by M. Poincaré. He has found cylindrical pointed elements, with cuticles crossed by lines which seem outlines of cells, and granulated. He thinks they may be phases or metamorphoses of tænioides, causing tænia in some eaters of raw meat.—On the production of charbon by pasturages, by M. Poincaré. The disease was traced in one case to the grass of a meadow being constantly wet with a liquid of marshy look; in this were found numerous bacteridia like those in the blood, and injection of it into a guinea pig produced charbon.—Observations on the origin of fibrillæ in the bundles of connective tissue, by M. Laulanié.—On the Echinida of the tertiary strata of Belgium, by M. Cotteau.

MULTIPLE SPECTRA[1]

II.

I CONCLUDED my last article under the above heading with a reference to the case of carbon, and gave the results successively arrived at by Attfield, Morren, Watts, and others; these went to show that besides the line-spectrum of carbon mapped by Ångström there exists a fluted spectrum of this substance.

Now comes my own personal connection with this matter.

In the year 1878[2] I communicated to the Royal Society a paper in which the conclusion was drawn that the vapour of carbon was present in the solar atmosphere.

This conclusion was founded upon the reversal in the solar spectrum of a set of flutings in the ultra-violet.[3] The conclusion that these flutings were due to the vapour of carbon, and not to any compound of carbon, was founded upon experiments similar to those employed in the researches of Attfield and Watts, who showed that the other almost exactly similar sets of flutings in the visible part of the spectrum were seen when several different compounds of carbon were exposed to the action of heat and electricity. In my photographs the ultra-violet flutings appeared under conditions in which carbon was the only constant, and it seemed therefore reasonable to assume that the flutings were due to carbon itself, and not to any compound of carbon; and this not alone from the previous work done in the special case of carbon, but from that which had shown that the fluted spectra of sulphur, nitrogen, and so forth were really due to these "elementary" substances.

Professors Liveing and Dewar have recently on several occasions called this result in question. Prof. Dewar, in a paper received by the Royal Society on January 8, 1880, writes as follows :—

"The almost impossible problem of eliminating hydrogen from masses of carbon, such as can be employed in experiments of this kind, prove conclusively that the inference drawn by Mr. Lockyer, as to the elementary character of the so-called carbon spectrum from an examination of the arc in dry chlorine, cannot be regarded as satisfactory, *seeing that undoubtedly hydrogen was present in the carbon* used as the poles."

Subsequently in a paper received by the Royal Society on February 2, Messrs. Liveing and Dewar wrote as follows :—

"Mr. Lockyer (*Proc. Roy. Soc.*, vol. xxvii. p. 308) has recently[4] obtained a photograph of the arc in chlorine, which shows the series of fluted bands in the ultra-violet, on the strength of which he throws over the conclusion of Angström and Thalèn, and draws inferences as to the existence of carbon vapour above the chromosphere in the coronal atmosphere of the sun, which, if true, would be contrary to all we know of the properties of carbon. We cannot help thinking that *these bands were due to the presence of a small quantity of nitrogen.*"

It will be seen that on January 8 Mr. Dewar alone attributed the flutings to a hydrocarbon, while on February 2 Mr. Dewar, associated with Mr. Liveing, attributed them to a nitrocarbon.

In fact in the latter paper Messrs. Liveing and Dewar published experiments on the spectra of various carbon compounds, and from their observations they have drawn the conclusion that the set of flutings which I have shown to be reversed in the solar spectrum is really due to *cyanogen*, and that certain other sets of flutings shown by Attfield and Watts to be due to carbon are really due to hydrocarbon.

As Messrs. Liveing and Dewar do not controvert the very definite conclusions arrived at by Attfield, Morren, Watts, and others, I can only presume that they took for granted that all the experimental work performed by these men of science was tainted by the presence of impurities, and that it was impossible to avoid them. I therefore thought it desirable to go over the ground again, modifying the experimental method so as to demonstrate the absence of impurities. Indeed I have started upon a research which will require some time to complete. Still, in the meantime, I have submitted to the notice of the Royal Society some results which I have obtained, which I think settle the whole question, and it is the more important to settle it as Messrs. Liveing and Dewar have already based upon their conclusions theoretical views which appear to me likely to mislead, and which I consider to have long been shown to be erroneous. To these results I shall now refer in this place.

The tube with which I have experimented is shown in Fig. 1: A and B are platinum wires for passing the spark inside the tube; E is a small tube into which carbon tetrachloride was introduced; it was drawn out to a long narrow orifice to prevent the rapid evaporation of the liquid during the exhaustion of the tube. The tube was bent upwards and a bulb blown at C in order that the spark might be examined with the tube end-on, as it is found that after the spark has passed for some time a deposit is formed on the sides of the bulb immediately surrounding the platinums, thus obstructing the light. After a vacuum had been obtained the tube was allowed to remain on the Sprengel pump, to which it was attached by a mercury joint for the purpose of obtaining a vacuum for a long time, in order that the last traces of air and moisture might be expelled by the slow evaporation of the liquid.

The carbon tetrachloride was prepared by Dr. Hodgkinson, who very kindly supplied me with sufficient for my experiments.

On passing the spark without the jar in this tube, the spectrum observed consists of those sets of flutings which, according to Messrs. Liveing and Dewar, are due to hydrocarbon, and the set of flutings which is reversed in the sun, and ascribed by Messrs. Liveing and Dewar to cyanogen, also appears in a photograph of the violet end of the spectrum, Fig. 2. On connecting a Leyden jar with the coil and then passing the spark the flutings almost entirely vanish and the line spectra of chlorine and carbon take the place of the flutings without either a line of hydrogen or a line of nitrogen being visible.

As a long experience has taught me that these tubes often leak slightly at the platinums after they are detached from the pump, so that the evidence of such a *pièce justificatif* is only good for a short time, I took the occasion afforded by a visit of Dr. Schuster to my laboratory while

[3] The approximate wave-length of the brightest member on the least refrangible edge is 3881·0.

[4] That is, in 1878.—J. N. L.

the experiments were being made to get my observations confirmed. He has been good enough to write me the following letter and to allow me to give it here:—

"*March* 21

"MY DEAR LOCKYER,—The following is an account of the experiment which I saw performed in your laboratory on Monday, March 15:—

"A tube containing carbon-tetrachloride was attached to the Sprengel pump. As exhaustion proceeded the air was gradually displaced by the vapour of the tetrachloride. The electrodes were a few millimetres apart. If the spark was taken without a condenser in the vapour the well-known carbon bands first observed by Swan in the spectrum of a candle were seen with great brilliancy; I also saw the blue band which you said was identical in position with one of the blue bands seen in the flame of cyanogen or in the spectrum of the electric arc. When the condenser and air-break were introduced this spectrum gave way to a line spectrum in which I could recognise the lines of chlorine. *The lines of nitrogen were absent, not a trace of the principal double line in the green being seen.* The hydrogen line $H\alpha(C)$ was faintly visible when I first observed the spectrum, but it got gradually weaker and *finally disappeared altogether. When this line was no longer visible the condenser was taken out of circuit*

FIG. 1.

again, and the same carbon bands were seen as before. These bands, therefore, show themselves with great brilliancy when a strong and powerful spark does not reveal the presence either of hydrogen or nitrogen.

"March 21, 1880 (Signed) ARTHUR SCHUSTER"

This result, which entirely endorses the work of Attfield and Watts, has been controlled by many other experiments. I have also repeated Morren's experiment and confirm it, and I have also found that the undoubted spectrum of cyanogen is visible neither in the electric arc nor in the surrounding flame.

Hence then in the case of carbon, as in the prior cases of hydrogen, nitrogen and the like, those who hold that the flutings are due to impurities must, it would seem, abandon their position; for the flutings are undoubtedly produced by carbon vapour. Nor is this all; the suggestion that the various difficulties which have always been acknowledged to attend observations of this substance may in all probability be due to the fact that the sets of carbon flutings represent different molecular groupings of carbon, in addition to that or those which give us the line spectrum, and that the tension of the current used now brings one set of flutings into prominence and now another, seems also justified by the facts. This suggests

FIG. 2.

the view that a body may have a fluted spectrum of compound origin as well as a line spectrum.

This conclusion is greatly strengthened by the preliminary discussion of a considerable number of photographs of the spectra of various carbon compounds.

A general comparison of the photographs first enables us to isolate the lines in the blue and ultra-violet portions of the spectrum (wave-lengths 4300–3800) of the substance associated with the carbon in each case.

In this manner the lines seen in the photographs of the spectra of CCl_4, $C_{10}H_8$, CN, CHI_3, CS_2, CO_2, CO, &c., have been mapped, and both the common and special lines and flutings thus determined.

The phenomena seen with more or less constancy are a blue line, with a wave-length of 4266; a set of blue flutings, extending from 4215 to 4151; and another set of ultra-violet flutings, which extend from 3885 to 3843 (all approximate numbers).

In a photograph of the spectrum of the electric *arc* (with a weak battery) between carbon poles in an atmosphere of chlorine, the blue flutings alone are visible, whilst, when the *spark* is similarly photographed, the ultra-violet flutings and the blue line (4266) are also visible, whilst the blue flutings become fainter.

From this we may assume, in accordance with the working hypothesis of a series of different temperature furnaces, as set forth in the paper of December, 1878 (see Fig. 3), that the different flutings and the line correspond to different temperature spectra, the blue flutings to the lowest and the blue line to the highest temperature, whilst the ultra-violet flutings occupy an intermediate position.

FIG. 3.—Action of three different temperatures on a hypothetical substance, assuming three stages of complete dissociation.

According to this working hypothesis there should be a series of horizons forming a perfect gradation between the spectrum which contains the blue line alone and that which contains the blue fluting alone (Fig. 4). In comparing the spectra of carbon under different conditions, I find this to be true. *The blue line never appears in conjunction with the blue flutings, unless the ultra-violet flutings are also present.* In other words, the highest and the lowest hypothetical temperature spectra are never visible together without the spectrum of the intermediate hypothetical temperature.

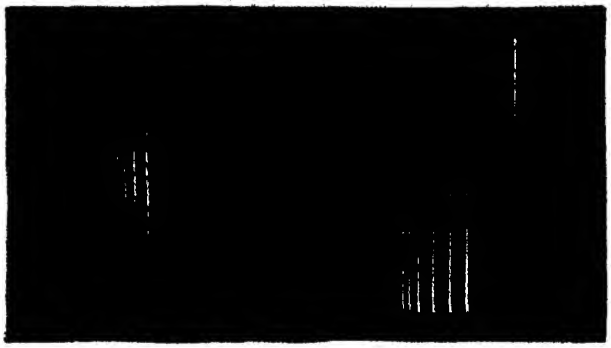

FIG. 4.—Spectra of the hypothetical substance in intermediate furnaces, assuming that the vapours are not completely dissociated.

But this is not all. By placing the spectra of the substances at different heat-levels, so to speak, I was enabled to construct a map, which not only indicates the mere presence or absence of the lines and their relative intensities, but shows a perfect gradation between the spectrum which contains the line alone and that which contains the blue flutings alone (Fig. 5). I would point out that there is nothing theoretical in this map. All the horizons depicted are copied from photographs of carbon under the conditions indicated, and theory has merely enabled me to arrange them *in order*.

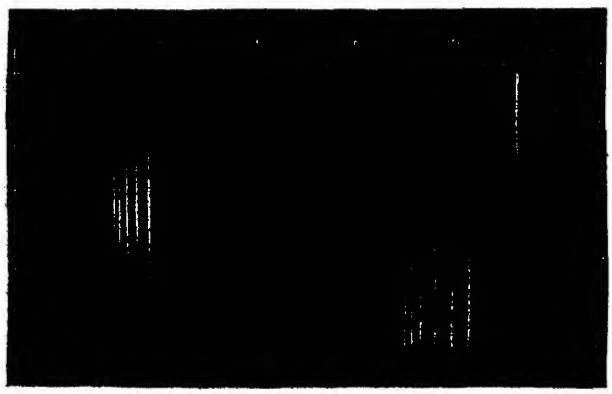

FIG. 5.—The photographed spectra of some carbon compounds.

This map I submit, therefore, bears out the hypothesis of differences of temperature indicated above, for it is seen that, while the blue line gradually thins out, the ultra-violet flutings appear first and grow in intensity. As these increase the blue flutings become visible, and further, as the latter augments and the line disappears, the ultra-violet flutings gradually die out altogether.

It is philosophical to infer from these observations that not only are the line and flutings in question produced by carbon, but that the blue line (4266), since it is visible at the highest temperature, corresponds to the most simple molecular grouping we have reached in the experiments, and the flutings to others more complex.

The result to which attention is most to be directed in this place is that touching the two sets of flutings, and should future research justify the double conclusion (1) that these flutings are truly due to carbon, a result I accept, though it is denied by Ångström and Thalèn; and (2) that the different flutings really represent the vibrations of different molecular groupings; a great step, and one in the direction of simplification, will have been gained.

Indeed it is much to be hoped that this ground will be at once worked over again by men of science who are both honest and competent: that the truth is sure to gain by such work is a truism.

I have so often taken occasion to refer with admiration to the work of Ångström and Thalèn that I shall not be misunderstood when I say that their conclusions, to which such prominence is given, and on which such great stress is laid by Messrs. Liveing and Dewar, rest more upon theory and analogy than upon experiment.

Their work, undertaken at a time when the existence of so-called "double spectra" was not established upon the firm basis that it has now, and when there was no idea that the spectrum recorded for us the results of successive dissociations, gave, as I have previously taken occasion to state, the benefit of the doubt in favour of flutings being due to compounds, and it was thought less improbable that cyanogen or acetylene should have two spectra than that carbon or hydrogen should possess them.

Indeed, later researches have thrown doubt upon the view that the fluted spectra of aluminium and magnesium are entirely due to the oxides of those metals instead of to the metals themselves—and this is the very basis of the analogy which Ångström and Thalèn employed.

The importance of the observations to which I have referred is all the greater because of the general conclusions touching other spectra which may be drawn from them. Thus from what I have shown it will be clear that if my view is correct the conclusions drawn[1] by Messrs. Liveing and Dewar from the assumed hydrogen-carbon bands touching both the spectrum of magnesium and the spectra of comets, are entirely invalid. These conclusions are best given in their own words:—

"The similarity in the character of the magnesium-hydrogen spectrum, which we have described, to the green bands of the hydrocarbons is very striking. We have similar bright maxima of light, succeeded by long drawn-out series of fine lines, decreasing in intensity towards the more refrangible side. This peculiarity, common to both, impels the belief that it is a consequence of a similarity of constitution in the two cases, and that magnesium forms with hydrogen a compound analogous to acetylene. In this connection the very simple relation (2 : 1) between the atomic weights of magnesium and carbon is worthy of note, as well as the power which magnesium has, in common with carbon as it now appears, of combining directly with nitrogen. We may with some reason expect to find a magnesium-nitrogen spectrum. . . .

"The interest attaching to the question of the constitution of comets, especially since the discovery by Huggins that the spectra of various comets are all identical with the hydrocarbon spectrum, naturally leads to some speculation in connection with conclusions to which our experiments point. Provided we admit that materials of the comet contain ready-formed hydrocarbons, and that oxidation may take place, then the acetylene spectrum might be produced at comparatively low temperatures without any trace of the cyanogen spectrum or of metallic lines. If, on the other hand, we assume only the presence of uncombined carbon and hydrogen, we know that the acetylene spectrum can only be produced at a very high temperature, and if nitrogen were also present that we should have the cyanogen spectrum as well. Either, then, the first supposition is the true one, not disproving the presence of nitrogen, or else the atmosphere which the comet meets is hydrogen only, and contains no nitrogen."

The importance of the question here treated of comes out very well from these two extracts. We find the same spectral phenomenon at once called into court, and very properly called in, both to suggest the existence of chemical substances of which the chemist has never dreamt, and to explain the chemical nature of a large group of celestial bodies.[1]

There is little doubt that when a complete consensus of opinion is arrived at among the workers, other suggestions more far reaching still will be derived from the prosecution of these inquiries. For the present, however, the chief point to bear in mind is that both in line-spectra and in fluted spectra we have indications which I think favour the view that in each case the origin is compound rather than simple. J. NORMAN LOCKYER

Oban, July 20

[1] Paper read February 12, 1880.

[1] With special reference to this last question, that of cometary spectra, one of acknowledged difficulty, I may perhaps be permitted to add here by way of note that the view I put forward some years ago touching the relation of this spectrum to that of the nebulæ has been lately strengthened by the observation that at a low temperature one of the brightest lines in the spectrum of iron is that coincident with the chief line in the nebula-spectrum.

THE EDUCATION DEBATE

THE chorus of approval with which Mr. Mundella's report on the progress of elementary education was received on Monday cannot but be gratifying to all who have at heart the highest welfare of the country. With one or two unimportant exceptions—members whose vision is so bizarre as to discern communism in the education of the children of the working classes, and who connect the increase of weeds with the spread of education—what criticism there was referred to details of method. All the members whose opinions are of any weight agreed that vast good had resulted to the country by the working of the Code. As to the special subjects, among which science is included, the weight of opinion was decidedly in favour of their retention. The greatest friends of the Fourth Schedule will admit that there is still much room for improvement in the teaching of these subjects; it cannot be expected that so great a novelty in the system of elementary education in the country can all at once be taught to perfection. About the success of the compulsory system of education it may be said that the House was all but unanimous. The analogy between the treatment of

paupers and the free education of the children of the working classes will not hold water. In the one case we are simply keeping from starvation people whose improvidence or misfortune have made them a dead burden on their fellows; in the other case we are feeding the minds of those who one day will have to bear the brunt of the work of the nation. The better these future workers are educated, the more intelligently and the more effectively are they likely to do their work, and the less likely are they to become inmates of our workhouses and prisons. As Serjeant Simon testified, even already is there a marked decrease of embryo criminals in our streets. The conclusion come to by Mr. Mundella and those who, like him, have the interests of education at heart, is not that we have gone too far, but that we have not gone far enough; not that we have reached finality, but that we have only made a good beginning. The figures he adduced to prove the success of the existing Education Act were practically admitted to be irrefutable; and we only trust the progress in the next ten years will be at an equal ratio to that achieved during the past decade. "Many of us," he truly said, "would pass away without seeing the full effect of the work we are doing." As to the propriety of encouraging the retention of exceptionally clever boys in elementary schools beyond the regulation age, the figures showed that it would be cruel and unjust to forbid this. Until we have a State system of secondary education in England similar to that about to be sanctioned in Scotland, until an equally decisive step is taken with regard to educational endowments in the one country as in the other, the nation would be doing a gross injustice to force exceptionally clever boys to leave school just when their intellects were beginning to shoot into full vigour. Mr. Mundella showed by his figures that Scotland is still ahead of England in the matter of education; that extra or special subjects are more widely sought after and with greater success, and that a larger percentage of children in elementary schools proceed to secondary education. But it should be remembered that this is the result of many generations of universal education, and that in Scotland it has long been considered as great a disgrace to be uneducated as in England it is considered to be immoral. There among the great majority of the working classes compulsory education was scarcely needed, and this will no doubt be the case in England in the course of a century or so, when education will have become as great a necessity as decent clothing. Again during the debate was it shown by those who have the best means of knowing that where science is properly taught there the children are as a rule more intelligent and bright, and better up in the ordinary subjects than in schools where science is neglected. Sir John Lubbock gave a remarkable instance of the favour with which properly conducted science-teaching is received by the children themselves:—

"He had lately," he said, "visited some of the Lambeth schools, and in one of the last he asked the children which subject they themselves preferred. Out of 229 children in the upper standards, 2 liked grammar best, 11 geography, 31 arithmetic, 38 history, and 147 elementary science. He did not quote this from any wish to exclude the other subjects, but because it seemed conclusive evidence against the proposal to omit elementary science. He knew that many hon. members, when they thought of children learning these extra subjects, pictured to themselves anxious and weary children poring over a difficult and distasteful task. He wished they would go and see the reality—the bright, happy, intelligent faces of the children, and their delight as they found themselves able to answer the questions rapidly asked them by the master."

We have no intention of repeating the arguments we have so often adduced in favour of the teaching of at least such elementary science in our national schools as will be of practical use in after life and help to render the hard lives of the working classes brighter and nobler, and thus elevate the whole nation. The debate on Monday confirms all that has been adduced in favour of such education, and is the best possible reply to the attack of Lord Norton in the Upper House, an attack which the debate showed to be an anachronism. The whole tone of Mr. Mundella's address must convince all but the most prejudiced that the education of the country could not be in better or safer hands, and that he is not in the least likely to take any step that could be considered rash.

Quite in keeping with the tone of his Education address were his remarks in connection with the vote for the Science and Art Department. With regard to the vote of 4,000*l*. for scientific research, Mr. Mundella said that it was expended under the advice of the Committee and members of the Royal Society, and that of the presidents of the various other scientific bodies. He thought the country could well afford to spend 5,000*l*. on the matters that had been alluded to. "As it was we did not spend too much on science and art." This is a remarkable admission to make by our Minister of Science, for such the Vice-President of the Council is in reality if not in name. We do not wish a penny to be deducted from the grant for elementary education, which we hope to see gradually increased; indeed we would strongly urge Mr. Mundella to devote his energies, so long as he has opportunity, to perfecting the teaching of science in our elementary schools. When once a proper system is fairly established, there will be no danger of retrogression—rapid progress will be certain. Not only so, but we are sure that the nation will be convinced that at the other end of the scale the neglect to encourage by national funds scientific research is quite as disastrous to the highest welfare of the country as the neglect of elementary education. In Germany and France the national necessity of both is practically recognised, and they are both amply provided for. If Mr. Mundella is of opinion that we do not spend too much on science, that can only mean that the nation must suffer for this parsimony. It was admittedly as an experiment that the 4,000*l*. was added to the 1,000*l*., which, by the by, but for the want of faith of the scientific nabobs of the time, might have been 10,000*l*., and that many years ago. Over and over again have we pointed out the benefit which the nation would reap from research when adequately encouraged, and that we can never hope to hold our own in this matter with foreign countries under existing conditions, in which some of our best men are compelled to waste their exceptional powers in teaching for the sake of bread and butter; while some among the "professors" whom in the view of some we were exclusively to look for research

not only neglect research, but even their students in the most unblushing manner, in their greed of gold. We hope that when next Mr. Mundella has to ask for a vote for the Science and Art Department, he will present as strong a case for the encouragement of advanced science as he has done for the teaching of elementary science. The facts and figures in favour of the one are as strong as those in favour of the other.

EUROPEAN CADDIS-FLIES

A Monographic Revision and Synopsis of the Trichoptera of the European Fauna. By Robert McLachlan, F.R.S., F.L.S., &c. (London: Van Voorst, 1874-1880.)

MOST persons have seen those curious aquatic insects called caddis-worms, which live at the bottom of the water, protected by tubular cases formed of bits of stick, stones, sand, or shells, and are much used as bait by anglers; being, as Izaak Walton remarked, "a choice bait for the chub or chavender, or indeed for any great fish." It is also generally known that these caddis-worms are the larvæ or grubs of winged insects, known as caddis-flies or water-moths, which abound in the vicinity of rivers or ponds and often fly into houses attracted by the light; but few persons except entomologists are aware that there are nearly a hundred and fifty different species in the British Isles, while between four and five hundred are known from various parts of Europe—that they constitute a distinct order of insects, named "Trichoptera," from their hairy wings—and that they possess peculiarities of structure of the greatest interest as serving to connect, however imperfectly, such distinct and highly specialised orders, as the Hymenoptera and the Lepidoptera.

The perfect insects are characterised by four ample membranous wings, of which the hind pair are usually the largest, while the front pair are somewhat more leathery in texture. The wings are always more or less clothed with hair, sometimes to such an extent as to form a dense coat which completely hides the nervures; and it is this peculiar hairy covering which has given the name to the family. The neuration of the wings consists of longitudinal branching veins with a few cross veins forming cells, very different from the netted veins of most of the Neuroptera, with which the Trichoptera were formerly united, but bearing a considerable resemblance to those of some of the smaller moths. The body is also hairy, the legs long and spined, while the antennæ are usually longer than the body, slender and thread-like; and when the insect is in repose these are directed forward, and so closely pressed together as to appear like one. The mouth is very small with quite rudimentary mandibles, and Mr. McLachlan thinks that the insects usually take no nutriment whatever in the perfect state, "existing on the superabundant vitality acquired during their long larval stage," but he adds: "some of the larger species frequent flowers at night after the manner of moths, and are even attracted by the mixtures used by lepidopterists to attract their favourite insects, facts which prove that some, at any rate, partake of liquid nutriment." The exact mode in which this is effected is not yet clearly ascertained.

The eggs are gelatinous, and stick together in a mass which is attached to aquatic plants below the surface of the water, into which the female is said sometimes to enter for the purpose of depositing them in a proper situation. The cases formed by the larvæ are built up of various substances fastened together by silken threads spun from the mouth in the same manner as caterpillars spin their cocoons—another curious point of resemblance to the Lepidoptera. These cases vary greatly in the different families and genera, and though at present very imperfectly known it seems probable that every species has a distinctive form of case. The Phryganeidæ, for example make cylindrical cases of morsels of leaves or fibres arranged in a spiral manner, the cases are open at both ends, and it is believed that the larvæ have the power of turning in them. When about to change into a pupa the larva closes up the ends with vegetable matter and attaches the case to an aquatic plant. They live only in ponds, lakes, or marshes. Another family—the Limnophilidæ—have some genera which live in still, others in running waters, and their cases vary greatly, the most curious being those formed entirely of shells, often taken while their inmates are alive. One genus of this family—Enoicycla—is altogether anomalous, since the female has rudimentary wings and its larva lives in moss, often in woods far away from water, forming a case of fine sand intermixed with vegetable matter. One species is found in England. In the next family—Sericostomatidæ—the larvæ live generally in streams, forming cylindrical cases of sand or small stones, but sometimes the cases are broad and flattened, in others quadrangular, while in one genus—Helicopsyche—they are spiral, formed of sand grains, and often so closely resembling the shells of fresh-water molluscs, that some of them have been described as species of Valvata, Paludina, &c.! In the Hydropsychidæ and Rhyacophilidæ the larvæ are carnivorous, and form irregular cases of small stones fixed to larger stones at the bottom of the water, and sometimes several larvæ appear to live in company under a common covering of vegetable and other *débris* fastened together with silk. These are obliged to quit their retreats when wandering about in search of food, and they accordingly have the body and abdomen of a firmer consistency. The Rhyacophilidæ especially frequent torrents. Lastly, the Hydrophilidæ live in more or less seed-like, movable cases, formed of silk with minute sand-grains, and having a slit at each end forming two apertures, from either of which the larva can protrude its head. They are found among water-plants, on the surface of stones at the bottom of streams or ponds, and have the power of spinning a silken thread by which both the case and its inhabitant can float securely in the water. The insects produced from these larvæ are the smallest of the order, and often appear in great numbers.

When the larvæ of Trichoptera are about to change into pupæ they close up the apertures of their cases either with a network of threads or with other materials, and some of them besides spin an inner cocoon. The pupæ, though quite motionless, bear a considerable resemblance to the perfect insect, the antennæ, legs, and wings being fully formed, but shorter, and all inclosed in separate sheaths and arranged on the breast. The head is however armed with a pair of strong horny hooks or jaws

quite different from those of the larva or the rudimentary jaws of the perfect insect. These are to enable the pupa to cut its way through the cocoon and outer case, when it is ready to assume the perfect state. It then becomes active, swimming by means of its two middle legs, the tarsi of which are densely fringed with long ciliæ, forming admirable oars. By means of these the pupa reaches the stem of some aquatic plant, up which it creeps out of the water, and then sheds its pupa-skin, and lives a short aërial life which seems wholly devoted to the duty of continuing the species.

From the foregoing brief sketch of the main features of this order of insects, it will be seen that they form what is probably a very ancient group, which has preserved some of the characteristics of several distinct orders. Though, owing to the structure of the rudimentary mouth, the Trichoptera have to be classed among the mandibulate or gnawing insects, and are supposed to be allied to both the Neuroptera and the lower Hymenoptera, yet in the neuration of the wings, their hairy clothing, the silk-spinning and case-bearing larvæ, and the form and habits of the perfect insect, they more nearly resemble some of the smaller moths, with which Mr. McLachlan believes they have a real affinity. So, in the curious activity of an otherwise quiescent pupa, which possesses special organs for gnawing and for swimming, these insects seem intermediate between the groups with an imperfect and those with a perfect metamorphosis, though far more closely allied to the latter; and owing to these various peculiarities the Trichoptera may be said to constitute a "critical" group, whose study cannot fail to throw light on the affinities and genealogy of insects generally. Owing however to their obscure colours and slightly varied forms they have attracted comparatively little attention, though a few ardent workers have for many years devoted themselves to this branch of entomology; but the appearance of the present elaborate work, which is a model of conscientious labour and research, will form an important era in the study of the group.

This large and handsome octavo volume is devoted to a complete description of all the species of Trichoptera which have been discovered in Europe and Northern Asia, or in what is now termed the Palæarctic Region. These descriptions have all been drawn up from specimens of the insects themselves—often of the greatest rarity—and the fact that the chief museums and private cabinets of Europe and America have placed their collections in Mr. McLachlan's hands for the purposes of this work, is the best proof of the high reputation he has attained as a master in this branch of entomology. The book is illustrated by fifty-nine plates containing about 2,000 distinct figures (all drawn by the author himself), illustrating generic and specific characters mostly derived from the neuration of the wings and the structure of the anal appendages. These latter organs are wonderfully varied from species to species while constant in each; and by carefully delineating them by means of the *camera lucida*, species have been shown to be distinct which appear in all other respects to be identical; and the fact of such distinctness in a considerable number of cases is one of the most curious and interesting results of Mr. McLachlan's researches.

The work has occupied nearly six years in its publication, and it has had the effect of stimulating inquiry to such an extent that a large number of new species have been discovered during its progress, rendering the book half as large again as was anticipated; yet the author believes that a comparatively small portion only of the European species are yet known, while in less familiar regions there is a wide field for the discovery of new and remarkable forms. There remain also a number of larvæ which have not been identified with the perfect insect, and an interesting and useful line of observation is thus open to entomologists both at home and abroad. Under these circumstances every naturalist will appreciate the value of a work which has collected together and thoroughly worked up all the material available to the latest date. Such a book cannot, from its nature, be a popular one. Its production has been a labour of love, and is to that extent its own reward; but the expense of producing such a volume is very great, and in order to encourage and even to render possible the production of such works it becomes the duty of all who wish to advance the study of nature to do what in them lies to relieve such enthusiastic workers from the pecuniary burthen which their self-denying labour brings upon them. If every scientific institution and every Naturalist's Field Club in the kingdom were to purchase a copy of this admirable volume for the use and instruction of their members, they would do much to render the production of such works more common, besides really furthering the progress of research, perhaps even more than by the publication in full of their own Proceedings.

This is undoubtedly the most important British work on Entomology since the completion of Mr. Stainton's "Natural History of the Tineina" thirteen years ago, and it is well worthy of the high reputation of its author; while the clearness of the type, the excellent systematic arrangement, the full indices, and the beautifully engraved figures, are equally commendable. Any detailed criticism on such a book could only be given by a worker in the same group; but as one who has often to refer to natural history volumes for information, the present writer would suggest that the absence of any *family* names as headings to the pages is a great inconvenience, as there is no means of ascertaining what group a genus belongs to or of finding the commencement or end of a family without constantly turning to the index. So far as the typography and general arrangement of the volume are concerned this is the only defect that has been noticed, and that it is so small a one may be taken as an indication of the care and attention which has been bestowed upon the publication, no less than on the composition of this notable volume.

A. R. W.

OUR BOOK SHELF

Ornithological Journal of the Winter of 1878-79; *with Collected Notes regarding its Effects upon Animal Life, including Remarks on the Migration of Birds in the Autumn of* 1878 *and the Spring of* 1879. By John A. Harvie-Brown, F.Z.S., M.B.O.U. (*Proc.* Nat. Hist. Soc., Glasgow, 1879.)

Mr. Harvie-Brown, well known as one of the most active and practical of our home-ornithologists, has endeavoured to chronicle the abnormal effects of an

unusually severe winter on bird-life. To this end the scattered notices on this subject which have appeared in various journals and periodicals have been collected, and are supplemented by communications from private correspondents and by personal investigations. The result is the memoir now before us, in which the observations thus collected are arranged in a systematic form.

The southern migration in the autumn of 1878 was by all accounts unusually early and rapid. The outer Hebrides appear to have been almost cleared of their smaller birds. Visitors to Tyree in December remarked on the "extraordinary scarcity of common birds," and on the "unusual number of winter visitants." On the Solway Firth also "early notice of the coming winter was afforded by the arrival of vast numbers of wild fowl." Herr Gaetke of Heligoland reports that while in ordinary seasons the autumnal migration in that wonderful island often continues until the end of February, in the autumn of 1878 every migratory bird had sped past by the close of November.

Numerous other testimonies to these facts which are adduced by Mr. Harvie-Brown, leave no doubt as to the general effects produced on bird-life by the unusually severe winter of 1878-79, in which a January "colder than any for forty-one years" followed a December "the coldest of any for twenty-one years." The bulk of the memoir is taken up by a series of notes on the different species systematically arranged, a perusal of which is sufficient to show without doubt that the author's general conclusions are amply borne out by the particulars which he has collected.

On Mining and Mines in Japan. By C. Netto. (Tokio, 1879.)

THE substance of this pamphlet was given as a lecture by the author before the German Natural History and Ethnological Society of Eastern Asia, and it now appears with the above title as vol. ii. of the *Memoirs* of the Science department of the University of Tokio. It is mainly a discussion of the present state of mining and metallurgical industry in Japan, with suggestions for improvements by the introduction of machinery, the establishment of model dressing and reduction works, the formation of private companies, and more particularly the introduction of foreign capital, which is at present prohibited by the Japanese law. These points are treated in some detail, and the moderation with which the author expresses his conclusions shows a practical familiarity with the subject such as is likely to command the confidence of those persons who may be interested in the subject. It is however to be regretted that the author has not been fortunate enough to receive the co-operation of some of his literary colleagues in the production of the work in its present form, as the text, even by the greatest stretch of international courtesy, can scarcely be called English, and the directors of the University must certainly have been unaware of its character when they allowed it to appear among their Records. It is necessary to mention this, as an impression is to some extent current that the translation is of Japanese origin.

The Automatic Multiplier: for Performing Multiplication without Calculation and without Writing down any Figures except the Answer. By John Sawyer (London: George Bell, 1880.)

The Automatic Calculator, for cwts. qrs. lbs. at per lb., Supplying the Cost of any Weight at any Price up to 11s. 11¾d. per lb. By the same.

IN NATURE, vol. xviii. p. 327, we noticed "Automatic Arithmetic" by the same author. We need only endorse the remarks we previously made with regard to the former work, and commend the present admirably compact and handy calculators to practical men who, after a little time spent in getting over the manual difficulty to beginners in manipulating the vertical and horizontal slips, will find these works very serviceable as ready reckoners. Multiplication is reduced to a mere addition of digits: the earlier work facilitated the operation of division as well. We may add that the "Multiplier" is issued in three forms, *i.e.*, for multiplying 4 figures by 4 figures, 6 figures by 4 figures, and, as in the specimen we have, 8 figures by 6 figures.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Freshwater Medusa

THE explanation of the discrepancy between Prof. Allman's and my own citation of my article in NATURE, vol. xxii. p. 147, appears to be that Prof. Allman has unfortunately received a copy of NATURE differing from the majority of the issue of that date in the fact that it was printed off before the final corrections, sent to the office of NATURE on Wednesday, had been inserted. These corrections were made before the greater number of the issue was struck off, and I have only just ascertained, to my great surprise, that any of the uncorrected copies had been circulated. The error as to the marginal canal was also present in the proof of my paper, marked "uncorrected proof, confidential," which was circulated among the Fellows at the meeting of the Royal Society on June 17, but the error was corrected by me *before the reading of the paper.*

Accordingly, so far as any *publication* or the public expression of my conclusions is concerned, I have not committed myself to the erroneous notion that the marginal canal is absent, although in the course of my inquiry I did entertain that and many other provisional conceptions as to the structure of Limnocodium.

I shall be glad to see some explanation from the publishers of NATURE of the curious and highly inconvenient phenomenon of dualism in NATURE which has mystified both Prof. Allman and myself. E. RAY LANKESTER

[Premising that we are supposed to leave NATURE in the printer's hands ready for press at 2 p.m. on Wednesday, we have no difficulty in giving the explanation asked for by Prof. Lankester.

His revised proof was received by us on Wednesday morning, June 16, with numerous corrections, which were given effect to. After the paper had been made over to the printer on the afternoon of that day a postcard was received by the printer with an additional correction, which was also duly made. On the morning of Thursday, the 17th, the following note, dated "Wednesday afternoon," was received by the printer after the printing of the American edition had been completed and that of the English one had commenced:—

"DEAR SIR,—If there is time please alter in my diagnosis—

'MARGINAL or RING CANAL *obliterated or much reduced*' into 'MARGINAL or RING CANAL voluminous.'

"Similarly please alter

'RADIATING CANALS terminating cœcally' into 'RADIATING CANALS opening into the marginal canal.'

"Truly yours,
"E. RAY LANKESTER"

Although one-third of the edition had been printed off, the printer, knowing our anxiety to give contributors every facility for corrections, stopped the press, and made the alterations which were asked for "if there is time." Possibly Prof. Lankester has no idea of what is involved in stopping a steam press. However this may be, the press was stopped in order to carry out to our utmost what we considered to be Prof. Lankester's wishes, and we are astonished that he can have put any other interpretation upon what happened. Prof. Lankester's letter given above is undated, but it was received on July 31 at mid-day. On the 28th he wrote, stating that he had found there were "two issues of NATURE of June 17," and requesting us to "state this if necessary." This does not

seem to accord well with the statement above (July 31) that he had only "just ascertained" the fact to his "great surprise."—Ed.]

Subterranean Kaolinisation

A year ago Mr. John Arthur Phillips, in criticising, before the Geological Society, my theory of kaolinisation as a source of superficial rock temperatures, made a point which is interesting in its bearing upon the composition of derived or secondary lithological products. He endeavoured to ascertain the number of tons of felspathic rock that must be yearly kaolinised in order to supply the quantity of alkalies known to be contained in the mine waters of the Comstock silver lode in Nevada, and in doing so he began with the supposition that in the process of kaolinisation *all* of the alkali in the felspar goes into solution and is removed. This assumption is undoubtedly incorrect, for even the surface clays which are deposited from running water, and therefore must have been subjected to a maximum leaching, almost invariably contain potassic and sodic salts, as any one may learn by studying the subject of fireclays.

But when the clay is formed by the alteration of rock at great depths, beyond the line of ready drainage and in the presence of a minimum quantity of water, the product is, or may be, quite different from the clay of sedimentary deposition. It is in fact merely the original rock hydrated, and from the example given in the Comstock region the alteration product does not seem to lose much, if any, of its original alkalies. This is demonstrated by the analyses given in Mr. King's Report on the Fortieth Parallel. All the existing analyses of the clays in this region were made on specimens obtained in the first thousand feet of depth, and most of them were taken within 500 feet of the surface. That is, they all come from the region of active drainage, the oxidising and other effects of atmospheric action being well marked in this lode down to the depth of 600 feet. The mean of four analyses of clays shows 4·72 of alkalies and 10·86 of water, CO_2 and P_2O_5. One of the specimens has been very strongly altered, having lost about 10 per cent of silica, while another seems to have gained about half as much of the same constituent. As to the composition of the original rocks (propylite and andesite,) it is impossible to be exact, for the alteration in the region has been so extensive and thorough that all attempts to obtain an unaltered specimen have failed. The least altered specimen of propylite from the Virginia range of mountains in which this lode is found contains 5·08 per cent. of alkalies, with 1·02 loss by ignition. The most altered specimen contained 5·26 per cent. of alkalies, and 6·53 loss by ignition. Andesite showed in the least altered specimen 4·7 alkalies and 2·8 loss; in the most altered specimen 7·37 alkalies and 4·35 loss. It is impossible to compare the clays of this district with unaltered rock from other localities, for the reason that the composition of these eruptive rocks varies strongly, especially in the percentage of alkalies. On the whole I think that any one who will compare the tables of analysis given in vols. i. and iii. of Mr. King's work will be convinced of the truth of what I have asserted above—that subterranean kaolinisation is merely the hydration of a rock in place without other serious alteration. The fact has importance in its relation to the origin of some hydrated aluminous rocks.

Mr. Phillips calculates that the average proportion of alkalies in these rocks is 6·4 per cent., that 813 tons of alkalies are removed yearly in the mine waters, and that "it consequently follows" that the felspar in 12,703 tons of rock "must be annually kaolinised, and the whole of the alkalies removed in solution." It seems to me that a metallurgist of Mr. Phillips' experience should have known that the alkalies are never completely removed in kaolinisation. That he is not acquainted with the peculiar and remarkable conditions of the Comstock is not surprising, for the lode receives but little attention, and that of the most hasty kind, from visitors. I ask your permission to add the following summary of facts which rebut Mr. Phillips' criticism:—

1. The removal of alkalies in subterranean kaolinisation, if it is judged by the existing incomplete series of analyses, seems to vary from less than one-fifth of the quantity of alkalies in the present rock down to almost nothing.

2. The whole results of kaolinisation are not represented in the mine waters. In the vast areas of dry rock alteration has been extensive, and seems to be going on now by means of water-vapour, and none of this action supplies alkalies to the mine waters.

3. The liberation of hot gas which is an accompaniment of kaolinisation by atmospheric waters conveys the heat produced in the dry areas to all parts of the mass, and especially to such channels as watercourses and mine-openings.

4. Kaolinisation in the Comstock region is not produced by the action of cold water on cold rock, but by the combination of water and rock, both already heated before the action to very nearly the temperature they attain after it. The heat of the rock is cumulative, its present temperature being mainly the result of ages of previous kaolinisation, the heating effects of which were preserved from dissipation by a blanket of rock 1,000 feet thick. The water which takes part in the action at existing depths of the mine has been heated by its percolation through 1,000 to 1,500 feet of hot rock lying below the blanket spoken of. Mr. Phillips calculates that 85° are added to the temperature, but in fact the actual increment of temperature by kaolinisation is, in the locality given, but a small fraction of this quantity. Considering the small rainfall of Nevada, and the depth at which the waters are now drawn from the rocks, and the perfect correspondence of depth and temperature, it is more probable that the actual gain of heat does not exceed one or two degrees, and may even be less.

5. Mr. Phillips' calculation that 330 tons of water are heated by the kaolinisation of one ton of rock has no foundation in the known facts, but is probably more than 99 per cent. from the truth. His further error in supposing that the increment of heat is 85° F. instead of being in the neighbourhood of 1°, as is more probable, relieves his criticism of whatever weight it might have if it had been adjusted to the well-known facts of the case.

"On a Mode of Explaining the Transverse Vibrations of Light"

I venture to call attention to what appears to me to be (possibly) an objection to the views advanced by Mr. S. Tolver Preston in his interesting article, "On a Mode of Explaining the Transverse Vibrations of Light" (Nature, vol. xxi. p. 256). Mr. Preston's hypothesis I understand to be a special modification of Lesage's, the speciality being that the corpuscles which by their impact on the cage-atoms of ordinary matter cause gravitation, are also the carriers of some vector property, the changes in which constitute radiant energy, and that in fact there is no ether except just this assemblage of minute corpuscles co-existing in the ultra-gaseous state (*i.e.*, with a mean free path of great length). Now, as far as I can see, it is a strict corollary from this exceedingly fascinating hypothesis that the velocity of propagation of gravity must be identical with that of light. In other words, the acceleration of a material particle at any instant (I) caused by the attraction of a second particle must be directed to the spot occupied by that second particle, not at the instant I, but at some instant prior to I, the interval between the two instants being the time taken by the ultramundane corpuscles, and therefore by light, to travel from the one particle to the other. But do not the observed planetary motions necessitate the assumption that gravity, even if propagated in time at all, is propagated with a velocity vastly in excess of that of light? At any rate this statement is frequently met with in discussions on the nature of gravity, and is much prized by advocates of "action at a distance." If it is true, does it not constitute a fatal objection to Mr. Preston's hypothesis?

Some two years ago it occurred to me that the ether might consist of particles in the ultra-gaseous state, and might thus, in accordance with Lesage's hypothesis, give rise to the mutual gravitation of the grosser atoms immersed in it. I was then unaware of the late Prof. Clerk Maxwell's suggestion that these particles, by being the carriers of some vector property undergoing periodic reversal, might account for the propagation of light; and vaguely hoped that it might receive some explanation from the fact, also discovered by Clerk Maxwell, that a body in the ultra-gaseous state behaves like a solid towards any confining boundaries to the extent that, like a solid, it opposes a certain resistance to change of shape. But I deemed the whole theory to labour under the fatal objection of not giving a sufficient velocity of propagation to gravity.

I write in the hope that Mr. Preston or another of your readers will inform me whether my objection is a valid one.

Expansion of Glass by Heat

THE reproduction in your "Physical Notes" (NATURE, vol. xxii. p. 157) of Mr. R. H. Ridout's neat experiment for illustrating the "Expansion of Glass by Heat" (*Phil. Mag.* for June, 1880), recalls to mind an equally striking method of exhibiting this property of glass to a class of students in physics. Select a straight glass tube 50 or 60 centimetres in length and 1 or 2 centimetres in diameter. Place it transversely in front of a fire, in a horizontal position, properly supported near its two *ends* on two horizontally-adjusted rods of hard smooth wood of about the same diameter as the tube; the glass tube will gradually *roll towards the fire*. Now let the supporting rods be transferred to either side of the centre of the tube, so as to support it near its *middle*; the tube will now gradually *roll from the fire*.

It is scarcely necessary to remind the reader that the greater dilatation of the glass on the side of the tube which is nearer the fire renders it *curved*, with the convexity next to the source of heat, so that, when supported near the *ends*, the *falling* of the *central parts* of the curved tube rolls it *towards* the fire; but when supported near the *middle* the *falling* of the *ends* of the similarly curved tube rolls it *from* the fire. These experiments, it is evident, succeed better when the *cold* tube is first adjusted near the fire than when it has been so long exposed to the action of the heat as to have become heated throughout its mass.

It seems that about the year 1740 this behaviour of glass tubes under similar conditions was noticed by Mr. C. Orme, of Ashby de la Zouch, while heating some barometer tubes. The Rev. Granville Wheler, who carefully verified the experiments of Mr. Orme, very correctly ascribes the phenomena to the *distortion* of the tube due to the action of heat (*vide Phil. Trans.*, No. 476; also *Edinburgh Encyclopædia*, 1st Am. ed., 1832, vol. ix., article "Glass," p. 773). Nevertheless in the United States this behaviour of glass tubes, when placed before a fire, has been frequently classed among the *unexplained mysteries of glass!* As recently as 1865 Mr. Deming Jarves, of Boston, in his little volume entitled "Reminiscences of Glass-Making," p. 10 (2nd ed., N.Y., 1865), refers to the phenomena, but with not one word of *explanation*. In fact not long ago some of our semi-scientific journals characterised these phenomena as *mysterious* and *inexplicable*. Hence I have for the last twenty or thirty years employed such experiments, not only as exhibiting *visible* manifestations of the expansion of glass, but also as affording an *instructive and significant illustration of how completely the most obvious mechanical results may be overlooked or obscured under the inspiration of the propensity to seek for the marvellous in nature!*

Berkeley, California, July 8

Fascination in Man

HAVING frequently seen it stated in popular works on natural history as well as in some books of travels (chiefly Australian) that certain snakes possessed the power of so fascinating, with their gaze, birds and other creatures as to be able to seize upon and devour them without any difficulty, I am induced to inquire if such a power is peculiar to the serpent tribe or not, and incidentally to ask if any instances of its influence or extension can be traced, up the scale of creation, to man himself. Being of opinion that such is the case, while it has occurred to me that many of the fatal accidents that occur in the streets of large cities, such as London, &c., might be ascribed to some such agency or sensation, I am induced to call attention to the circumstance in these pages, and to submit the following as my own personal contributions towards the inquiry:—

Describing certain incidents of the siege of Gibraltar, Drinkwater says, "History," p. 75, that "on the 9th Lieut. Lowe . . . lost his leg by a shot on the slope of the hill under the castle," and the italics are mine throughout. "He saw the shot before the fatal effect, *but was fascinated to the spot*. This sudden arrest of the faculties was not uncommon. *Several instances occurred to my own observation where men totally free have had their senses so engaged by a shell in its descent that, though sensible of their danger, even so far as to cry for assistance, they have been immediately fixed to the place.* But what is more remarkable, these men have so instantaneously recovered themselves on its fall to the ground as to remove to a place of safety before the shell burst."

Alluding to the first casualty that occurred at Cawnpore during the siege of the entrenchment there in 1857, Mowbray Thomson says ("The Story of Cawnpore," p. 66) that "several of us saw the ball bounding towards us, and he (McGuire) evidently saw it, but, *like many others whom I saw fall at different times*, he seemed fascinated to the spot"; and an old and now deceased departmental friend, who went through the whole Crimean campaign, assured me that he was once transfixed (fascinated, he called it) after this fashion in presence of a shell that he saw issuing from Sebastopol, and whose every gyration in the air he could count. Other military friends have discussed the point with me in this same wise, and I think there is some allusion to it in one or other of the works of Larry, Guthrie, Ballingall, or others of that ilk.

Monkeys in the West Indies

IN consequence of my removal from the West Indies to the West Coast of Africa, and of illness since my arrival here, I have not until now had time to read in the back numbers of NATURE the controversy on the subject of "Monkeys in the West Indies," which, it may be said, I created by my communication in NATURE, vol. xxi. p. 131. I trust, therefore, I now may be permitted to reappear on the scene and to sum up my case.

In my communication I quoted, from Prof. Mivart's lecture on "Tails," an extract which appeared in your columns (NATURE, vol. xx. p. 510), viz.: "Monkeys are scattered over almost all the warmest parts of the earth save the West Indies, Madagascar, New Guinea, and Australia," and I added, with the utmost respect for Prof. Mivart, that the above statement was not "quite correct," adducing as proof the fact that they were found in St. Kitts, Nevis, and Trinidad. Mr. Sclater, F.R.S., the distinguished zoologist, answered my letter (NATURE, vol. xxi. p. 153), explaining that Prof. Mivart was correct in his statement; that the monkeys of St. Kitts were not "indigenous" to that island, and that Trinidad originally was part of the mainland of South America. Mr. Sclater said nothing about the Nevis monkey. Dr. Imray of Dominica followed with a quotation from Père Labat (NATURE, vol. xxi. p. 371), and as regards St. Kitts and Trinidad, the monkey question was closed.

But it subsequently came to my knowledge, through hearsay evidence, that monkeys existed in large numbers in Grenada, one of the Windward group of islands, although travellers and historians from the time of Père du Tertre to that of Bryan Edwards seemed to be ignorant of the fact. As I had left the West Indies when I obtained this information, I at once called Dr. Imray's attention to it, begging him to ascertain its accuracy and then to communicate with NATURE. Dr. Imray has done so (NATURE, vol. xxii. p. 77), and, by a curious coincidence, his letter appears in the same number in which a Grenada correspondent, signing himself D. G. G., charges me with being "quite as much in error as Prof. Mivart," and makes me say that "*the only islands* in the West Indies *where monkeys are to be found are St. Christopher* [*i.e.*, St. Kitts] *and Nevis*." The italics are my own, but I think D. G. G. should at least be careful to quote accurately.

I have no wish to trespass further on your valuable space. What I desired to show and what I have shown is that monkeys *do* exist in many of the West India Islands, and that, although nearly four hundred years have passed away since the discovery of the islands, their natural history is still very imperfectly known. And yet these islands are within easy steaming distance from England; they are inhabited by people whose kindness and hospitality to visitors are proverbial. Their mountains afford all the varieties of healthy climate, and for the botanist, the geologist, the entomologist, and the man of science generally, there are few, if any, richer fields of instruction and enjoyment.

Utricularia

CAN any of the readers of NATURE inform me whether the sharp clicking noises produced on removing Utricularia from the water (particularly for the first time) have been noticed or described? I have not succeeded in determining the species, as the plants are not yet in flower.

J. W. CLARK

R.I.E. College, Cooper's Hill, July 30

The British Association and Provincial Scientific Societies

THE list of delegates of provincial scientific societies prefixed to the list of members attending the annual meeting of the British Association having appeared to me to be practically useless, being in reality merely a list of "temporary members" of the general committee—with the object of making it of some value to the societies represented, and also eventually to the Association, I suggested, at the meeting at Bradford last year, an alteration in the rule of the Association which affects this list of delegates. My suggestion being favourably received by the Council, the alteration proposed was adopted at a meeting of the General Committee.

The effect of this alteration is to admit as a temporary member of the Committee the *secretary* of any scientific society publishing *Transactions* as well as the president, or in his absence a delegate representing him. My object in proposing it was, as I then stated, to admit of a meeting or conference of the presidents and secretaries of societies thus represented being convened under the auspices of the Association, at which matters concerning such societies (their management more especially) might be talked over and arranged, &c., a thing which could not be attempted in the absence of the secretaries, they, as a rule, having almost the entire management of their societies.

As the revised rule first comes into operation at the approaching meeting of the Association at Swansea, I should be glad if you will draw attention to it, either by the insertion of this letter or in any other way. JOHN HOPKINSON

Intellect in Brutes

THE following story was told me by the mistress of the dog herself. The event occurred in a small village in Essex, some years ago.

"A little black and white King Charles, beloved by its mistress, but not by its master, was one day lying on a rug in the drawing-room when the master came in, having just paid its tax. He said: 'I have just paid that dog's tax'; and looking at it with a severe expression added: 'and he's *not worth* his tax." The little dog immediately got up, and with a crestfallen appearance put its tail between its legs and left the room. It was never seen afterwards, nor was it ever heard of again, although inquiries were made at the time in every direction."

GEORGE HENSLOW

Chipped Flints

A FEW days ago a man who had been cutting turf in this neighbourhood came to tell me that he found a quantity of small flints at the bottom of the "bog-hole," and he brought some of them for my inspection. Seeing that they all bore very obvious marks of handicraft, while a few were more or less rudely shaped like arrow-heads, I immediately went to the place, accompanied by the man, and succeeded in getting a number of specimens, of which some fifty or sixty show pretty plainly the design of the workman. Among them are a few white flints, evidently from the Chalk, and indeed with some chalk attached to them. This is worthy of remark, as there is no chalk nearer than the North of Ireland, nor are there any chalk flints among the boulders here, where the drift was unmistakably derived from the limestone, silurian, mica slate, and syenite rocks of the west and south-west. The other flints are black, like the chert, which occurs plentifully enough in the carboniferous lower limestone formation of the district. Several pieces of charcoal were mixed with the flints, showing probably that fire was used in breaking them up in the first instance. The final operation of chipping seems to have been done with a very delicately-pointed instrument, not thicker than a large sewing-needle. Its marks, both where it struck off the chip and where it failed to do so, are as plain and fresh-looking as if they were made quite recently. It must have been used as a punch and worked with a hammer, and there must have been some contrivance like a vice to hold the flint during the operation. It is really hard to think that the instrument with a point at once so minute and powerful could be other than metallic; but then, if there was metal available, why have recourse to flint? Perhaps these flints might be referred to a time late in the neolithic period, during the transition from stone to metal, when the latter, being scarce, was used only for tools. At one time I fancied that I made a capital discovery of metallic particles struck off and lodged in the stone, but with a pocket lens they were found to be only specks of pyrites. A small sandstone slab, quite smooth on one side, lay among the flints, but it was either taken away or thrown into one of the turf holes filled with water before I came to the place, and I failed to find it. By its impression in the turf which remained untouched it appeared that one surface was quite polished. The other was described as rough. Whether it was used in the manufacture of the arrow-heads or not I cannot surmise. The shape of a large sandstone pebble that I found might suggest its use as a hammer, but it showed no signs of abrasion. At one time there must have been at least twelve feet of turf over the flints. They lay immediately above the roots of a pine close to a short piece of the stem that remained. The tree was most probably growing when the flints were worked, and it may be of some interest to note that the craftsman selected the shade or solitude of a wood for his *atelier*.

In this bog is found the striking phenomenon of two growths of trees, one overlying the other. The lower was chiefly pine, identical with, or nearly allied to, the *P. sylvestris*, and rooted in the drift clay or gravel. The upper trees were principally oak, and grew in the turf formed from the prostrate wood that preceded them. This is remarkable, showing a wide difference in the habitats of both kinds and those of their representatives of the present day, when we find the oak growing in clayey soils, while in general the moor agrees well with the firs and pines.

J. BIRMINGHAM

Milbrook, Tuam, July 12

Lunar Rainbows

THE following communication has been forwarded to me by a lady of considerable ability, and can be relied upon. As a lunar rainbow is a rare phenomenon, perhaps you may deem the notice worthy of a place in NATURE. J. KING WATTS

St. Ives, Hunts., July 30

"On July 19 a most brilliant lunar rainbow was visible in this village of Over, Cambridgeshire, and was observed by other persons as well as by myself. For several days previously there had been a succession of violent storms, with much thunder and lightning, and the falling of vast quantities of rain. The whole atmosphere was evidently in a very perturbed condition, with considerable electrical disturbance. The wind had for several days previously been exceedingly variable, veering from point to point with rapidity, and on the day in question it had veered much from one point to another. At 10 p.m. the wind blew strong and steadily from the south-west, thereby driving the great masses of cloud to the north-east. To the front of the position I was in, the clouds had been pushed or rolled up into a dark mass extending from the north, north-east, east, and nearly to the south-east, up to the zenith, so that one portion of the horizon was cloudless and the other portion black and sombre. The moon was very clear and nearly to the full. The sky had a singular appearance, one part being most brilliant and clear, and the moon riding in it free from every particle of cloud, and the other part to the north-east was most intensely dark. At 10.35 a beautiful and brilliant silvery white arch was formed (north-east), extending nearly from the zenith down to the horizon. The arch was most perfect in all respects. The force of the wind had abated. There were no prismatic colours visible, but the whole arch, standing out, as it were, in bold relief on the black cloud, had a most awe-like but beautiful appearance, and the sight can never be forgotten. The singular phenomenon was brilliantly visible for a considerable length of time, thereby clearly indicating the slow progress at which the shower was then moving onward. Such a phenomenon is very seldom to be seen. The sky continued clear during the remainder of the night. "ANNE GIFFORD

"Over, Camb."

W. E. WILLINK.—The "substance" you send us is a well-known alga, *Nostoc commune*. See the "Treasury of Botany," *sub voce* Nostoc.

BRICKMAKING.—A "Brickmaker" asks if any of our readers can tell him of a book on Brickmaking which gives good and trustworthy information about the operations, machines, &c. He has a book by E. Dobson, but it is thirty years old, and therefore of very little use.

CARBON AND CARBON-COMPOUNDS

THE wayward and inconstant train of coloured light-bands that spectroscopists have noted and distinguished in the spectra of various carbon-compounds in flames and gas-vacuum tubes are as yet far from having all received their full and appropriate interpretations. The extent to which they abound as impurities in almost all spectral vacuum-tubes is a common observation, and in a survey of this kind, aiming at no systematic exploration, of a variety of end-on vacuum-tubes in the large and perfect spectroscope erected by Prof. Piazzi Smyth for the examination of *auroræ*, I have had from time to time, at his kind invitation, excellent opportunities for discriminating some of the component groups and clusters of the carbon-denoting series from each other pretty clearly.

Among the least alterable and changeful in its appearance of these coloured ranks is the five-tongued spectrum of wedge-like bands best seen in the end-on prismatic view of a coal-gas blow-pipe flame. Its bands have shaft-lines at the edge and on their fading slopes, with the exception of the last or violet one, just including within its bright edge the solar line of Fraunhofer's spectrum, G. This has a fine-line precursor, nearly coincident with Hγ, and a faint haze-band preceding it. Close to the place of b_1 in the solar spectrum appears the bright edge or chief shaft-line of the green band, fitly styled the "green giant," as it is the real Anak of the coal-gas flame-spectrum. Its less refrangible similitudes in the yellow-green and orange-red are quite subordinate groups, the latter being only discernible in spectroscopes of large aperture and of very great transparency. The fifth finger of this spectral gauntlet is a blue band, or quintett of five close lines pretty equally spaced and pretty equal in brightness, with little haze between them, lying once or twice its own breadth on the more refrangible side from Hβ (F). The frontispiece of Watt's "Index of Spectra" contains a figure of this spectrum; and wave-length positions and symbols and descriptions of its groups are given in the body of the work, under the title "Carbon, Spectrum I." α, γ, δ, ϵ, f (β and η *carent*) are the five familiar potentates of the blow-pipe flame; but the two line-bands ζ, θ, one on each side of f, added in the figure and in the text of Watt's "carbon-spectrum I.," are not visible in the blow-pipe flame-spectrum. Along with a similar ultra-violet cluster just following H K in the solar spectrum, they form a triumvirate, the spectral origin of which Professors Liveing and Dewar have recently affirmed to be cyanogen. A reason to question the correctness, however, of Messrs. Liveing's and Dewar's surmise presented itself to me in my examination of the end-on tubes by the spectacle of the six-lined violet cluster θ rearing itself, without any accompaniment of its blue associate ζ, into extraordinary magnificence in a Marsh-gas tube. The grey or ultra-violet member of the trio was indeed weakly discernible at the same time; and in just this relative brightness and condition of extreme isolation from every other spectral feature I have recently observed these two violet and ultra-violet line-clusters in the blue flame part of the arc between particularly pure carbon poles in the Brush's or Anglo-American Company's electric light.

Another reason for suspecting multiplicity of form in the carbon-spectrum by itself occurred to me in an examination of the spectrum of cyanogen in an end-on tube. A perfect counterpart, it is well known, of the blow-pipe flame spectrum is producible by the induction-spark in vacuum-tubes of olefiant gas. Accompanying it however is another spectrum which in its fullest purity and intensity is equally well known to be produced by a weak induction-spark in tubes of carbonic oxide and carbonic acid gas. The blue quintett and the violet G-band are wanting in this spectrum. The edges of the green, citron and orange-red bands are displaced, and these bands are devoid of shaft-lines, being composed entirely of haze and fine linelets which smoothly shade them off. The olefiant gas and "carbonic oxide" spectra mingle together, usually in divers proportions in the carbon-impurities of gas-vacuum tubes.

Two cyanogen tubes (one of them of hardest glass) prepared by M. Salleron betrayed alike only the smallest trace of hydrogen by its red line, when they were lighted up by the induction-coil. Aqueous and atmospheric oxygen may therefore be presumed to have been pretty completely expurgated from these tubes, and the gas which charged them to have been an exceptionally pure compound of nitrogen and carbon. Far brighter, notwithstanding this, than in any other vacuum-tube, the smooth-shaded "carbon-oxide" bands made their appearance; and equally splendid with them was the close-ribbed red and yellow fluting forming the less-refrangible part of the spectrum, figured and described by Ångström and Thalèn as that of "nitric oxide." The coincidence with the same spectrum of the bright cyanogen-tube lines in the blue and violet spectral regions was not closely examined; but as far surpassing in brightness the red-end view of it obtained in any other nitrogen-holding vacuum-tube (nitric oxide itself not excepted), the rasp-like ridges of the so-called nitric oxide spectrum were immediately measured with great care and accuracy. Ångström's positions and *tableau* (exactly reproducing that of Plücker and Hittorf) of this region were completely verified; and the discussion of the well-based determinations left no doubt that while a simple order reigns sensibly among the small linelet features of each separate ridge, the ridges have no perceptible connection with each other or with the linelet-intervals upon them in the pitch of their wave-frequencies, although they follow each other closely in a gradually narrowing succession. In the rest of the nitrogen-spectrum, where the ridge-intervals are much wider, it is again not possible to trace between the ridges any simple wave-period connection.

Were I not from these measures, and from the foregoing considerations disposed to regard shaded spectral bands as independent systems of vibration, indicating most probably particular atomic groupings in a molecule, I should have beheld with some surprise the complete and thorough metamorphosis shown me by Mr. Lockyer since the above particulars were noted, which the smooth-banded "carbon-oxide" spectrum undergoes by introducing a condensing-jar, or better, a jar and air-break, into the circuit of the induction-coil. The smooth shadings disappear, the shaft-lines, the "Anak and the sons of Anak" of the olefiant-gas or blowpipe-flame spectrum make their appearance in their place; even the blue quintett of that spectrum comes forth from its hiding-place; and, as far as I could examine the spectral appearance of the carbonic-oxide tube in the now condensed discharge with complete precision, the whole blow-pipe flame, or so-called "hydro-carbon" spectrum, is perfectly reproduced. If we cannot admit, as I think that the cyanogen-tube experiment forbids us to do, that a chemical transformation has taken place, then we must acknowledge that among the forms which the spectrum of carbon is capable of assuming, there may, by subdivision of its molecule into separate vibrating systems, exist not one, but as many different "low-temperature" spectra of that Briareus-like, hundred-fisted, or Proteus-like, hundred-visaged element, as the electric discharge is capable of dividing its evidently complex gaseous molecule into separate spectroscopically individual groups.

A. S. HERSCHEL

PHYSICS WITHOUT APPARATUS

I.

IT is almost a proverb in science that some of the greatest discoveries have been made by the most simple means. It is equally true that almost all the

more important facts and laws of the physical sciences can be illustrated and explained by the help of experiments made without special or expensive apparatus, and requiring only the familiar objects of common life for their performance. The greatest exponents of popular science—and amongst them notably Faraday—delighted in impromptu devices of this kind. It is indeed surprising how throughout the whole range of natural philosophy the hand of the master can turn to account the very simplest and rudest of apparatus. A silver spoon, a pair of spectacle lenses, a tumbler of water, and a few sheets of paper suffice to illustrate half the laws of geometrical optics. A few pieces of sealing-wax, some flannel, silk, writing paper, pins, and glass tumblers will carry the clever experimenter a long way into the phenomena of electricity. These are things which any person can procure, and which any person can be taught to use. But their right use depends on the possession of accurate scientific knowledge and a clear understanding of *what* the various experiments are to prove. In fact the art of experiment and the science of inductive reasoning are the essential qualifications necessary to make *Physics without apparatus* profitable.

The short series of papers which it is now proposed to publish in NATURE under the title of *Physics without apparatus* will deal with some of the more important and interesting of these simple matters of experiment. The subject of them has been more immediately suggested by the publication in our contemporary, *La Nature*, of a kindred series of articles by Mons. G. Tissandier, from which a number of the illustrations we present to our readers are taken. The matter of the present series is however new.

Amongst the simple mechanical laws with which a beginner in physics must acquaint himself is that commonly referred to as the *law of inertia*, which is, however,

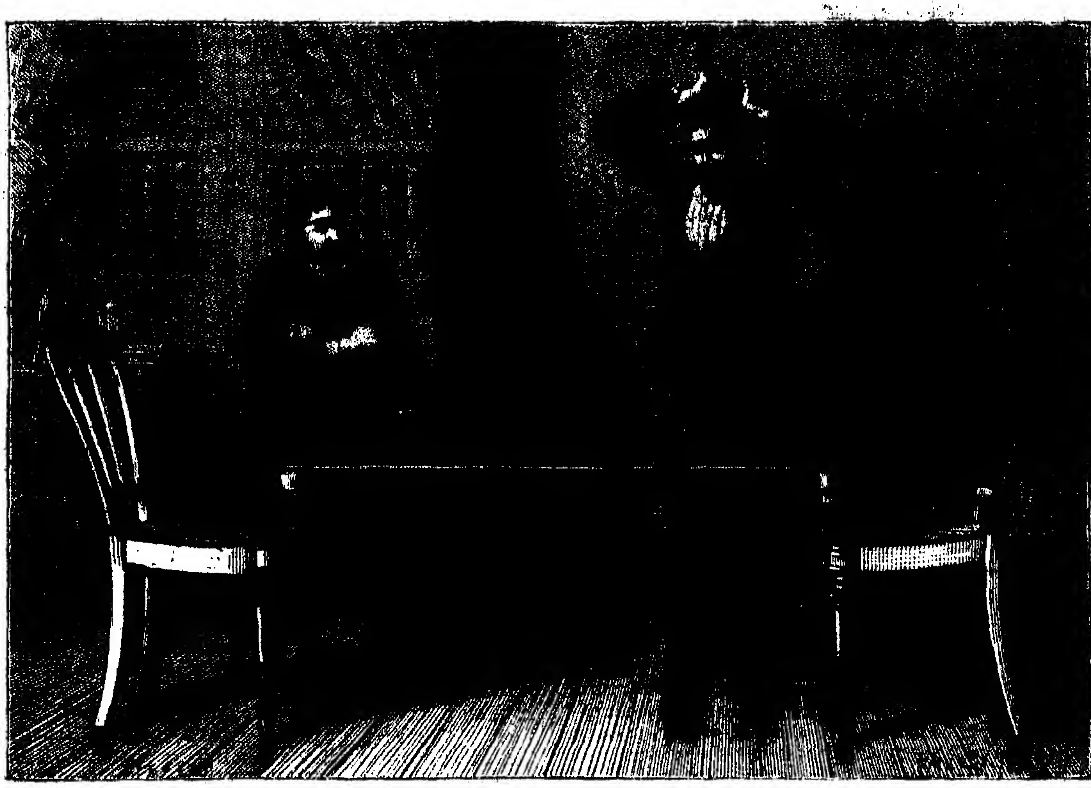

Fig. 1.

very often so imperfectly expressed as to be misapprehended. It requires force to move matter, not because matter is inherently lazy or sluggish, but because it possesses *mass*. The greater the mass of matter in a ball, the harder work is it to send it rolling. Force is also required to stop matter that is moving, the reason again being that a mass moving under the impulse of an impressed force possesses a certain moving energy which cannot be at once reduced to nothing. In either case—either to move a mass or to alter the motion of a mass—force must be employed and energy expended. Of this law of inertia many examples might be given: and there are many curious facts which this law serves to explain. Some of the most striking of these are those in which the effect of sudden forces is different from that which might have been expected. In Fig. 1 we give an illustration of an experiment of this nature. A wooden rod—say a broomstick—has a couple of needles fixed into its ends, and it is then supported upon two wine-glasses resting upon two chairs. If a heavy poker is now brought down very violently upon the middle of the stick it will break in two without the needles or the glasses being broken. A feeble or indecisive blow will fail to do this, and will break the glasses or the needles, or both. Here the moving energy of the heavy mass, the poker, is suddenly transferred to the middle of the stick, so suddenly that it is broken asunder before the thrust has *time* to reach the fragile supports.

Another simple experiment on inertia is equally instructive. Lay any ordinary visiting-card upon the knuckle, or upon the top of an inkstand or other convenient support. On the card place a brass weight, or a spool of thread, or any other small heavy object. Now flip away the card with the finger and thumb; it will fly out, leaving the heavy object where it was. In the same way if a dozen draughtmen are piled up one upon another

in a column, the lowest one can be removed without making those above it fall, by hitting it aside with a very rapid stroke with a table-knife. Here again a feeble stroke will fail.

Our second figure illustrates inertia in another way. A heavy metal ball is hung by a thread to the ceiling or to a shelf, and another thread is attached below. Tug at the lower thread, and it will break. If the tug be slow the ball will come down too; but if the tug be sharp and fierce

FIG. 2.

the thread will break off *below* the ball, breaking, in fact, before the pull has time to impart to the mass of the heavy ball a sufficient moving energy to enable it to rupture the string by which it hangs.

Many other illustrations of a similar kind might be narrated. Of these probably the most telling is that of firing a tallow candle from a gun through a deal board, in which it leaves merely a hole, as the writer can testify from several repetitions. Here, however, we are passing into the region of "apparatus," and must not pursue the matter further.

COUNT POURTALES

"IN the death of Louis François de Pourtales science has met a heavy loss. He was the Swiss representative of an old family, which had branches also in France, Prussia, and Bohemia. Trained as an engineer, he emigrated in early manhood to the United States at nearly the same time as the late Prof. Agassiz, to whom he was much attached, and whose pupil and fellow-worker he was. He entered the Government service in the department of the Coast Survey, and continued in it many years. His talents and industry made him a man of mark, to whom was intrusted much work that required original thought. Especially did he show interest in the problems of deep-sea soundings and the structure of the ocean bottom, an interest that led to profound observations on the physical geography of the Carribean Sea and the Gulf Stream. His papers on this subject were of the first order, and established his reputation in Europe as well as in America.

"By the death of his father he succeeded to the title, and received a fortune which enabled him to devote himself wholly to his favourite studies, and to do much in continuing the great work of Louis Agassiz. Appointed keeper of the Museum of Comparative Zoology, he gave himself, with untiring devotion, to carrying out the arrangement so laboriously planned by his friend and master. Dividing the task with the curator, Alexander Agassiz, he pushed forward his part of the work with the easy power of a strong and highly-trained intellect. Every day and all day at his post—now pursuing special investigations, and now directing the details of the museum—he was the model of an administrative officer.

"He had not an enemy, and could not have had one; for, although firm and persevering in temper, he possessed the gentleness of a child and a woman's kindness. His modesty amounted almost to a fault; and people wondered why a man who was master of three languages should talk so little. But with intimate friends he would speak freely, and never without giving information and amusement. His range of learning was very wide, and his command of it perfect; nor was it confined to mathematics, physics, and zoology. He did not scorn novels and light poetry, and was knowing in family anecdotes and local history. Indeed, it was a saying in the Museum that if Count Pourtales did not know a thing it was useless to ask any one else.

"His strong frame and temperate mode of life gave hope of a long period of usefulness, for he was only fifty-seven, and in the prime of his powers. But it was not to be. Stricken, without apparent cause, by an obscure internal disease, he succumbed, after some weeks of suffering heroically endured. In seven short years he has followed Louis Agassiz, and there seems no hand to take up his burden."

The above account of Count Pourtales appears in the *Boston Daily Advertiser* of April 20, and is, we believe, from the pen of Prof. Theodore Lyman. We would here, in addition, refer briefly to some of Count Pourtales' scientific work. Almost from the commencement of his connection with the United States Coast Survey he deeply interested himself in deep-sea questions, and some of the earliest observations on the nature of the deep sea bottom and of Globigerina mud were made by him. He wrote on the structure of Globigerina and Orbulina, and described the occurrence of the small Globigerina-like shells bearing spines in the interior of certain Orbulinæ, which he concluded were the swollen terminal chambers of Globigerinæ containing young in progress of development. The first step in deep-sea investigation in the United States was taken by the late Prof. H. D. Bache on his assuming the duties of the United States Coast Survey in 1844, when he ordered the preservation of specimens brought up by the lead. Every specimen was carefully preserved and labelled, and deposited in the Coast Survey Office in Washington. The microscopical examination of the specimens was commenced by the late Prof. J. W. Bailey, and after his death this work passed into the hands of Pourtales, who devoted his time to it in the intervals of other duties. That most important deposit, Globigerina mud, was first discovered by Lieutenants Craven and Maffit, U.S.N., during Gulf Stream explorations in 1853. In 1867 systematic dredging in deep and shallow water was commenced on the assumption of the superintendence of the Survey by Prof. B. Pierce, who ordered the dredging. At the suggestion of Louis Agassiz, dredgings were made down to a depth of 1,000 fathoms. In Prof. Agassiz' report one of the richest grounds for deep-sea corals, lying off Cape Florida, was named Pourtales Plateau. In 1871 Pourtales published what is probably his best-known work, namely, his "Deep-Sea Corals" ("Ill. Cat. Mus.

Comp. Zool.," Harvard, No. iv.), a most excellent memoir, containing valuable disquisitions on the affinities of various genera, and excellent notes on the geographical distribution of the species and the nature of the bottom on which the dredgings were made. The memoir contains the results of some interesting researches on the relations of the Rugose to the Henactinian corals, in connection with the account of the aberrant genus Haplophyllia. The deep-sea Antipalliaria and Actinidæ are described in it, as well as the stony corals, and the genus Pliobothrus, with great acumen, referred to its proper place amongst the Hydrozoa. A second memoir on deep-sea corals was contributed by Count Pourtales to the account of the zoological results of the *Hassler* Expedition, and many others on this and other zoological subjects are to be found in the *Bulletin* of the Harvard Museum of Comparative Zoology. The last work which appeared from his pen is the description of the plates of corals in the Report on the Florida Reefs, by the late Prof. Agassiz, which has just been published by Alexander Agassiz, by the permission of the superintendents of the U.S. Coast Survey. These plates are the most perfect and beautiful representations of corals that have as yet been published anywhere. They were drawn under the immediate direction of Prof. Agassiz.

Count Pourtales' name is indissolubly connected with deep-sea zoology by means of the genus Pourtalesia, named after him. Pourtalesia, a sea-urchin, one of the Spatangidæ allied to Ananchytes, was found by the *Challenger* expedition to be one of the most ubiquitous and characteristic deep-sea animals. Numerous species of the genus new to science were obtained by the expedition in deep water, some of them being of most extraordinary shapes. In conclusion it need only be added that Count Pourtales' kindness and good-nature were as much appreciated by English naturalists as elsewhere. He was most generous, always ready to give advice to naturalists working in the same most difficult field as himself, to supply them with specimens for investigation, and to discuss in the freest manner, with perfect impartiality, any question of systematic arrangement. He will be regretted by many friends in England, to which he paid frequent visits on his way to his native country, his last visit having been made in the spring of the present year.

H. N. MOSELEY

THE BRITISH ASSOCIATION AT SWANSEA

PREPARATIONS of the most unstinted kind are now being made at Swansea to insure to the members of the British Association a hearty, hospitable welcome, a good opportunity for the interchange of scientific results, and an instructive and healthful summer holiday during their visit in the week commencing on Wednesday, August 25 next. The Excursion Committee have already made arrangements for visiting the more interesting places in the district. The presidential address will be delivered on Wednesday, and a portion of Thursday, August 26, will be devoted to an excursion, limited to 200 members, to the celebrated iron-works and collieries at Dowlais, by special invitation of G. T. Clark, Esq., of Dowlais House. As this excursion will take place so early, members who intend joining in it should send in their names to the Local Committee as soon as possible before their arrival in Swansea. The return will be made in time for the reception *soirée*, which the Mayor of Swansea (Alderman John Jones Jenkins) will give in a fine wooden pavilion capable of accommodating 6,000 people.

Saturday, August 28, will be almost entirely devoted to excursions to the Gower Coast, Penrice Castle, Oxwich Bay, Arthur's Stone, Worm's Head, Bishopstone Valley and its underground river; Bacon Hole and other bone-caves, with the Bays; the Via Julia at Langhor, with ruins of castle, hospitium, sanctuary, and collieries and tin-works; Llandilo, Golden Grove, Carreg-Cennen, and Dynevor Castle; and by sea to Lundy Island and Ilfracombe.

Among the sciences geology this year takes the foremost place in the person of the distinguished president, Prof. Ramsay. There are few districts which comprise, within so small an area, so many geological formations as Swansea, and fewer still that offer such problems for solution and such advantages for useful study. To the west of the town an axis of old red sandstone is thrust up through lower shales and limestones, and the stratifications of the whole neighbourhood have been dislocated and curiously denuded. Along the coast of the Bristol Channel for twenty miles the grand limestone cliffs are fissured and distorted until they exhibit almost every variety of dip and strike. Here are bold projecting torrs, inhabited by sea-birds; undisturbed sandy bays, the realised dream of the bathing enthusiast; and the celebrated bone caves, explored by Buckland and Col. Wood, and described by Falconer. The list of their fossil contents is a long one, including, with the exception of the *Drepanodon* (*Machairodus*) of Kent's Hole, all the larger-sized extinct carnivorous and herbivorous mammalia found in all the caves of England put together. Of the smaller-sized genera, too, Bacon Hole and its neighbouring caverns contained representatives of every one save *Lagomys* and *Spermophilus*. In Mewslade Bay Mr. Prestwich discovered a fine example of raised beach, and beneath the sands of Swansea Bay are well-exposed beds of peat—roots, stems, branches, and leaves of the silver birch, and larger vegetation, the remains of a forest still retained in local tradition. On the other side of the bay, in these deposits, have been found antlers of splendid proportions, and British and Roman implements. The *Pholas candida* is found in the decayed wood, and the rocks at the western extremity of the bay abound with *Lithophagi*, the most numerous being *Saxicava rugosa*. The South Wales coalfield, the largest but one in Britain, is brought within easy workable range by a great east and west anticlinal and several smaller axes, and is so cut into by deep river valleys that the coal is generally worked by means of adits and galleries. As a consequence of this fortunate conformation of carboniferous strata and surface, the deepest coal-pit in the whole basin—Harris's Deep-Navigation Steam Colliery, in the Aberdare Valley—does not exceed 700 yards of vertical depth. There is still considerable difference of opinion as to the identity of certain beds which occupy the place of the millstone grit. To the north and east of the basin the grit is of the usual kind, save where the sands and gravels are compacted into a hard, whitish, quartz-like rock; but to the west of Swansea the equivalent beds change into siliceous under-clays, with coal-seams above them. At Lilliput, in Swansea Bay, there are two interesting outcropping ridges of this kind; and a little farther west still the coal-measures are found to lie conformably on the limestone, with the exception of those in the neighbourhood of Oystermouth Castle, where Sir Henry de la Beche found a section "of a kind of lenticular mass which fines off to the east and west," and "was formed under minor conditions of a different nature." At the head of the Swansea Valley there is said to be "a seam of coal occurring in the millstone grit." The Town hill sandstones, which form the highlands in the neighbourhood of the town, and the high bold escarpments of which may be traced almost all round the Basin, are equivalent to the Pennant rocks of the Bristol district. They are peculiarly interesting for the great quantity of *detrital* coal they contain. A few minutes' walk from the town to the quarries enables the geologist to see the curiosity *in situ*. Even the same coal pebble is sometimes seen to consist of coal of two distinct ages. The markings beautifully show how the newer plants were pressed down

around the coal-pebbles, which, from their greater hardness, have left their impress in the plants; but the crystallisation of the former has a uniform parallelism with the faces of its cleavage, while the cleavage of the older coal is parallel with the sides of pebbles, which occur in all positions, sometimes in the form of a rhomboid, with its edges and corners rounded by attrition. To the east of Swansea, near Southern Down and Dunraven Castle, there are remarkably fine exposures of Lower Lias full of *Gryphea incurva*, with large ammonites and belemnites. Last year an enormous slab was dug out of the Trias rocks at Shortlands, which bears five trifid impressions in a clear series. The length of each footprint is 9¼ inches, and it appears to have been made by "some solidly-built short-legged creature." A little further east the Rhætic Passage Beds are laid open for a distance of more than twenty miles to Penarth Headland, where *Cardium rhæticum* and numerous other characteristic fossils are found. Through these strata there are many railway cuttings and no less than six passenger stations, so that this district is perhaps the best in the whole country for the study of Rhætic strata in the fields. The peninsula of Gower, west of Swansea, besides offering such scientific attractions as bone-caves, underground water-courses, raised beaches, &c., is remarkable for the great beauty and variety of its scenery. Bold highlands and beetling cliffs alternate with heathery downs and commons, well wooded valleys through which trout streams flow, and rocky gorges, half hidden by luxuriant growths of fern. Tumuli, Druidic stones, Roman and Danish earthworks, and a round dozen Norman castles, dating for the most part from the days of William Rufus, lend additional charm to the district, which is peopled by the descendants of a colony of Flemings, who still retain many characteristic words, idioms, and customs, which the ethnologist may profitably study. The lonely granitic rocky island at the entrance to the Bristol Channel is associated with the geology of the Barnstaple district; but it has a history all its own, and a peculiar species of rat. Ilfracombe, on the Devonshire coast, is only two hours from Swansea Pier by a fast-going steam-boat. At Pembroke Dock, on the occasion of the visit, there will be a considerable number of notable ships and corvettes of war, and the *Great Eastern*. Minor excursions will run through the magnificent haven of Milford, and to Tenby, while arrangements are made to take fifty persons by road to St. David's City and Cathedral, with the ruined palace and colleges of the see of Menevia, in the utmost limits of Pembrokeshire.

All these excursions are fixed for Saturday, the 28th, and the Local Committee exact that all applications be sent in before 1 p.m. of the previous Thursday.

On the succeeding Thursday, September 2, the excursions, which are very numerous, will be for the most part to collieries and works. Perhaps the chief interest attaching to Swansea is its metallic industries, of which the district is a chief centre. The copper trade has flourished here for a century and a half to two centuries, but though various new processes have been tried from time to time, practically the oldest dry process, called the Welsh method, is still in use. It is affirmed that nine-tenths of the copper-smelting of the kingdom is done here. The sulphurous and arsenious fumes from these works have entirely denuded the hill-sides of verdure, but it cannot be shown that they injure human health. Among the many inventions for the consumption of this smoke, are washing it with water, collecting the sulphurous acid and converting it into sulphuric acid, and the use of deposit chambers and high chimneys. These processes may be seen at Hafod, the works of Mr. H. H. Vivian, M.P. The other excursions on the same day include various large tin works, where the whole of the processes of making the iron sheets and tinning them may be seen, and the visitors will be entertained at luncheon by the Worshipful Mayor at his Cwmbwrla Tin-plate Works; to the Landore Siemens Steel Works, where steel is made in gas regenerative furnaces by the Siemens-Martin process, and hammered and rolled and tested for rails, armour-plates, ship and boiler plates, knives, needles, wire, and all other commercial purposes, and visitors will be entertained at lunch by Dr. Siemens; to the Dyffwyn Collieries at Neath, the Navigation Colliery at Quaker's Yard, the Penrhiwceiber Colliery, Mountain Ash, &c., the most important coal winnings in the district, at each of which places visitors will be entertained. Visitors to Neath Abbey and district will take luncheon in the ruined refectory, and those to the Vale of Neath Waterfalls in the caves. At their Melyn Decorative Tin Works Messrs. Leach, Flower and Co. will show their extremely interesting processes and give a luncheon; Mr. J. T. D. Llewelyn, of Penllergare, will receive 100 visitors at his ancient and beautifully-situated residence five miles from Swansea; and Mrs. Crawshay will entertain on this day fifty visitors at Langorse Pool, Brecon. The oyster-dredging expedition in the Bay will start from Swansea Piers, and visit the Lighthouse Rock and Battery, luncheon being served on board. The neighbouring works, which may be easily reached from the town, include the manufacture of patent fuel in the old and in a perfectly new perforated form; sulphuric acid, phosphate manures, cobalt, silver, nickel, lead, spelter, sulphate of ammonia, oxalic acid, distillation of wood, alkalies, &c., &c.

Applications for tickets for these excursions on Thursday, September 2, must be made not later than the forenoon of the previous Monday.

Among the special attractions which will take place concurrently in Swansea are an agricultural show, a flower show, and especially an exhibition of local productions and processes. The exhibition of machinery will be on an extensive scale, and the greater part will be in motion. The more interesting portions of the machinery in motion and the loan exhibition of scientific instruments will be retained as an additional attraction to the second *soirée*.

The accommodation in the town and in the picturesque suburban watering-place of Oystermouth or The Mumbles is in every way ample, and the hospitality will be generous, but it would much facilitate the work of the Local Committee and add greatly to the satisfaction of visitors themselves if they would give timely and sufficient notice of their intention to be present on the occasion.

THE HIGH PLATEAUX OF UTAH[1]

UNTIL a few years ago the geography of the high grounds of the western part of North America was depicted, even on the best maps, in a manner which now appears almost like a caricature of nature. So much had been said and written about the Rocky Mountains that the popular imagination was wont to picture them as a colossal, rugged, and almost impassable range, extending continuously down the backbone of the continent, and serving generally as the watershed between the Atlantic and Pacific Oceans. The progress of research, however, dissipated this delusion by showing that, instead of one continuous chain of mountains, a vast area of country, extending from the British possessions far down into the Southern States, has been upraised into elevated plains or table-lands, and that these at various distances have been ridged up by lenticular mountain-chains, sometimes parallel, sometimes *en échelon*, and trending generally in a meridional direction. The term "Rocky Mountains" is now commonly restricted to the most easterly line of

[1] "Report on the Geology of the High Plateaux of Utah." With Atlas. By Capt. C. E. Dutton, U.S.A. Geographical and Geological Survey of the Territories. J. W. Powell in charge. (Washington, 1880.)

mountains, which serves as a divide or water-parting between the Atlantic slope and the regions lying to the west. But though the traditional glories of the Rocky Mountains have thus been dimmed, and though the most enthusiastic traveller through their still little-known solitudes must in fairness admit that they cannot boast among their innumerable ranges, hitherto visited and described, one which for variety and majesty of outline can be named with the Bernese Oberland, yet this merely nominal degradation is more than compensated by the discovery that these western territories contain a type of high ground to which there is probably no adequate parallel elsewhere on the face of the globe—a type so strange and overwhelming in its first aspect, so weird and almost incredible in its history, that the ordinary language of scenic description fails to convey the impression which the overawed beholder wishes to produce, and he finds himself obliged to borrow a new vocabulary, yet even with its aid is conscious that his narrative, exaggerated as it may seem, falls infinitely short of doing justice to the marvels he has seen.

To the portion of this region which, bounded by the Colorado Park Mountains on the east and by the ranges which border the Great Basin on the west, stretches from Southern Wyoming far into New Mexico and Arizona, the name of the Plateau Country has been given. It is drained mainly by the Colorado River and its tributaries. Its surface at lower levels than 7,000 feet above the sea is a blazing desert, bright with strange mineral colours—glaring red, livid purple, verdigris green, toned white, and ashy grey. On these plains hardly any vegetation grows. Not a solitary tree, save here and there a gnarled cedar, affords a scanty shade, and little but stunted sage-brush or prickly cactus in scattered tufts varies the eternal monotony of the burning soil. It is a region of perpetual drought, for the springs are believed not to average one in a thousand square miles. Yet the land is traversed by a network of rivers, which, however, wind along in profound chasms, to be crossed only by the birds of the air. So deep and sombre are many of these gorges (that of the Colorado being in some places more than a mile deep), that the very sound of their running waters never reaches the level of the plateau above. Only a dim daylight reaches the bottom, and the stars are said to be visible in certain narrow gorges at midday. But where the level of the plateaux rises high enough to condense some of the moisture which the air-currents carry across them the verdureless aspect of the lower plains is replaced by luxuriant forests and open glades carpeted with rich grass and wild flowers. So colossal, however, are the table-lands that some of them slope gradually out of the range of tree-growth to a height of from 11,000 to 12,000 feet above the sea, and almost lie within the limit of perpetual snow.

So far as yet known, the Plateau country reaches the fullest development of its extraordinary features in the southern portions of the Territory of Utah. This region was partially explored by Prof. Powell during his surveys from 1869 to 1874, and by the parties under Capt. Wheeler, especially by Mr. Howell and Mr. Gilbert, whose published reports form a valuable portion of the third volume of the "Geographical and Geological Explorations west of the One Hundredth Meridian," conducted by Capt. Wheeler. In 1875 Mr. Powell secured the services of Capt. Dutton for the investigation of a large volcanic tract among the Utah Plateaux as part of the survey under his direction. Capt. Dutton spent the seasons of 1875, 1876, and 1877 at the task assigned to him. We have now the result of this labour in the handsome quarto volume and beautiful atlas which have just appeared. This publication is undoubtedly one of the very best of the many admirable contributions to geology which have recently been made by the official surveys of the United States. With the aid of the letterpress, maps, and sections any geological reader can follow and realise to himself the almost incredible magnificence, as well as simplicity, of the structure of these high Plateaux.

The geology of the area may be briefly described as presenting a succession of nearly horizontal sedimentary formations from the upper Carboniferous up to the Eocene lacustrine deposits of the West, thrown into a succession of broad folds, cut into segments by a series of important faults, and overlaid towards the north by vast sheets of volcanic ejections, the whole of the rocks, aqueous and igneous, having been carved into valleys, gorges, escarpments, outliers, and isolated plateaux of the most imposing magnitude.

From the Carboniferous up to the top of the Cretaceous series there does not appear to be any general physical break in the continuity of the stratification. The Carboniferous rocks are only partially exposed, but their overlying beds—the singular deep purple, chocolate, slate, and brownish-red Shinarump group—attain a greater development, exhibiting their peculiar regularity of sedimentation and their sculptured terraces and outliers. These characteristic strata have been classed as Permian or Lower Triassic, but the researches of last year have, we believe, brought to light fossils which point unmistakably to their Permian age. An occasional want of conformability is observed between them and the overlying Trias, but as a rule the latter follow without discordance, and rise into the succession of bright red and orange sandstones and shales which constitute the great cliff-forming series throughout the Plateau country. A geologist accustomed to the scenery of the "New Red" plains of Central England may find it hard to believe that the Trias of Western America forms ranges of vermilion-coloured cliffs 1,000 or 1,500 feet high, projecting in vast promontories, retiring into deep bays, and stretching with the same brightness of colour and the same regularity of front for hundreds of miles. No very satisfactory line has yet been drawn between the Trias and the Jura. The latter series consists in the Plateau country of two members, the lower being a massive grey or white sandstone of great thickness, the upper a series of calcareous and gypsiferous shales from 200 to 400 feet thick. This sandstone, according to Capt. Dutton, was laid down over an area which cannot fall much short of 35,000 square miles, with an average thickness of more than 1,000 feet. Yet so persistent were the conditions of its deposit that from bottom to top, sometimes through a depth of nearly 2,000 feet, it everywhere consists of intricately false-bedded sandstone without layers or partings of shaly or other heterogeneous matter. From the Upper Jurassic calcareous beds distinctive fossils have been obtained.

The Cretaceous system presents here the usual massive development of sandstones and shales which form so prominent a feature in the geology of the West. The Lower Cretaceous Dakotah group is recognised by its lithological resemblance to the corresponding beds in Colorado and elsewhere, and by the occurrence of species of *Ostrea*, *Gryphæa*, *Exogyra*, *Plicatula*, &c. The overlying shales are identified with the Laramie group, which the author places as Upper Cretaceous. The whole of the Cretaceous series is more or less lignitiferous; a considerable number of workable coal-seams in it being already known. At the close of the deposition of the Laramie group the first important break in the succession of the rocks occurs. Extensive disturbance took place along the old Mesozoic shore-line which now bounds the Great Basin on the east, and this was accompanied and followed by such enormous denudation that the Cretaceous series, several thousand feet in thickness, was entirely removed and the oldest Tertiary strata accumulated on the exposed surface of Jurassic beds. Yet so local were these movements that in adjacent tracts the whole Cretaceous series of the region is present, and

appears to be followed without interruption by a conformable suite of Eocene strata.

The geographical changes that closed the Cretaceous period in the West were among the most important in the evolution of the American continent. Over many thousand square miles the floor of the sea was raised into land which has never since been again submerged. The lacustrine conditions which began in Cretaceous times now received a far greater development. The waters of the ocean, inclosed into inland seas, from brackish became fresh, and one or more lakes, of perhaps even greater dimensions than those of Eastern America, stretched between the heights of the Great Basin and the Rocky Mountains for as yet an unknown distance to the south. The history of these lakes has been studied by Hayden, King, Powell, and other geologists, and their marvellously rich ichthyic, reptilian, and mammalian fauna has been described by Leidy, Marsh, and Cope. Much remains to be done before the history can be regarded as even approximately filled in. In the meanwhile it is certain that this lacustrine area was undergoing slow subsidence during Eocene time, that sediment was being continually washed into it from adjoining mountains, that eventually 5,000 feet or more of strata were laid down over its site, and that the area of fresh water progressively diminished.

A new chapter in this eventful history is revealed by Capt. Dutton. He tells how in Southern Utah the lake, even as far back as the time of the Middle Eocene, was the theatre of volcanic discharges, and how these, after vast intervals of quiescence and almost incredible denudation, have been from time to time renewed down even to a period so recent that it can hardly be believed to date so far back as the days of Cortez and the Spanish Conquest. He shows that this volcanic district discloses a remarkable variety of phenomena, nearly every form of eruption being exhibited, and every great group of volcanic rocks being represented in it. The earliest volcanic rocks are tuffs, which he regards as probably derived in chief measure from the degradation of older lavas and the deposit of the resulting sediment on the floor of the lake. The next phase of volcanic activity was marked by the outpouring of masses of propylite and hornblende-andesite, and was succeeded by the third and grandest of all, when floods of trachytes and rhyolites, alternating with augitic andesites and dolerites, rolled far and wide over the plateaux. The author is doubtful whether these extravasations proceeded from Ætna-like summits or craters, and is rather inclined to look upon the larger deluges as having issued from local fissures. Certainly if any true lofty volcanic cones existed, all external trace of them has been completely effaced by denudation. The closing event in this long volcanic period, if indeed the record can be properly regarded as even yet closed, consisted in the emission of abundant streams of lava round the larger areas of previous activity. Capt. Dutton notices some remarkable examples of a feature which occurs on a much smaller scale in the volcanic region of the Rhine and Moselle. The basalt cones and craters whence the streams have emanated seldom appear at the base of the great cliffs or at the bottoms of the deep cañons. They are often crowded together near the crests of the terrace walls, or the lava has broken out from the face of a wall. They commonly lie near lines of fault, yet appear almost always on the uplifted instead of the depressed side of the dislocation. "The least common place for a basaltic crater is at the base of a cliff." Among the volcanic masses special attention is given to the enormous accumulations of conglomerate and tuff, which cover nearly 2,000 square miles of area, and range from a few hundred feet to nearly 2,500 feet in thickness. These vast piles of coarse detritus the author attributes to the atmospheric disintegration of previously erupted lavas, and he describes in detail the process by which similar conglomerates are at the present moment being formed by frost, rain, and mountain-torrents. The highly important observation was made by him among the older tuffs, that in some places they have been so metamorphosed that the product of alteration is a rock possessing all the ordinary characters of a lava.

The chronological sequence of volcanic rocks among the Plateaux of Utah has been recognised as obeying generally the order enunciated by Richthofen. Capt. Dutton, starting from this observed sequence, devotes two long chapters to theoretical discussion—one on the classification, the other on the origin of volcanic rocks. To his work in the field he has added careful labour indoors, especially studying the microscopical and chemical characters of volcanic rocks. No one can read his pages without recognising their suggestiveness, even though the conclusions reached in them may sometimes appear doubtfully valid. His remarks upon the texture of volcanic rocks (pp. 91–99) offer an excellent sample of his critical treatment. Pointing out how different may be the texture assumed by the same original magma according to whether the mass has cooled and consolidated at the surface or beneath it, he is disposed to regard the intrusive condition as a kind of intermediate stage between volcanic rocks which have issued above ground and non-eruptive masses which have remained inactive deep beneath it, and he regards the porphyritic texture as especially characteristic of this "qualified eruption." This generalisation is only partially supported by the volcanic history of Britain. Among our older Palæozoic rocks, indeed, the intrusive or injected masses very generally possess the porphyritic structure. But from the time of the Lower Old Red Sandstone onwards to the Miocene volcanic period inclusive, the intrusive sheets are for the most part non-porphyritic, while the porphyritic structure is found among the superficial lavas. The classification our author proposes is as follows :—

ACID SERIES—Group I. RHYOLITES.

Sub-group 1. Nevadite or granitoid rhyolite.
2. Liparite or porphyritic rhyolite.
3. Rhyolite proper, or hyaline rhyolite.

SUB-ACID SERIES—Group II. TRACHYTES.

Sub-group A. Sanidine Trachytes.
1. Granitoid Trachyte.
2. Porphyritic Trachyte.
3. Argilloid Trachyte.
4. Hyaline Trachyte.

Sub-group B. Hornblendic Trachytes.
5. Hornblendic Trachyte.
6. Augitic Trachyte.
7. Phonolite.
8. Trachytic Obsidian.

SUB-BASIC SERIES—PROPYLITE AND ANDESITE.

Sub-group 1. Hornblendic Propylite.
2. Augitic Propylite (?).
3. Quartz-Propylite.
4. Hornblendic Andesite.
5. Augitic Andesite.
6. Dacite or Quartz-andesite.

BASIC SERIES—BASALTS.

Sub-group 1. Dolerite.
2. Nepheline-dolerite.
3. Basalt.
4. Leucite-basalt.
5. Nepheline-basalt.
6. Tachylite.

The fifth chapter is entitled "Speculations concerning the Causes of Volcanic Action." The author propounds a very ingenious trial hypothesis, by which he believes the sequence of volcanic phenomena throughout at least the Rocky Mountain region may be explained. He assumes that volcanic phenomena are brought about by a

local increase of temperature within certain subterranean horizons. But, as he himself admits, this way of putting the case brings us no nearer to what may be the ultimate cause of such a local increase of temperature. He seeks to prove that all the phenomena of volcanic action point to local excitation, and that the observed order of appearance of lavas is what on this view might theoretically be anticipated. It would be beyond the necessary limits of this article to follow him into the details of his argument. But one or two points may be briefly referred to. He regards lavas as mainly derived not from primeval subterranean magmas, but rather from the fusion of such rocks as the crystalline schists and sedimentary formations. In the mechanics of eruptions he believes that the outpouring of lava does not arise from the expansion of vapours absorbed within the molten magma, but is merely a hydrostatic problem of the simplest order—the lava being forced out by the weight of the rocks overlying its subterranean reservoirs.

According to this hypothesis two preliminary conditions are requisite for an eruption of lava—the rocks must be fused, and their density in the molten state must be less than that of the overlying rocks. The author regards the observed order of appearance of the lavas to be determined by their relative density and fusibility, the more siliceous requiring a higher temperature to fuse them, and the more basic, though less refractory, demanding a higher temperature to give them such a diminution of density as will permit them to be erupted. At an early stage of eruption he holds that the acid rocks may be light enough to be ejected, but are not yet melted, while the basic rocks may be melted but must await further expansion by access of heat before they are capable of being poured forth. Hence some intermediate rock will be selected as the first to issue, and this rock the author believes to be propylite. A further increase of temperature produces hornblendic andesite and trachyte, and so on to the rhyolites, and finally the basalts. All rocks more basic than propylite are stated to present evidence of superfusion, these rocks, according to the theory, being those which possess so high a density as to demand a much greater accession of heat than that required for mere fusion, in order that they may become lighter than the overlying crust, and thus be erupted. Basalt in particular is cited as an example of a superfused rock.

The author tacitly assumes that the density of a lava at the time of its outflow is necessarily less than that of the rocks through which it ascends, otherwise it could not be erupted. It is a pity that no experimental demonstration of this assertion was given, for it forms so fundamental a postulate in the hypothesis. But even on the supposition that the lava is forced out by the descent of heavier overlying rock, what ought to be found as proof of this action? Ought we not to meet with abundant evidence of subsidence at volcanic foci? Every mass of lava derived from the local fusion of rocks at no great depth beneath the surface and driven out by the weight of rock overlying it, should have an accompanying and proportionate subsidence of the crust over the site of its source. Occasional proofs of collapse at volcanoes have long been known indeed, but admit of other explanation, such as "evisceration," to use Mr. Mallet's phrase. Instead of subsidence, the emission of volcanic material has generally been accompanied with upheaval. Capt. Dutton's own magnificent Plateaux of Utah should furnish copious proofs of a sinking or sagging of the nearly horizontal strata round the eruptive vents. But there is no trace of any structure of this kind in his instructive and carefully-drawn sections.

Again, the alleged superfusion of the basic rocks can hardly be admitted upon the evidence here brought forward in its support. The fact that thin streams of basalt have had a greater liquidity and have retained it for much greater distances than the acid lavas, has long been recognised. But as Reyer has recently suggested, it is capable of a different interpretation from that of superfusion. The author appeals also to the microscopic structure of basalt as favouring his view of former intense ignition. He cites, for example, the presence of glass particles, the absence of water-cavities, the isotropic base, the compactness and vitreous structure of this rock. But are not these characters present in far more striking development among the vitreous acid rocks, which he supposes to have had a temperature little more than sufficient for fusion? The exceptions which the author candidly admits to occur in the normal succession of lavas—basalts, for example, appearing before rhyolites, or quartz propylite and quartz-andesite simultaneously with the hornblendic members of their respective groups—seem fatal to the hypothesis.

From another point of view the idea that the order of emission of lavas has been determined in the way supposed presents great difficulties. The author affirms that "we must at least admit that the source of lavas is among segregated masses of heterogenous materials," and he supposes that "this arrangement would be well satisfied by a succession of metamorphic strata [gneiss, hornblendic and augitic schist] resting upon a supposed primitive crust or magma having a constitution approximating that of the basaltic group of rocks." But every known mass of metamorphic strata presents endless interstratifications of very various materials. By what process of selection are the elements of these diverse rocks grouped successively into definite volcanic compounds? How is it that out of the simmering subterranean broth just so much silica and alumina as are needed for one type are ladled out at one time, while a careful hand is kept on the lime, alkalies and iron-oxides, only the right proportions being dealt forth for each lava?

The remarkable persistence of type among the different species of lava all over the world has long been recognised. It is not easy to see how this persistence should exist, nor why there should not be far more varieties of lava and transitional grades between the varieties if they are due to the local melting up of various masses of heterogeneous materials within the crust.

The volume is illustrated by a series of heliotype plates, from photographs taken in the course of the survey, representing some of the more remarkable external forms assumed by the sedimentary and volcanic rocks. The Atlas contains a valuable series of topographical and geological maps. Among these a relief-map of the Plateaux, on the scale of five miles to an inch, is specially instructive. There are likewise two plates of sections, which bring before the eye in a clear and concise form the structural details of the region. In point of execution the plates of the atlas are altogether admirable. In his preface Capt. Dutton states that he undertook the task of exploration assigned to him with considerable diffidence in his ability to accomplish it. He must be congratulated on having achieved a signal success. His work bears everywhere marks of the most conscientious and painstaking industry, great acuteness of observation, and not a little literary skill in the marshalling and presentation of the facts observed. Let us hope that the arrangement by which he was enabled to exchange the routine duties of an army officer for geological field-work may be prolonged, and that in further prosecution of his explorations in the West he may live to issue other volumes as interesting and valuable as that which is noticed here. ARCH. GEIKIE

TWO NEW PLANETARY NEBULÆ

A PLANETARY nebula in R.A. 18h. 25·2m. and Dec. − 25° 13′ was discovered at the Harvard College Observatory on the evening of July 13. A second

nebula was found on the following evening in R.A. 18h. 4'3m. and Dec. $-28^{\circ} 12'$. Both, but particularly the first, are only minute, and can be with difficulty distinguished from stars, except by their spectra. The discovery was not the result of accident but of a search with a direct vision prism inserted between the objective and eyepiece of the 15-inch telescope. A star appears as a coloured line of light, while a planetary nebula forms a bright point, and is recognised instantly in sweeping. Many hundred or thousand stars can thus be examined very rapidly, and a single nebula picked out from among them. This method promises to add very greatly to the list of known planetary nebulæ, which now number about fifty. Probably a systematic search for these objects crossing a considerable part of the heavens will be made at this Observatory. Our knowledge of that distribution will thus be greatly increased, and we shall know that their absence in certain parts of the sky is not due to an omission to look for them. Any planetary nebula as bright as a twelfth-magnitude star would probably be detected by the method proposed. Bright lines or other peculiarities in the stellar spectra will also be looked for.

Doubt has been thrown on many of the attempts to measure the parallax of planetary nebulæ owing to the haziness of the borders of these bodies. The minuteness of the disks of the nebulæ noted above could permit their positions to be determined with great precision, and would thus show a very minute parallax.

Cambridge, U.S., July 15 EDWARD C. PICKERING

NOTES

AN influential committee has been formed from among the members in the Section of Zoology of the Paris Academy of Sciences and others eminent in that department, to obtain subscriptions for a medal in honour of M. Milne-Edwards, the *doyen* of French zoologists.

A MOVEMENT has been set on foot to obtain subscriptions to a memorial fund in honour of the late Rev. J. Clifton Ward, whose name must be well known to our readers as a working geologist who made valuable contributions to his science. Mr. Ward, moreover, did great service in promoting a love of science in Cumberland, and the Association for the Advancement of Literature and Science, for which he did so much, has taken the fund heartily up. It ought to receive many subscriptions outside of the Association, and we commend it to the liberality of our readers. Subscriptions should be sent to the Rev. Canon Battersby, St. John's Parsonage, Keswick, and to Mr. Edwin Jackson, hon. treasurer, Keswick Library and Scientific Society. It is proposed to expend the fund in the erection of a mural tablet in the church of St. John, Keswick, and the remainder in laying the foundation of a fund for the education of Mr. Ward's two daughters.

IN answer to a question in the House of Commons as to the cause of the delay in the removal of the Natural History Collection from the British Museum to South Kensington, and when that removal would be completed, Mr. Walpole said he believed the delay had been caused by the facts that the building in which the collection was to be placed was not handed over to the Trustees of the British Museum until June, and that the grant made by the Treasury was not sufficiently large to cover the whole estimated expense for the cost of the removal. He believed the removal of the mineralogical, geological, and botanical collection would be completed by the end of the year or in the spring of next year; and that as far as the zoological collection was concerned, its removal would depend very materially upon the grant which the Treasury might feel itself at liberty to make for the purpose.

PROF. ED. VAN BENEDEN is at present at Bergen for the purpose of working out the embryonic development of the Lemming, which is likely to prove extremely interesting, because that of the guinea-pig is so abnormal.

A FEW months after Leverrier's death a commission was established for determining the best means of protecting collieries from fire-damp. The Commission has written a very long report recording the causes of 420 accidents. Sixty-four projects presented by private individuals have been examined, and some new instruments have been designed and are being constructed, viz., an anemometer by Vicaire, a manometer by Le Chatellier, and a registering apparatus for the quantity of air introduced into the galleries. But the composition of coal explosive dust has not been determined, nor the extent of its influence on catastrophes; the chemical analysis of Grisau has not been completed, and the salvage question has not been exhausted. The only substantial benefit is a compilation of mining regulations and a series of propositions which have been transmitted to the French Ministry, and will be laid before Parliament next session.

THE detailed programme of the annual meeting of the Iron and Steel Institute, to be held at Düsseldorf on August 25, 26, 27, and 28, is now published. The proceedings commence with a concert at the Tonhalle on Tuesday evening, August 24. On Wednesday there is to be in the morning a general meeting of members at the Tonhalle, where the institute will be received by the local authorities; in the afternoon a visit to the exhibition and to works near Düsseldorf; and in the evening the annual dinner of the institute at the Tonhalle. On Thursday and Friday there are to be general meetings in the morning for the reading and discussion of papers; the afternoons are to be devoted to excursions by special trains to various iron and steel works in the neighbourhood of Düsseldorf, followed by concerts in the evenings. The whole will be brought to a close by a Rhine excursion on Saturday, which is timed to bring members by 10.30 p.m. to Cologne, *viâ* Rolandseck, Bingen, and Coblentz. The general secretary is Mr. J. S. Jeans, whose address up till August 19 is 7, Westminster Chambers, Victoria Street; and after that date, Tonhalle, Düsseldorf.

THE Aldini gold medal (worth 1,000 lire) will be awarded by the Academy of Sciences of the Institute of Bologna to the best memoir on galvanism (animal electricity). Memoirs to be written in Italian, Latin, or French, and sent in before June 30, 1882.

THE Beneke prizes (first, 1,700 marks; second, 60 marks) of the Philosophical Faculty of Göttingen University are offered for investigation, theoretical and experimental, of diffraction phenomena in the case of non-homocentric light sources, as, especially, a circular and a square luminous surface of uniform brightness of the emitted simple or compound white light. Memoirs to be written in German, Latin, French, or English, and sent in before March 11, 1883.

A NEW process for obtaining stereotypes for printing has been discovered by M. Emile Jeannin, a sculptor of Paris, who proposes to employ for that purpose the material known as *celluloid*. The process of preparation takes only half an hour, when the types are once set up, and the plates thus produced are remarkably suitable for working on cylinder machines running at a high speed, being very light, flexible, and very durable. In this last respect indeed they surpass metal plates, affording, it is said, 50,000 impressions, whereas even an electrotyped copper plate backed with lead will only last for 30,000.

THE astronomical observatory established on the Trocadéro, is not the only scientific establishment which has found a home in the palace of the last Universal Exhibition. A number of microscopes have been arranged in a special room for the benefit of public instruction. The instruments lent by M. Joubert have been placed on the top of one of the towers, where a lift

has been arranged for helping visitors to find their way to this exalted situation.

A VERY curious telephonic experiment has been made in Switzerland on the occasion of the Federal *fête* of singers. A telephone had been placed in the Zürich Festhalle and two conductors connected with the Bâle telegraphic office, where a large audience had congregated. The distance from Bâle to Zürich is about 80 kilometres. The Bâle audience enjoyed the singing about as well as if they had been placed in the upper circle of an ordinary Opera House. At the end of the performance they proved their satisfaction by clapping hands, which the telegraphic wires transmitted with perfect fidelity to the Zürich performers.

A CREDIT of 25,000 francs has been voted by the French Parliament for establishing, on solid foundations, one signal at each extremity of the Melun base line, which was used by Delambre for measuring the distance from Dunkerque to Perpignan, and establishing the length of the metre. This operation was begun by Delambre and Laplace on 17 Vendémaire, An VI. (October 1797) and terminated in six weeks. This base has a length of 6,000 toises, and was situated on the margin of a public road going from Lieusaint to the crossing of the Brie and Paris roads.

A STRONG shock of earthquake was felt at Smyrna at 5.10 a.m. on July 29. The walls of the telegraph office were split in two or three places. Four or five houses were thrown down, and many others were much damaged by the oscillation. Two of the inhabitants were killed, and five or six injured. Much damage has also been done in the country near Smyrna. At Burnabat the shock caused eleven houses and several cafés to fall in. Two minarets were also thrown down and two people were killed, and ten more or less injured. Slight shocks continued to be felt from time to time.

THE new edition of the "Guide to the Gardens of the Zoological Society" brings the notices of the tenants of the Gardens up to the latest date. Mr. Sclater's name as editor of the Guide is a sufficient guarantee for its accuracy, while the numerous illustrations render it both attractive and instructive. By means of this very cheap Guide a visit to the Gardens will be rendered doubly enjoyable and profitable.

THE *Gardeners' Chronicle*, in advocating the establishment of school gardens where practicable, as an instrument of useful scientific education, refers to the success of such gardens in Bavaria, Belgium, Sweden, and other countries. In Sweden alone there are nearly 2,000 school gardens.

WE have received a copy of the *American Antiquarian*, No. 3, vol. ii., published at Chicago by Jameson and Morse, and edited by the Rev. S. D. Peet. It seems to us to be doing useful work in collecting information on early America, though several other serial publications in the States are doing the same thing to a greater or less extent. Excessive subdivision of labour of this kind in any special department is apt to embarrass the student.

THE subject of a depraved taste in animals is an interesting one, which has not been studied as much perhaps as it might. In human beings it would seem to depend on ill-health of either body or mind, but in animals it would seem as if it might be present and the animal enjoy good health. One remarkable instance in an herbivorous animal we can vouch for. It occurred in a sheep that had been shipped on board one of the P. and O. steamers to help to supply the kitchen on board, but while fattening it developed an inordinate taste for tobacco, which it would eat in any quantity that was given to it. It did not much care for cigars, and altogether objected to burnt ends; but it would greedily devour the half-chewed quid of a sailor or a handful of roll tobacco. While chewing there was apparently no undue flow of saliva, and its taste was so peculiar that most of the passengers on board amused themselves by feeding it, to see for themselves if it were really so. As a consequence, though in fair condition, the cook was afraid to kill the sheep, believing that the mutton would have a flavour of tobacco. Another very remarkable case has just been communicated to us by Mr. Francis Goodlake: this time a flesh-eating animal in the shape of a kitten, about five months old, who shows a passionate fondness for salads. It eats no end of sliced cucumber dressed with vinegar, even when hot with cayenne pepper. After a little fencing it has eaten a piece of boiled beef with mustard. Its mother was at least once seen to eat a slice of cucumber which had salt, pepper, and vinegar on it. The kitten is apparently in good health, and its extraordinary taste is not easily accounted for. Even supposing it once got a feed of salmon mayonaise, why should it now select to prefer the dressing to the fish?

THE *American Journal of Microscopy and Popular Science* (vol. iv., 1879, of which is before us) is now published monthly. Besides various original articles, some of which are illustrated, it contains from time to time abstracts of the transactions of many of the microscopical societies of the United States. This journal, without aiming at a standard to be compared with the European journals relating to microscopical science, seems to perform its part well, and we are glad to know that it has done much to encourage the use of the microscope in the States. We may trust soon to see some results from all this work, and to find the chief articles in the *American Journal of Microscopy* the result of original researches among the minute algæ, fungi, rhizopods and infusoria of America, and that the extracts from the various European journals may be relegated to a second place. There is without doubt an abundant field for work of this nature in America—witness Leidy's volume on rhizopods—nor do we understand why the labourers should be so few.

THE *Ceylon Observer* has published letters from Mr. Morris, who was recently transferred to the Botanical Gardens, Jamaica, detailing his recent experiences with regard to the cultivation of cinchona, and his views on the coffee-leaf disease in Ceylon. He still maintains the usefulness of dusting with lime and sulphur.

FURTHER rich discoveries of gold are reported to have been made in Northern Queensland and Tasmania. It is also stated that gold has been discovered under the basalt in the Brook Mountains, in New South Wales, the first instance of the kind in the colony.

IN a memoir published by the *Revue Scientifique*, M. Ernest Maindron, archivist of the Academy of Sciences, shows that the Academy is possessed of an income of 116,000 francs, to be awarded in about thirty prizes, of which the periodicity varies from one year to ten.

FROM the Fifth Annual Report of the Hertfordshire (formerly the Watford) Natural History Society, we are glad to learn that that society is now prosperous, its membership having greatly increased during the past year.

THE *Proceedings* of the Nottingham Literary and Philosophical Society for 1879-80 is mainly occupied with the president's (Rev. R. A. Armstrong) address on "What is Science?" papers on "Sandstones," by Mr. J. H. Jennings; "Philosophy in the Middle Ages," by Mr. G. B. Kidd; and "Structure of Molecules," by Mr. J. J. Harris Teall. A large number of lectures on scientific subjects were given during the session, and several special papers read in the Natural History Section.

THE *Transactions* of the Norfolk and Norwich Naturalists Society for 1879-80 contains a favourable report of the present

condition of the Society. The address of the president, Mr. T. Southwell, is on the Extinction of Native Races. Among other papers of interest are: "Notes on Collecting Lepidoptera in Norfolk, 1878," by Mr. F. D. Wheeler; "Discovery of Remains of *Emys lutaria* in the Mundesley River-bed," by Mr. H. B. Woodward; The Bird-Life and the Geology of the Shiant Isles, by Mr. Harvie-Brown and Prof. Heddle respectively; Notes on Hawking in Norfolk, by Prof. Newton and Mr. J. E. Harting; Ornithological Notes and Meteorological Observations.

THE *Proceedings* of the Liverpool Naturalists Field Club for 1879-80 contains notes of the excursions and meetings of the Society. The only papers given are by the president, the Rev. H. H. Higgins, one being "Biographical Sketches in Zoology, from its Origin to its Union with Botany in the Science of Biology."

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. J. Anson; a Side-Striped Jackal (*Canis lateralis*) from East Africa, presented by Commander Owen, R.M.S. *Anglian*; a Common Ocelot (*Felis pardalis*) from Mexico, presented by Mr. A. L. Schütte; two Common Peafowls (*Pavo cristata*) from India, presented by Mrs. Joseph Hoare; four Globose Curassows (*Crax globicera*), a Little Guan (*Ortalida motmot*) from British Honduras, presented by Mr. F. P. Barlee, C.M.G.; ten Amaduvade Finches (*Estrelda amandava*) from India, presented by Mr. J. W. Wilson; a Mississippi Alligator (*Alligator mississippiensis*) from North America, presented by Mr. T. L. M. Rose; two Horrid Rattlesnakes (*Crotalus horridus*) from Nicaragua, presented by Messrs. Holt, Lord, and Co.; an Anaconda (*Eunectes murinus*) from South America, presented by Mr. G. H. Hawtayne; a Bonnet Monkey (*Macacus radiatus*) from India, an Arctic Fox (*Canis lagopus*) from the Arctic regions; a Nilotic Crocodile (*Crocodilus vulgaris*) from Africa, deposited; a Nylghaie (*Boselaphus pictus*) from India, a Collared Peccary (*Dicotyles tajaçu*) from South America, two Common Otters (*Lutra vulgaris, jv.*), British; a Ground Hornbill (*Bucorvus abyssinicus*), an Elate Hornbill (*Buceros elatus*) from West Africa, a Virginian Eagle Owl (*Bubo virginianus*) from North America, a White-necked Crow (*Corvus scapulatus*) from Africa, purchased; a Collared Fruit Bat (*Cynonycteris collaris*), born in the Gardens.

ON CURRENTS PRODUCED BY FRICTION BETWEEN CONDUCTING SUBSTANCES, AND ON A NEW FORM OF TELEPHONE RECEIVER[1]

IN a communication to the Royal Society of Edinburgh of date January 6, 1879, I showed that "electric currents were produced by the mere friction between conducting substances." The existence of these currents can be easily demonstrated either by a telephone or a Thomson's galvanometer. I have since found that these currents are, for all pairs of metals which I have yet tried, in the same direction as the thermo-electric current got by heating the junction of the same two metals. They are also, approximately at least, stronger in proportion as the metals rubbed are far apart on the thermo-electric scale—the strongest current, as far as I have yet observed, being got by rubbing antimony and bismuth together. These observations clearly point to a thermo-electric origin for the currents; but it is possible that they may be due partly to the currents suggested by Sir William Thomson as the cause of friction, and partly, also, to contact force between films of air or oxide adhering to the surfaces of the metals.

Having ascertained that these friction-currents are of some strength and fairly constant, I proceeded to make several kinds of machine for producing currents on this principle. One of them consists of a cylinder of antimony, which can be rotated rapidly, while a plate of bismuth is pressed hard against it by a stiff spring. When this machine is included in the same circuit with a microphone and a Bell telephone, the current got from it is quite sufficient to serve for the transmission of musical sounds and also loud speaking. The transmitter, which I have found most serviceable in my experiments, is made by screwing two small cubes of gas-carbon to a violin, and placing between them a long stick of carbon pointed at both ends, the points being made to rest in conical holes in the carbon cubes. The looseness of the contact is regulated by a paper spring. This forms an excellent and handy trasmitter for all kinds of musical sounds, and also serves very well for transmitting speech.

Seeing that friction between metals clearly produces a current, it seemed natural to inquire if the converse held good, that is, if a current from a battery sent across the junction of two metals affected the friction of the one upon the other. I have tested for this in a variety of ways, and the results obtained leave me in doubt whether to attribute them to variations in the friction, or to actual sticking produced by fusion of the points of contact through which the current passes. The most noticeable effect is produced when one of the rubbing bodies is a mere point, and the other a smooth surface of metal. This led me to make a modification of the loud-speaking telephone of Mr. Edison, in order to get audible indications of changes of friction produced by the passing of a variable current. It consists of a cylinder of bismuth accurately turned and revolving on centres. The rubbing-point is made of a sewing-needle with its point bent at right angles, and its other end attached to the centre of the mica disk of a phonograph mouthpiece. It is evident that this is only a loose contact, which can be perpetually changed. When this apparatus is included in the circuit with the violin-microphone and three or four Bunsen cells, the violin sounds, as was to be expected, are heard proceeding from the loose-contact, even when the cylinder is not rotated. They are increased, however, in a remarkable degree by rotating the cylinder slowly, so much so that a tune played on the violin can, with proper care, be distinctly heard all over an ordinary room.

With regard to the explanation of this effect, it is evident, that electrolysis can in no sense come into play, as is supposed to be the case in Edison's instrument. I am inclined to look for the explanation rather in the direction of the Trevelyan rocker, although the circumstances are considerably different in the two cases. In the rocker we have the heat passing from a mass of hot metal through two points of support to a cold block, whereas, in the other case, the heat is only intense at the points of contact, the rest of the metals being comparatively unaffected. The variations in the current produced by the transmitting microphone must cause corresponding variations in the heat at the point of contact of the needle with the cylinder, and this again produces a mechanical movement of the pressing point, as well as of the air surrounding it, sufficient to give forth sound-waves. If such be the case the effect should be different for different metals, those answering best which have the lowest thermal conductivity and also the lowest specific heat. That this is really so is shown by substituting cylinders of other metals for the bismuth, all other things remaining the same. In this way I have compared lead, tin, iron, copper, carbon, and find that they all give forth the simple loose contact-sound when the cylinder is stationary, but that it is only with bismuth that there is any very great intensification of the sound when the cylinder is rotated. Now, by consulting the appropriate tables I find that bismuth is a fraction lower than any other common metal in specific heat, while it is much below them all in thermal conductivity. This seems to bear out my explanation to a certain extent.

[1] Abstract of a paper read before the Royal Society of Edinburgh by James Blyth, M.A., F.R.S.E., on May 3, 1880.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The subject for the Sedgwick Prize essay, 1883, is "The Classification of the Cambrian and Silurian Rocks." The prize is open to all graduates of the University of Cambridge who have resided sixty days during the twelve months preceding October 1, 1882. The essays must be sent in to the Registrary on or before October 1, 1882.

SCIENTIFIC SERIALS

Proceedings of the Academy of Natural Sciences of Philadelphia. Part 1, January to April.—Thomas Meehan, on disarticulating branches in Ampelopsis (the annual growth is dis-

articulated at just one node above that one made the previous year, the branch thus gaining but one node in the year. This reminds one of the South Pacific Vitis, which produces tubers on the end of the branches, and at the end of each season disarticulates them).—On germination in acorns (in *Quercus virens*. Mr. Mazyck has noticed that the two petioles instead of being short were produced to a length of $1\frac{1}{2}$ inches before the plumule and hypocotyledonary portions of the young plant commenced their growth, and a small tuberous projection nearly one-fourth the size of the acorn preceded the growth downwards of the radicle and upwards of the plumule. The cells in all of these were gorged with starch).—Dr. Leidy, notice of *Filaria immitis* in the dog, and on a Filaria reported to have come from a man. —W. N. Lockington, on the Pacific species of *Caulolatilus*.—Heilprin, Angelo, on the stratigraphical evidence afforded by the tertiary fossils of the peninsula of Maryland.—J. S. Kingsley, carcinological notes: I. (chiefly relates to the genus Thelphusa, describes two new species from Ceylon and one from West Africa; also a new species of Dilocarcinus. II. Revision of the Gelasimi, plates 9 and 10).—Dr. Allen, description of a fœtal walrus, and on the mammæ of bats.—Dr. R. Bergh, on the nudibranchs of the North Pacific Ocean, with special reference to those of Alaska, Part 2, plates 1 to 8.—Howard Kelly, on a sartorius muscle in the gorilla. This muscle was reinforced six inches from its origin by a muscular slip a quarter of an inch in breadth; it arose at the lower part of the middle third of the femur, between the origin of the quadriceps extensor and the insertion of the adductors joining the sartorius opposite the knee joint.—J. H. Redfield, on *Rochelia patens* (Nuttell), decided by Dr. Gray to be *Echinospermum floribundum*.—Report on plants introduced by means of the International Exhibition 1876.

Bulletins de la Société d'Anthropologie de Paris, tome 3, fasc. 1, 1880.—The present number contains the address of M. Sanson, president of the Society for 1880.—A communication from M. Mantegazza, on the Lapps.—A paper by M. Emile Goldi, on the migration of races in Egypt, which gave rise to an animated discussion, in which Mad. C. Royer opposed the author's view of the Asiatic origin of the Egyptian races.—M. Topinard proposed new methods for obtaining means differing from those suggested by M. Broca, which he considers to be based upon too small numbers.—M. Robin, Inspector of Primary Instruction in the Departement de Loir-et-Cher, invites the attention of the Society to the question whether it would not be desirable, to require from teachers in the public schools reports of the stature, growth, &c., of the pupils under their observation. M. Broca was of opinion that anthropological characteristics are of little value except in the case of adults, and that the important question of growth can only be satisfactorily considered when large numbers of children are simultaneously submitted to observation.—This number of the *Bulletins* devotes nearly seventy pages to the reprint of the "Inventory of the Megalithic Monuments of France," in which we have the combined result of the carefully-conducted observations of the General Commission for the registration of these remains, which was formally appointed by the Minister for Public Instruction in November, 1879. In this survey the country was divided into six sections, each of which was placed under the direction of one of the commissioners, while the general work was further subdivided into two groups, those of erratic boulders and megalithic monuments.—The last paper, by M. Paul Broca (on a new instrument invented by himself, and named "le goniomètre d'inclinaison et l'orthogone"), has a specially melancholy interest from the fact that it is connected with some of the latest work done by this eminent savant before his death.

Journal of the Franklin Institute, July.—The belt-dynamometer of Dr. C. W. Siemens, by R. Briggs.—High railway speeds, by W. B. Le Van.—Economic vaporisation of a boiler, by Chief Engineer Isherwood.—Progress of the dephosphorisation of iron, by F. Gautier.—The involute of the circumference of a circle, by L. D'Auria.—A new pendulum suspension, by L. H. Spellier.—The puddling process, past and present, by P. Roberts, jun.

Bulletin de l'Académie Royale des Sciences (of Belgium), No. 5.—On a whale caught on the coast of Charleston (South Carolina) on January 7, 1880, by M. Van Beneden.—An application of accidental images, by M. Plateau.—Note on the illumination of mines with phosphorescent sulphides, by M. Montigny.—Researches on the property possessed by solid bodies of welding by the action of pressure, by M. Spring.—On the line of (so called) helium, by Abbé Spée.—Excretory apparatus of the Trematodes and Cestoides, by M. Fraipont.—Discovery of hæmoglobin in the aquiferous system of an Echinoderm, by M. Foeltinger.

SOCIETIES AND ACADEMIES

EDINBURGH

Royal Society, June 21.—Prof. Maclagan, M.D., vice-president, in the chair.—Prof. Chrystal read a paper on a differential telephone, and on the application of the telephone to electrical measurements. A differential telephone was exhibited. It differed from an ordinary telephone in much the same way that a differential galvanometer differs from an ordinary single-coiled one. Two thin wires were twisted together and wound round the magnet in the usual way. It was shown that when an interrupted current passed in opposite directions through the two coils of the differential telephone no sound was heard. In using the instrument, its two coils were put into the two branches of a multiple arc, which was inserted in the circuit of the interrupted current. The interrupted currents of the two branches passed in opposite directions through the coils. The conditions for perfect compensation were not only that the resistances of the two branches must be equal, but also that their co-efficients of self-induction must be the same. If only one of these conditions was fulfilled a minimum of sound could be got, but absolute silence was impossible. The necessity for this twofold adjustment had not been hitherto sufficiently recognised; and it was to its neglect that the main difficulties in using Hughes' induction-balance were no doubt to be referred. Some years ago Prof. Chrystal had worked out the mathematics of the subject, but had been unable till recently to corroborate his results by experiment. Prof. Chrystal then proceeded to indicate how such a differential telephone could be applied to the measurement of coefficients of self-induction in terms of an arbitrary unit. Two coils were prepared of exactly the same resistance, but one was so wound as to have practically no self-induction. The self-induction of the other was the arbitrary unit mentioned above. In the rough model shown, two coils, whose distance apart could be varied at will, were introduced into each branch of the multiple arc above referred to, and were first adjusted so as to produce perfect compensation in the differential telephone. The other two equal resistance-coils were then introduced, one into the circuit of each induction pair, with the necessary effect of destroying the compensation. By a readjustment of the induction of one of the pairs, compensation was again secured, the change of distance of the coils of the altered pair corresponding therefore to the arbitrary unit. The two single coils were then removed, a fresh compensation obtained by alteration of the other induction pair, the single coils again introduced, a fourth compensation effected and a second stage reached in the formation of a graduated scale of self-induction in terms of an arbitrary unit; and so on till a complete scale was formed. Prof. Chrystal further pointed out how his instrument might be used for measuring capacities, and for investigating the real nature of the *opposition* offered by electrolytes to the passage of electric currents.—Prof. Tait communicated a paper on the determination of the specific heats of saline solutions, by Mr. Thomas Gray, B.Sc.—Mr. J. Y. Buchanan described a "navigational sounding-machine" of very simple construction. A glass tube, closed below by a plug kept sufficiently tight by a close-fitting india-rubber band, was provided above with a peculiarly-formed capillary orifice. The tube was first allowed to fill with air, and then sunk to the required depth in the sea. The air was compressed under the increased pressure, and the water began to trickle in from above. The quantity of water which so gained admittance was the datum from which the pressure, and therefore the depth, could be calculated. The water was removed by taking away the bottom plug; and the instrument was once more in a state suitable for use. Mr. Buchanan also communicated some experiments on the compressibility of glass. The value he obtained was greater than that obtained by Grassi by $2\frac{1}{2}$ per cent.—Dr. Macfarlane read a short paper entitled "Suggestions on the Art of Signalling." He advocated the use of *three* qualities or symbols in preference to the dot-and-dash or two-symbolled alphabet of Morse, arguing that such a system would be found more rapid than the latter.—Dr. R. M. Ferguson communicated a note on the wire telephone, following

up the results obtained formerly by himself and those more recently arrived at by Preece and Chrystal. He showed that the sound emitted by a stretched iron wire through which an interrupted current was passing varied in a remarkable way with temperature, reaching a most evident maximum about a dull red heat. This variation he regarded as being in some way connected with the magnetic properties of iron, and on that ground criticised Prof. Chrystal's explanation of the De la Rive phenomenon as being due to rapid contractions and dilatations of the thin wires through which the current passed. In the remarks which followed Prof. Chrystal admitted the influence of magnetism in the case of the *iron*, a thick wire of which was as efficient as a thin wire; but in the case of what are usually reckoned non-magnetic metals, only *thin* wires of which are efficient for reproducing continuous sounds, he still thought that the true explanation was to be found in their changes of length. The altogether *peculiar* action of iron—though probably nickel and cobalt would have a similar action—seemed to him rather to favour this view than the other.

Boston, U.S.A.

American Academy of Arts and Sciences, June 9.—Prof. Joseph Lovering, vice-president, in the chair.—Dr. A. Auwers of Berlin, and Prof. Descloizeaux of Paris, were elected Foreign Honorary Members.—The Rumford medal was conferred on Prof. Josiah Millard Gibbs for his researches in thermodynamics.—The Hon. Charles Francis Adams resigned the office of president of the Academy, and Prof. Joseph Lovering was elected to the chair.—Dr. Oliver Wendell Holmes was chosen vice-president, Prof. Josiah P. Cooke corresponding secretary, and Prof. John Trowbridge recording secretary.

Paris

Academy of Sciences, July 26.—M. Edm. Becquerel in the chair.—In name of a committee lately formed, M. de Quatrefages asked the Academy to open a subscription with the view of striking a medal in honour of M. Milne-Edwardes' services to science. Agreed.—Apparatus for measuring the heat of combustion of gases by detonation, by M. Berthelot. It consists essentially of a bomb suspended in a calorimeter.—On the dissolution of chlorine in water, by M. Berthelot. His observations point to the existence of a perchloride of hydrogen, probably a trichloride.—On the theory of the sines of superior orders, by M. Villarceau.—On the same, by M. Farkas.—Substances addressed to the Museum mistakenly as meteorites, by M. Daubrée. Most frequently they are scoriæ from works, and pyrites; but iron ores and a variety of substances are sent, and the senders are often men of scientific note. Bolides are often thought to fall near, while really far away.—On the successive transformations of the photographic image by prolongation of the luminous action, by M. Janssen. Beyond the second neutral state he gets a second negative image (requiring a million times the luminous intensity for the first), and a third neutral state, with uniform dark tint.—Report on the project contained in documents deposited by M. de Lesseps for the interoceanic canal. This reviews the past history of the question.—Report on a memoir by Dr. Companyo, entitled "Project of Organisation of the Service of Health of the Panama Interoceanic Canal," by M. Larrey.—M. Boutigny described some new experiments on the spheroidal state.—On the transformation of linear differential equations, by M. Appell.—On a property of algebraic functions and curves, by M. Pickard.—On the causes of interior alteration of steam boilers, by M. Lodin. From experiments with iron wire in sealed tubes holding various waters, he finds the predominant cause of oxidation to be the oxygen of dissolved air, and that this is not more intense in the case of distilled water than of calcareous, but the opposite. The action of some disincrustants is studied.—On a method of direct autocollimation of objectives and its application to measurement of indices of refraction of the glasses composing them, by M. Martin.—On the employment of the spherometer, by the same. He has improved it in certain points.—On the causes of terrestrial magnetism, by M. Lemström. He magnetises a vertically-suspended bar of soft iron, by rapid rotation of a paper tube, with two concentric walls round it. The earth he supposes similarly magnetised by rotating in a space of ether.—On an electrodynamic paradox, by M. Gérard-Lescuyer. When the current of a dynamo-electric machine (Siemens) is sent into a magneto-electric machine (Gramme), the latter moves with increasing speed; then it slackens, stops, and turns in the opposite direction; this action is reversed in turn, and so on. The polarities of the inductors are reversed.—Researches on ozone, by MM. Hautefeuille and Chappuis. The tension of transformation of ozone in oxygen under the silent discharge increases rapidly with fall of temperature. In passing from 20° to − 23° it is nearly doubled. Increase of pressure favours the production of ozone.—On a new isomeric modification of hydrate of alumina, by M. Temmasi.—Observations on M. Bourgoin's note on the ultimate action of bromine on malonic acid, by M. Petrieff.—On the molecular heat and volume of rare earths and their sulphates, by MM. Nilson and Petersson.—On a new fermentation of glucose, by M. Boutroux. What he called *lactic* fermentation in a note on March 4, 1878, he now calls *gluconic*.—Absorption and elimination of poisons in cephalopoda, by M. Yung. Absorption takes place most promptly by the branchiæ (very weakly by the skin), and according to osmotic power of the substances. Elimination is by the liver and the sac of black liquid.—Velocity of transmission of the motor excitation in the nerves of the lobster, by MM. Fredericq and Vandevelde. It is about 6m. per sec. at + 10° to + 12° C., and 10 to 12m. at + 18° to + 20°.—On the differential sensibility of the eye for small luminous surfaces, by M. Charpentier. As the two illuminated surfaces are diminished the power of distinguishing them greatly increases.—Contributions to palæozoic flora, by M. Crié.—The Loire, the Loiret, and subterranean currents of the Valley of Orleans, by M. Sainjon.—On the bed of cut flints at El Hassi (Algerian Sahara), by M. Rolland.—On the means of obtaining photographic negatives in a free balloon, by M. Desmarets. In a recent ascent he used an obturator like M. Janssen's.

Göttingen

Royal Society of Sciences, April 7.—On the conditions of geysers, by H. O. Lang.—On the extension of Abel's theorem to integrals of any differential equations, by L. Koenigsberger.

May 1.—Notices on some Australian volatile oils, by Baron von Müller.—Analysis of electric discharges, by W. Holtz.—An improved centrifugal machine for schools, by the same.

June 5.—On three-point contact of curves, by H. Schubert.—On those algebraic equations between two variable quantities which allow a number of rational univocal reversible transformations into themselves, by G. Hettner.

July 3.—Voltaic element of aluminium, by F. Wöhler.—On the functions which arise by inversion of solutions of linear differential equations, by L. Fuchs.—On algebraic logarithmic integrals of non-homogeneous linear differential equations, by L. Koenigsberger.—On a new arrangement of the magnets of a galvanometer, by K. Schering.

ANCIENT GEOGRAPHY

A History of Ancient Geography among the Greeks and Romans from the Earliest Ages till the Fall of the Roman Empire. By E. H. Bunbury, F.R.G.S. With Twenty Illustrative Maps. Two Vols. (London: John Murray, 1879.)

THIS is one of that class of monumental and scholarly works which have almost died out in these days of multitudinous magazines and rapid publication, when authors have not patience to wait the completion of a work before they begin to publish. Mr. Bunbury's work is the task of a lifetime, and he well deserves the laurels bestowed upon him by the Geographical Society. It is both scholarly and scientific, the product of patient, wide, and thorough research, and treats a complicated subject with such completeness, clearness, and sound sense, that it is difficult to see how it can be supplemented or superseded. Much has been written on the subject of ancient, and especially classical geography, in Germany and France, and with all that has been written Mr. Bunbury is evidently familiar; his work, however, is in some respects superior to anything that has preceded it. His method is thoroughly scientific; he wastes but little space in endeavouring to extract a grain of sound geography from a bushel of legendary chaff, as so many of his pedantic predecessors have done. He weighs his evidence with rigid impartiality, is never content with second-hand authorities when the originals are attainable, and accepts no conclusions of previous writers unless led thereto by his own researches. He is thus compelled to reject much that has been hitherto accepted by those who have written on the subject.

Mr. Bunbury's book is no light reading. To do it justice requires long and patient study, and to review it fully and fairly would require the scope of a Quarterly. Every page bristles with learned notes, which cannot be passed over except at the risk of losing some important point in his well-knit narrative and close argument. Besides the foot-notes there are appendages of larger Notes to each chapter, in which disputed questions are discussed, and the scattered fruits of long research brought together. As the work is a History of Geography among the Greeks and Romans, the geographical knowledge of Egyptians, Jews, and Phœnicians is dismissed in a brief introduction. We should like to see Mr. Bunbury treat the geography of these two last interesting peoples in the same thorough manner as he has done that of the Greeks and Romans, and free it from the accretions of conjecture and fable that have encrusted it. Indeed it would be a matter of great interest if scholars as competent as Mr. Bunbury has shown himself to be in his own department would bring together for us in an equally compact and accessible form all that is known of the knowledge of geography possessed by all the old peoples who have left a literature. The Chinese especially, we believe, had a much more extensive knowledge of the geography, not only of Continental Asia, but of the Asiatic Archipelago, than any but a few special scholars have an idea of. It is a pity also that our Celtic and Teutonic forefathers had no permanent means of recording the tale of their wanderings westwards from their Asiatic fatherland; but surely the experiences they met with during these wanderings have left some impressions upon their extensive folk-lore. Still the first beginnings of solid geographical knowledge and theory rest with the Greeks and Romans, and even in a complete History of Ancient Geography everything must be made to centre in them.

Of course Mr. Bunbury in carrying out his weighty task is compelled to speak of the knowledge which those two peoples were likely to acquire from the nations with whom they came into contact, the Egyptians, the Carthaginians, the Persians, and the Indians. His discussion of the extent of the ancient Egyptian knowledge of the Nile and of the African interior is broad and interesting, and he shows a healthy scepticism as to the extent of the wanderings of the Phœnicians. This wholesome scepticism is a praiseworthy characteristic of his work throughout, from the Voyage of the Argonauts down to the Irish Annals. The Argonautic legend he dismisses as of really no geographical importance, but devotes considerable space to the geography of the Iliad and Odyssey. This he reduces to a very narrow compass of certainty, and dismisses as trivial the laboured attempts to identify the many names of places introduced into the Odyssean legend. Indeed the first certain knowledge of any countries beyond their own immediate shores came to the Greeks through the numerous colonies they founded, and even this scarcely extended beyond the environs of the settlements. The Greeks were doubtless enterprising enough in certain directions, but as a people they seem not to have been much given to exploration for its own sake. The knowledge of the regions beyond the confines of the Greek colonies on the Mediterranean and Euxine was for the most part extremely vague, consisting mainly of a multitude of names of tribes exceedingly difficult now to identify. They had for centuries the vaguest and most erroneous notions of the great physical features of Europe, Asia, and Africa, beyond the immediate neighbourhood of the shores of these continents; though by the time of Hecatæus of Miletus (520-500 B.C.) a wonderful amount of information had been accumulated in an unsystematic way. This knowledge had greatly increased and become more definite and accurate by the time of Herodotus in the next century. Mr. Bunbury's treatment of this large-minded and cautious historian is especially full and satisfactory, and betokens a vast amount of original research and full and accurate knowledge of the geography of the countries concerned. He clears away many erroneous opinions attributed to Herodotus, clearly proving by reference to the original that many statements attributed to Herodotus himself are really given by him as only second-hand reports to be received with caution. We all know how poor Livingstone met his death in a Quixotic search for the fountains in which the Nile was supposed to have its origin, an idea he attributed to Herodotus; but Mr. Bunbury shows clearly that the cautious historian held no such opinion himself, but merely related it as an incredulous story he had heard when in Egypt. With regard to the famous story of the circumnavigation of Africa by Necho, related by

Herodotus, Mr. Bunbury thinks it extremely improbable, but that it cannot be disproved.

Neither Greeks nor Romans, as we have said, troubled themselves much about exploration for its own sake; their geographical knowledge, which after the time of Herodotus accumulated at an increasing ratio, came to them mostly through their military expeditions. The wars of Alexander made vast additions to this knowledge, for he, like Cæsar, fond as he was of military glory, seems to have had a real love of acquiring a knowledge of new lands and peoples. Alexander brought within the sphere of fairly exact knowledge much of Western, Central, and Southern Asia, and the coast voyage, under his orders, of Nearchus from the Indus to the Persian Gulf is a landmark in ancient geography. Cæsar did for about one-half of Europe what Alexander did for Asia, and the merits of the former as an accurate observer are done ample justice to. The extension of the Roman Empire, begun under Cæsar, was continued by his successors, and how vast had been the strides in geographical knowledge during that period is shown by the careful and full examinations by Mr. Bunbury of the works of Strabo, Pliny, and Ptolemy.

Of the few genuine exploring expeditions of the ancient world Mr. Bunbury writes at length and with his usual caution and attention to accuracy and detail. The famous voyage of Hanno the Carthaginian, for example, along the west coast of Africa, about the end of the sixth or early part of the fifth century B.C., is done ample justice to, so far as the meagre records admit. This enterprise, when we consider the state of knowledge at the time and the means at the command of the leader, deserves all the praise that has been bestowed upon it. In a single voyage this daring navigator accomplished what the Portuguese of the fifteenth and sixteenth centuries took years to do. Mr. Bunbury is, we think, unusually successful in identifying most of the points named and clearing up the apparent difficulties in the brief existing account of this voyage that has come down to us; and there is no doubt that Hanno succeeded in reaching as far south as Sherboro, on the Sierra Leone coast, something like six degrees from the equator. Yet his example does not seem to have stimulated any one to complete his work. Pytheas is another well-known name in the history of ancient geography, and a name that should have a special interest for us, as he was the discoverer of Britain to the cultured nations of the period. (It is rather strange, by the by, that no enthusiastic geographer has ever suggested the appropriateness of erecting a monument to the venturous Massilian.) Mr. Bunbury rightly defends Pytheas from the attacks that have been made upon his veracity, and, as in the case of Herodotus, carefully distinguishes between what he states as the results of his own experience and the information he gives from the reports of others. It is not probable that he ever left the mainland of Scotland. Mr. Bunbury thinks it extremely difficult to identify the "Thule" of Pytheas, "six days voyage to the north of Britain;" he distinctly states that it belonged to the British group, which would certainly seem to exclude Iceland. Pytheas is well entitled to be considered a scientific observer; he added greatly to the knowledge which the Greeks had of tidal phenomena, and as might be expected was greatly struck with the astronomical phenomena of northern latitudes. Pytheas, moreover, as we know, set up a gnomon at his native town of Massilia, and thus determined the latitude of that place with a wonderful approach to accuracy.

Mr. Bunbury by no means devotes all his space to a record of the gradual extension of a knowledge of the earth's surface among the Greeks and Romans; he gives due attention to what is known as scientific geography, to the attempts of philosophers to discover the form and extent of the earth. At a comparatively early period it was conjectured that the shape of the earth must be spherical; by the time of Aristotle indeed it had become a generally received tenet among philosophers. Mr. Bunbury, however, considers Eratosthenes (born B.C. 276), the famous Alexandrine librarian, as the true parent of scientific geography; Strabo tells us that he made it the object of his special attention to "reform the map of the world" as it had existed down to his time, and to reconstruct it upon more scientific principles. "The materials at his command," Mr. Bunbury continues, "were still very imperfect, and the means of scientific observation were wanting to a degree which we can, at the present day, scarcely figure to ourselves; but the methods which he pursued were of a strictly scientific character, and his judgment was so sound that he proved in many instances to be better informed and more judicious in his references than geographers of two centuries later." Eratosthenes set himself to make a careful measure of the magnitude of the earth; his method was thoroughly scientific, though the data he had to start with were, as might be expected, by no means accurate. Under the circumstances the approximation he made to the measure of the earth's circumference was really wonderful. Mr. Bunbury's discussion of the method and results of Eratosthenes shows that he has mastered the scientific side of his subject as well as the historical; it is a fine example of careful and close reasoning. For an account of the work of Eratosthenes and other ancients in this direction we refer the reader to the series of articles on the Figure of the Earth in NATURE, vol. xviii. p. 356, *et seq.*

After all, even in the time of Ptolemy, the map of the world, after something like 800 years work, was of comparatively limited extent. Anything like accurate knowledge did not extend beyond Central and Southern Europe, Western and South-western Asia on the one side, and a small stretch of North Africa on the other. True a vague knowledge was on record of regions far beyond this, a knowledge however which had a vast amount of error mixed with a small modicum of truth. Still when we consider the limited means at the command of the Greeks and Romans, and that they had to overcome all the initial difficulties of the pursuit of knowledge, the results which they achieved are creditable to their enterprise.

Mr. Bunbury's history of these first beginnings of geographical exploration and geographical science is well worth a careful study, and will gain for him a high and permanent position in the literature of geography. Not the least valuable feature, we should say, are the numerous map illustrations of the progress of geographical knowledge at various periods.

THE MENHADEN

The Menhaden; being a History of the Fish. By G. Brown Goode. *With an Account of the Agricultural Uses of Fish.* By W. O. Atwater. (New York: Orange Judd Company, 1880.)

IN money value the American menhaden ranks fourth in the list of the fishes of the United States. First comes the cod, secondly the salmon, thirdly the mackerel, and then the menhaden. In absolute pounds' weight caught it would seem to come first of all, upwards of 460 millions of pounds' weight having been taken in 1876, whereas there was considerably less than half this weight of cod taken in that year, and all the salmon and mackerel taken if weighed together would not amount to much more than one-sixth of the weight. As its money value must depend on its economic value, it may be as well at once to briefly hint at its uses. As a table fish it is in favour in many parts of the United States, when perfectly fresh being considered superior in flavour to most of the common shore fishes. In the Washington fish market, when in season, they meet with a ready sale. Large quantities are salted, and there is a great export of these to the West Indies, where they serve as food for the negroes upon the plantations. Immense numbers are preserved in oil and spices and sold as sardines. Goodale's extract of fish is made out of menhaden, and the qualities of this preparation are testified to as being agreeable in flavour and decidedly nutritive as food for cattle. Menhaden scrap is a great success; sheep get rapidly fat on it. Hens, ducks, and turkeys prefer it to corn, and it need not be added that pigs greedily devour it. For bait it is extensively used in the cod and mackerel fisheries in New England and the British Provinces. Its popularity is no doubt chiefly due to the ease with which it may be obtained in quantity. As an article of commerce menhaden bait, it will be remembered, came under the consideration of the Halifax Commission of 1877; but perhaps even a greater future is open to the menhaden fisheries by the recently-established manufacture of oil and guano from these fish. The State of Maine claims to have been the first to discover its value, and now large factories turn out immense quantities of these materials. In 1874 from 50,000 to 75,000 gallons of oil was turned out from the Maine Works. The manufacture is simple in the extreme, consisting of three processes: boiling the fish, pressing and clarifying the expressed oil. The final operation is pumping it into immense bleaching tanks, where it becomes whiter and clearer in the rays of the sun. When well refined the oil is light-coloured, sweet, and of prime quality. The uses of this oil are manifold. It is chiefly employed, we are told, as a substitute for the more costly and popular oils, and to adulterate them. It is sold largely to tanneries for currying leather. The principal market for it is in Boston and New York, but considerable quantities are shipped to London, Liverpool, and Havre. But menhaden has still further uses. So far back in American history as 1621 we read that the Plymouth colonists learnt from an old Indian that they should use these fish as manure on their ground; and one Edward Johnson, writing in 1652, says, "But the Lord is pleased to provide for them [the New England colonists] great store of fish in the spring time. Many thousands of these they used to put under their Indian corn, which they plant in rills five foot asunder." Now as a result of the profitable utilisation of the menhaden for the manufacture of oil, the use of the whole fish as a fertiliser has gradually and almost entirely ceased, and the refuse from which the oil has been expressed is used instead. This is known as "fish-scrap" and "fish guano." In a wheat-growing country like North America the importance of the subject of artificial manures is great, and we quote from Prof. Cook's, of New Jersey, report to the State Board of Agriculture as follows: "Those who have tried a mixture of this fish guano with barn-yard manure and a little lime, say that it is superior to any guano in the market. When applied on corn the crop is considered as certain. The value of fish as manure is due mainly to the presence in it of nitrogen and phosphoric acid. The crops most assisted by fish manures are such as grass, grain, and corn, while leguminous crops, like clover, beans, and peas, are more benefited by mineral manures."

The above is but a brief *résumé* of one portion of Messrs. Goode and Atwater's interesting work, the title of which is quoted above. Their history was prepared for the Fifth Annual Report of the Commissioner of Fisheries for 1877. As reprinted, it forms an octavo volume of 540 pages and 30 plates.

The menhaden (*Clupea menhaden* of Mitchell) is, when adult, a most beautiful fish; its colour is pearly opalescent; each scale has all the beauty of a fine pearl, and the reflections from the mailed side of a fish just taken from the water are superb; the scales of the back and top of the head are of a purplish hue. Its importance to the States may be compared to the importance of the herring to Northern Europe. It is to be found at the same period during the year in the coast waters of all the Atlantic States from Maine to Florida. A surface temperature of about 51° is necessary for its appearance in waters near the shores. Its food is apparently for the most part minute algæ. The geographical range of the species, the arrival and departure of the "schools," the migration question, the peculiar movements of the "schools" of menhaden, are all subjects discussed at great length in this report, and from it many facts of great value to those interested in our own shore-fisheries are to be learnt.

The strange and unaccountable absence of the menhaden last year from the waters of Cape Cod are briefly alluded to in the Introduction. This absence was disastrous to many, and proved by a sad experience that the harvest of the sea will sometimes fail. The oil and guano factories lost a year's work; the factory hands and steamer's crew were entirely thrown out of employment; those were all on hand to begin work on June 1, and kept working, in the hope that the fish would "strike," until late in August. When they at last gave up all hope it was too late to engage in any other occupation to make money to carry them over the winter. This absence of the fish north of the Cape did not appear to be compensated for by any remarkable abundance in southern New England, but a much larger number of fish were captured in these waters in 1879, as so many more vessels went there to fish. We hope soon to hear of a good season's fishing at Cape Cod, and we strongly recommend this important report on the menhaden to the reader's notice.

OUR BOOK SHELF

Alphabetical Manual of Blowpipe Analysis. By Lieut.-Col. W. A. Ross. (London: Trübner and Co., 1880.)

OF late years the blowpipe has been very little used in practical chemistry. It has been felt that efficiency in qualitative analysis is not the final aim of the chemist; and this branch of chemical art has been more and more relegated to the position of an instrument for examination purposes.

There is however little doubt that a thorough training in qualitative analysis—such a course, for instance, as is furnished by Mr. Dittmar's manual—is of much service to the learner of chemistry; but even here the methods which are of most general application are founded on reactions "in the wet way."

The blowpipe, however, is beginning to reassert its claims to the favourable recognition of the chemical mineralogist. The little book in which Col. Ross condenses the results of his own and others' work is well calculated to advance these claims.

No regular course of analysis is given in this book beyond an outline of a method for classifying minerals for blowpipe examination, and an account of the Freiberg scheme of qualitative analysis of minerals. But under such headings as "Alloys," "Minerals," "Phosphoric Acid Reagent," &c., most useful information is presented to the worker in tabulated form. The table of "Reactions of ordinary Oxides at one View" is also useful.

Any mineralogist who has acquired some command of the blowpipe and has a fair elementary knowledge of chemistry must find this work of service to him; it contains in a small compass almost all that is required to be known in order to study the composition of minerals by "pyrological" reactions. Very many of the reactions described by Col. Ross are not to be found in other books. Not a few of his statements are opposed to generally-accepted facts. He gives a flat contradiction to the statement made in the text-books, that most metallic oxides are soluble in boric acid, or boron trioxide, at a red heat, whilst of course admitting their solubility in fusing borax; indeed he bases his system of blowpipe examination, or pyrology, to a large extent, on the non-solubility of metallic oxides in this reagent.

As is often the case with one who has undoubtedly advanced any branch of scientific work, Col. Ross is too ready to value his favourite method more highly than it deserves. Thus he is inclined to regard the blowpipe as "a more delicate analytical weapon than the spectroscope," and thinks that by its use he has proved that the production of D-lines is not always due to sodium!

U.S. Coast and Geodetic Survey. Pacific Coast Pilot. Coasts and Islands of Alaska. Appendix I. Meteorology and Bibliography. By W. H. Dall. (Washington, 1879.)

THE complicated title of this large quarto volume gives very little idea of the nature and value of its contents. In the first sentence of the Letter of Transmission we meet with a new and amusing use of an old enough English phrase, when Mr. Dall coolly informs the superintendent of the Survey that he has "the honour to *turn in* the results of an inquiry into the meteorology of Alaska and the adjacent regions." The results of which Mr. Dall speaks in this irreverent manner must have cost him stupendous labour; indeed they might very well have taken years of research by a small international staff of inquirers. The publication comprises an abstract or summary of all accessible meteorological material relating to the district in question; both of that which has been published and is widely scattered through numerous proceedings, annuals, and transactions of learned societies, buried in periodicals in the Russian and other languages, and otherwise difficult of access; and also of a very large amount of unpublished material from the archives of the U.S. Coast Survey, the Medical Department of the U.S. Army, the U.S. Signal Service, and numerous contributions from private sources. With the abstracts are included the fullest references to the sources from which the materials are derived, and all the data which could be obtained as to the conditions of observation. The list of charts, maps, and publications relating to Alaska and the neighbouring regions, and occupying something like 200 quarto pages, is a wonderful piece of well-arranged work, and must prove valuable for many purposes besides that for which it has been immediately compiled. The volume also contains charts representing the monthly and annual means of temperature and pressure, graphic figures of the direction of the winds at each locality, and of the annual curves of pressure, precipitation, and temperature. Mr. Dall probably knows more about the region to which this volume refers than any other man living, and is able from his own observations and experience to contribute greatly to the value of his report. Altogether this is one of the most creditable of the many creditable scientific publications of the United States, and Mr. Dall is evidently one of the most valuable scientific servants of that Government. We hope, both for the good of the States and the interests of science, that he will be afforded every facility for utilising his exceptional ability as a scientific observer.

The Tree Planter. By Samuel Wood, Author of "Good Gardening."

The Tree Pruner. By the same Author. (London: Crosby Lockwood and Co., 1880.)

THESE two books form Nos. 209 and 210 of Weale's Rudimentary Series. Considering the numerous books Mr. Wood has written, the titles of which are set forth on the first pages of the little volumes before us, it is clear the author is suffering from a continued attack of *Cacoëthes scribendi.* Agreeing with the author, for the sake of argument, that there was a real necessity for the information he desires to impart, we cannot see why the matter contained in the two books should not have been combined in one, for the subjects of propagation and pruning are so closely associated that they would have gone better together rather than being separated; besides which a good deal of useless repetition would have been saved. Writing in the first book of what the author calls plants of the "Hibiscus Class—the *Althæa frutex,*" he says they are "deciduous shrubs of great beauty, comparable to carnations on trees." In the second book, under the head of "The Hibiscus," it is said—"These plants are among our most beautiful flowering shrubs; many of them will compare with the carnation." As an illustration of the author's method of imparting botanical knowledge, we will quote only two paragraphs from the article on the holly. He says—"There are a great many varieties of the holly, and nearly all of them are natives of Great Britain. There is also one commonly called *knee holly,* which is not a holly at all. The holly belongs to the natural order *Aquifoliaceæ,* while the knee holly, or *Ruscus aculeatus,* belongs to the natural order *Liliaceæ, i.e.,* flowers resembling a diminutive lily, while the flowers of the former belong to a class quite different, Linn. class 4, and order 3, the latter having 6 stamens and 1 style.

"Aquifoliaceæ conveys no idea of the class, but simply refers to the plant belonging to those with prickly leaves. This being the case, I am disposed to look upon the term 'Aquifoliaceæ' as misleading, because there are some other genera possessing prickly leaves, and some hollies that have leaves with no prickles, and in the case of the *Ruscus,* which has prickly leaves, it may be and is called a holly, while it is of another genus." It is impossible to comment on this. The author may be practical, but he is not scientific.

Tables for the Analysis of a Simple Salt. By A. Vinter, M.A. (London: Longmans and Co., 1880).

MANY tables for the qualitative analysis of simple salts already exist; another set is just added to the list by Mr. A. Vinter. It is very probable that students who—like those for whom Mr. Vinter's tables are arranged—can only devote one hour a week to practical chemistry, would do well to add that hour to those allotted to some other study; but if school-teachers will give their boys so insignificant a smattering of practical chemistry, these tables will, we think, be found useful and generally accurate so far as they go, which is certainly but a very little way indeed.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The late Count L. F. de Pourtales

EVERY naturalist must have noticed with regret the news of the death of M. de Pourtales, of Cambridge, Mass., U.S., but those who have had the pleasure of his friendship and who have been fellow-labourers with him feel a most sincere sorrow at the loss which science has sustained.

The exploration of the deep sea brought Pourtales prominently before the scientific world, and his practical knowledge of the art of dredging not only produced results which were of great importance to Alexander Agassiz and Lyman, but they also provided him with a wonderful series of deep-sea corals, upon which he laboured with great success. The floor of the Gulf Stream in the Straits of Florida, the dredgings of the *Hassler* Expedition, and lastly, the examination of the results of the work done in the Caribbean Sea during the voyage of the U.S. steamer *Blake*, gave the opportunity, which was readily seized and utilised, of contributing largely and thoroughly to the knowledge of the interesting Madreporarian fauna of the depths. I can testify to the solid merit of the work done by my friend, and I can never forget his generous assistance, kindly criticisms, and desire to obtain the perfect truth. He spared no pains, and was ever at work in the difficult subject he especially chose; and he speedily grasped the relations of the past and present deep-sea coral faunas, and, besides adding largely to our knowledge of forms, contributed in a most important manner to the study of the generic and specific value of certain structures. Of his knowledge of the Crinoidea I need not write, but of the great value of the researches of the grave, courteous, and most genial man who is no longer amongst us I shall ever speak in terms of great admiration and gratitude.

Athenæum, August 8 P. MARTIN DUNCAN

The Recent Gas Explosion

ACCORDING to promise, I write to describe the continuation of the experiments on the above subject.

At present there is little else than failure to report, but as I am leaving home to-day and shall not be able to try any additional experiments for the next three or four weeks, I will merely mention the results obtained.

A piece of composition gas-pipe 10m. long, 15mm. internal diameter, and 2 mm. thick, was filled with a mixture of 2 vols. of hydrogen to 1 vol. of oxygen, and the gas exploded. The tube was not affected, the cork which closed it being projected.

It was then filled with a mixture of 10 volumes of coal-gas and 12 of oxygen, and in this case the tube withstood the explosion; a piece of india-rubber tube covered with calico tightly bound round it, which was used to connect the farther end of the tube to a metal stopcock, was however burst and the calico torn.

To-day I tried a tube made of paper. The tube is 7 mm. in diameter, and consists of eight layers of thin paper, stuck together with paste, and varnished on the outside with shellac.

This I have not succeeded in bursting with the mixture of hydrogen and oxygen; one of the caoutchouc stoppers which closed the glass tubes cemented to the end of the paper tube was blown off.

I hope to repeat the experiment with another paper tube which is not so strong. HERBERT MCLEOD

Cooper's Hill, August 9

Heat of the Comstock Lode

IN May, 1878, Mr. Church, who was at that time Professor of Mining at the University of Ohio, read a paper before the American Institute of Mining Engineers on the heat of the Comstock mines, which was subsequently, in an extended form, included in the author's volume on the Comstock lode, of which a review appeared in NATURE (vol. xxi. p. 511).

In this paper Mr. Church states that the temperature of the waters issuing from the mines worked upon the Comstock lode has always been somewhat high, but it was not until they had attained a very considerable depth below the surface that the workmen first became inconvenienced by extraordinary heat. At their present greatest depth (about 2,700 feet) water issues from the rock at a temperature of 157° F. (70° C.), and at least 4,200,000 tons of water are annually pumped from the workings at a temperature of 135° F. Mr. Church estimates that to elevate such a large volume of water from the mean temperature of the atmosphere to that which it attains in the mines would require 47,700 tons of coal. In addition to this, he calculates, 7,859 tons of coal would be required to supply the heat absorbed by the air passing along the various shafts and galleries through which it is diverted for the purposes of ventilation. It follows that to develop the total amount of heat necessary to raise the water and air circulating in these mines from the mean temperature of the atmosphere to that which they respectively attain, 55,560 tons of coal, or 97,700 cords of firewood would be annually required.

Mr. Church, in his paper, quotes four analyses of waters from the Comstock lode taken at different depths; these vary somewhat as to the relative proportions of the various substances present, but they contain on an average 42·62 grains of solid matter to the gallon. Of this amount 20·74 grains are calcic sulphate, 12·13 grains carbonate of potassium, 4·85 grains carbonate of sodium, and ·66 grain of chloride of sodium.

In order to ascertain approximately to what extent the production of the large amount of heat absorbed by the water may be ascribed to oxidation of sulphur and iron, the author first calculates the quantity which would be developed by the oxidation of pyrites equivalent to the calcic sulphate in solution. But having found that this amounts to only about $\frac{1}{10}$th part of that required, he seeks another solution for the difficulty, and without any calculations in support of the hypothesis, attributes this enormous development of heat to the kaolinisation of felspar in the subjacent rocks.

In a communication to the Geological Society of London, published in their *Quarterly Journal*, August 1879, entitled, "A Contribution to the History of Mineral Veins," I endeavoured to show that the kaolinisation of felspars is as inadequate to produce the effects observed as is the oxidation of pyrites, and a recent paper read by Mr. Church before the American Institute of Mining Engineers, as well as his letter on Subterranean Kaolinisation in last week's NATURE, have been written with a view of answering these objections.

In my communication to the Geological Society I applied to the kaolinisation of felspars a similar line of reasoning to that adopted by Mr. Church with regard to the oxidation of pyrites.

The average proportion of alkalies contained in the rocks of the district is 6·40 per cent., while the mean of the published analyses gives 11·30 grains of alkalies in the U.S. gallon of water. It follows that the 4,200,000 tons of water annually pumped out must contain 813 tons of alkalies, and that, as these are present in the rocks in the proportion of 6·40 per cent., the felspar in 12,703 tons of rock must be annually kaolinised and the alkalies removed in solution.

The amount of rock in which the felspar has been kaolinised being 12,703 tons, and the number of tons of water pumped out of the mines 4,200,000, it follows that $\frac{4,200,000}{12,700} = 330$ is the number of tons of water heated by each ton of completely altered rock.

In order, therefore, that one ton of rock should be enabled to heat 330 tons of water only 1° Fahr., and the specific heat of these rocks be taken at ·1477, that of blast-furnace slags, it would require to be heated by the kaolinisation of its felspar to a temperature above that of molten gold. Consequently to raise the water 85°, or to a temperature of 135°, at which it issues, the

kaolinisation of the felspar in each ton of rock would require to elevate it to an extent it would be difficult to estimate.

To this Mr. Church, who derives his heat from the hydration of silicate of aluminium during the formation of kaolin, objects that the whole of the alkalies liberated by the decomposition of felspar do not become dissolved in water, and that their amount cannot consequently be taken as a measure of the quantities of that mineral which have been decomposed.

In support of this argument he states that clays from the immediate neighbourhood of the Comstock lode still contain above 4½ per cent. of alkalies, and ignores the fact that the final result of kaolinisation is the production of a hydrated silicate of aluminium free from alkalies. The clays in question must consequently be regarded as containing undecomposed felspar which cannot have contributed to any increase of temperature.

Admitting however for the sake of argument that all the felspar has been decomposed, and that three-fourths of the alkalies present have been retained by the resulting clay, the heat corresponding to the decomposition and hydration of the felspars in a ton of rock must be reduced by three-fourths. If, therefore, as before, to simplify our ideas, we regard the heat required to produce the observed effects as due to a single variation of temperature, the original temperature must have been above twenty times higher than the melting-point of gold, which appears as improbable as that found on the assumption of the whole of the alkalies entering into solution.

The assumption now made, namely, that much of the kaolinisation of the felspar is accomplished by aqueous vapour which is entirely absorbed by the rock, and which does not give rise to any aqueous solutions, involves conditions of which we have no known example, and of which it is difficult to conceive the existence at such great depths below the water-level of the country.

This view of the question was not advanced by Mr. Church in his original paper of 1878, and has probably occurred to him subsequently to the publication of my observations in the *Quarterly Journal of the Geological Society* in the following year. If however the possibility of such an alteration were admitted, it certainly could not be ascribed to kaolinisation, since the removal of the alkalies in felspars is an essential factor in that transformation.

With regard to the hot spring which formerly issued from between slate rocks and an elvan dyke at Wheal Clifford Mine in Cornwall containing notable quantities of chloride of lithium and other alkaline salts, cited by Mr. Church in his recent pamphlet in support of his views with respect to kaolinisation, the effect has probably been taken for the cause. Hot water is known to be a better solvent of mineral matter than cold water, and it has been shown by Daubrée that at high temperatures and under great pressure it is even capable of rapidly dissolving silica out of glass, and of leaving it in the form of crystallised quartz.

We have no direct evidence that the dissociation of the constituents of felspar and the subsequent hydration of the clay produced give rise to any liberation of heat. It is well known that the temperature of mines situated in granite, where kaolinisation is constantly going on, is lower than that of those worked in clay-slate, while high temperatures or thermal springs are not more frequently observed in masses of kaolinised granite than elsewhere.

The mines on the Comstock lode are situated in a highly-volcanic region of very late tertiary age, and in the almost immediate vicinity of lava-flows and boiling springs. Until, therefore, stronger evidence than that yet furnished shall have been brought forward, it is probable that the majority of geologists may continue to ascribe these phenomena to the action of volcanic agencies. J. ARTHUR PHILLIPS

18, Fopstone Road, Kensington, S.W., August 9

British Museum Attendants

As you are a free lance in British Museum matters, will you not make some remarks on the attendants? They are, as a body, intelligent and desirous of learning, but no attempts seem ever to be made to instruct them in the subjects of their departments; and all the information they possess is picked up by scraps, from overhearing the remarks of their chiefs to distinguished visitors.

Many of them do what they can to teach themselves; but why should they not have some regular training, and be competent to give simple and informal description-lectures to parties who really go for instruction? It cannot be said that it would imperil their charges by occupying their attention, when we see how a far scantier supply of care-takers completely guard South Kensington.

The object is not to get a higher paid and superior class of men, but to give them the advantages they might reasonably enjoy, and use them as rational beings. I have heard some of them deplore the way in which they are treated, "like so many watch-dogs"; the snuff-taking to keep awake; the lapses of the stouter ones into afternoon naps; the forbidden conversations, even on the objects of their care, with visitors; the reading of all the advertisements of the *Times*, for lack of better interest; all these are familiar subjects, as you will find if you once tap the flow of forbidden talk successfully.

Some attention to them might prevent such a colloquy as I once had with a flashy-looking fellow on one of the many unlabelled objects in his department. I asked, "Do you know where that squared block is from that stands on that terminal ornament?" Gallio (with a flower in his button-hole): "Which do you mean?" "That one which has another rough block standing on it." Gallio (impatiently): "Well! what about it?" "Do you know where it came from?" Gallio (with ineffable contempt): "No! indeed; I don't know where it's from. I don't know anything about it." If you should care to quote this, I can vouch for its accuracy, as I noted it at the time.

Quassia and Mosquitos

IN NATURE, vol. xxii. p. 11, I read a letter in which the employment of a wash made from a decoction of quassia wood was recommended as a protection from the attacks of mosquitos and other insect pests. After reading the above-named letter I sent some of the quassia to my son, who is a surveyor camping out on the prairie in Dakotah Territory, U.S.A., in a part much infested in hot weather by mosquitos. In a recent letter my son states that he has repeatedly tried the wash with quassia, but without any beneficial results, the mosquitos having attacked him even before the solution had dried on his skin.

I have suggested that he should try carbolic acid ointment, if he can procure any, as English insects do not like the carbolic odour.

Possibly the mosquitos referred to in your correspondent's letter may have been much better fed than the North American tormentors.

If any of your numerous readers could communicate some effectual protection against the attacks of these pests, it would be a great boon to those who suffer so much from them.

Manchester, August 9 J. B. DANCER

Fascination

A VERY simple explanation may be offered of the seemingly mysterious facts of fascination, whether in man or the lower animals. Every one knows the old and ludicrous problem requiring us to decide what would happen to a hungry donkey placed at a spot exactly equidistant from two quite equally attractive bundles of hay. In theory the creature starves, being unable to make up its mind to choose one bundle rather than the other without any reason for such choice. In practice it is generally supposed that the unsteadiness of this world's affairs would speedily destroy the equilibrium of motives and leave the donkey free to make its meal of one or other of the bundles. But in critical emergencies, such as those mentioned in Mr. Curran's letter, when shot and shell are flying rapidly towards their victims, almost instantaneous decision is necessary. The circumstances are such that movement either to the right or to the left would be equally salutary and efficacious, but for the very reason that one movement would be just as good as the other, the mind makes its fatal pause of indecision. A man standing in the path of an advancing express train, and a small bird eyed by a snake, are probably affected both in the same manner. There need be no occult influence in the eye of the basilisk, as there can be no magical power in the iron and brass of the steam-engine, to transfix and fascinate the prey. Terror may no doubt in some instances paralyse the brain and make it incapable of choosing the method of escape, which to an intellect unembarrassed and free from panic would be the one obviously worthy of choice, but in the military examples cited by Mr. Curran it would be indecent to suggest such an explanation of the facts, and needless when the simpler solution is available.

Tunbridge Wells, August 9 THOMAS R. R. STEBBING

Strange Method of Crossing a Torrent

Having seen something very like, if not quite identical with, the following in the Himalayas, I am anxious to know if it is not a commoner device under similar conditions than is generally supposed everywhere. The story occurs in Gerard Boote's (Doctor of Physick) "Inland's Natural History," p. 59, and is related on the authority of "one Theophilus Buckworth, a Bishop of Dromore," in whose presence the feat was performed. His description of it runs as follows. After mentioning that the brook or river "that passeth by that town was greatly risen," he adds that "A country fellow who was travelling that way having stayed three days in hope that the water would fall, and seeing that the rain continued, grew impatient, and resolved to pass the brook whatever the danger was, but to do it with the less peril and the more steadiness he took a great heavy stone upon his shoulders, whose weight, giving him some firmness against the violence of the water, he passed the same without harm and came safe to the other side, to the wonderment of many people who had been looking on and given him up for a lost person."

Warrington

Intellect in Brutes

Not having seen any reference to Cowper's famous hares in any of the notices under this heading that have appeared in Nature, I am induced to refer to them, the more so as the creature is rarely credited with much gratitude or intelligence. My information is from Tegg's edition of "The Life and Works of William Cowper," p. 633. Describing, at this place, the capers of his favourite hare named "Puss," who "would suffer me to take him up and to carry him about in my own arms," our poet adds that "he was ill three days, during which time I nursed him, kept him apart from his fellows, ... and by constant care, &c., restored him to perfect health. No creature could be more grateful than my patient after his recovery, a sentiment which he most significantly expressed by licking my hand, first the back of it, then the palm, then every finger separately, then between all the fingers, as if anxious to leave no part of it unsaluted; *a ceremony which he never performed but once again upon a similar occasion.* Finding him extremely tractable, I made it my custom to carry him always after breakfast into the garden. . . . . I had not long habituated him to this taste of liberty before he began to be impatient for the return of the time when he might enjoy it. He would invite me to the garden by drumming upon my knee and by a look of such expression as it was not possible to misinterpret. If this rhetoric did not immediately succeed, *he would take the skirt of my coat between his teeth and pull it with all his force.*" He "seemed to be happier in human society than when shut up with his natural companions," and if these traits do not *betoken* something more than instinct, it is hard to say where this ends and intellect begins.

Warrington W. Curran

Anchor-Ice

Having lately read with much interest several letters to Nature on the subject of the formation of anchor- or ground-ice, I beg leave to inform your readers that it forms here every season in the Rock Island rapids of the Upper Mississippi River; any one desirous of studying its mode of formation would here have a good opportunity. Some observations of mine upon this phenomenon may be found in vol. ii. of the *Proceedings* of the Davenport Academy of Natural Sciences, p. 349.

Davenport, Iowa, U.S., July 10 R. J. Farquharson

Depraved Taste in Animals

While in Australia I kept at different times several koalas—all taken young. Of these three were inordinately fond of tobacco in any form. They would chew and swallow the strong Victorian black tobacco with the greatest gusto, and one, to which I gave a foul clay pipe saturated with tobacco oil, devoured the whole of the stem. Sitting on the nape of my neck, his usual place when I was writing or reading in the evening, "Ka-koo" would frequently stretch out one hand, take the pipe from my mouth, and begin to chew it if not promptly interfered with. During the day he passed most of his time rolled up on the rafters of the roof, bush houses being devoid of a ceiling, and on hearing the clinking of glasses, which betokened the preparation of the evening glass of grog, hurried down from his perch to receive his modest share of whisky and water. If a spoon were dipped in the raw spirit and given to him, he would take it in both his paws and lick it dry with manifest appreciation, and could only be prevented from making a raid upon every glass on the table by being tied with a handkerchief by the leg to the back of a chair. No ill effects ever followed these indulgences.

Arthur Nicols

THUNDERSTORMS[1]

When I was asked to give this lecture I was also asked to give a short list of subjects from which your directors might select what they thought most fit. I named three. Regarded from the scientific point of view, one of them was to be considered as fully understood in principle, and requiring only additional experimental data to make it complete. This was the *Conduction of Heat in Solids.* Another was to a certain extent scientifically understood, but its theory was, and still is, in need of extended mathematical development. This was the popular scientific toy, the *Radiometer.* The third was, and remains, scarcely understood at all. Of course it was at once selected for to-night. I might have foreseen that it would be. You may well ask, then, why I am here. What can I say about a subject which I assert to be scarcely understood at all? A few years ago no qualified physicist would have ventured an opinion as to the nature of electricity. Magnetism had been (to a certain extent, at least) cleared up by an assumption that it depended on electric currents; and from Örsted and Ampère to Faraday and Thomson, a host of brilliant experimenters and mathematicians had grouped together in mutual interdependence the various branches of electrodynamics. But still the fundamental question remained unsolved, *What is electricity?* I remember Sir W. Thomson, eighteen years ago, saying to me, "Tell me what electricity is, and I'll tell you everything else." Well, strange as it may appear to you, I may now call upon him to fulfil his promise. And for good reason, as you shall see.

Science and Scotland have lately lost in Clerk-Maxwell one of their greatest sons. He was, however, much better known to science than to Scotland. One grand object which he kept before him through his whole scientific life was to reduce electric and magnetic phenomena to mere stresses and motions of the ethereal jelly. And there can be little doubt that he has securely laid the foundation of an electric theory—like the undulatory theory of light admirably simple in its fundamental assumptions, but, like it, requiring for its full development the utmost resources of mathematical analysis. It cannot but seem strange to the majority of you to be told that we know probably as much about the secret mechanism of electricity as we do about that of light, and that it is more than exceedingly probable that a ray of light is propagated by electric and electromagnetic disturbances. It is one of the most remarkable advances made during this century.

But to know what electricity is, does not necessarily guide us in the least degree to a notion of its source in any particular instance. We might know quite well *what* is electricity and yet be, as I told you at starting we *are*, almost entirely uncertain of the exact source of *atmospheric* electricity.

To come to my special subject. I am not going to try to describe a thunderstorm. First, because I am certain that I could not do it without running the risk of overdoing it, and thus becoming sensational instead of scientific; and secondly, because the phenomenon must be quite familiar, except perhaps in some of its more singular details, to every one of you.

Science has to deal with magnitudes which are very much larger or smaller than those which such words as huge, enormous, tiny, or minute are capable of expressing. And though an electric spark, even from our most

[1] Abstract of a lecture, delivered in the City Hall, Glasgow, by Prof. Tait.

powerful artificial sources, appears to the non-scientific trifling in comparison with a mile-long flash of lightning, the difference (huge, if you like to call it) is as nothing to others with which scientific men are constantly dealing. The nearest star is as much farther from us than is the sun, as the sun is farther from us than is London. The sun's distance is ninety-three millions of miles. If that distance be called enormous, and it certainly is so, what adjective have you for the star's distance? Ordinary human language, and especially the more poetic forms of it, were devised to fit human feelings and emotions, and not for scientific purposes. A thoroughly scientific account of a thunderstorm, if it were possible to give one, would certainly be at once ridiculed as pedantic.

Let us therefore, instead of attempting to discuss the phenomenon as a whole, consider separately some of its more prominent features. And first of all, what are these features when we are *in* the thunderstorm?

By far the most striking, at least if the thunderstorm come on during the day, is the extraordinary darkness. Sometimes at mid-day in summer the darkness becomes comparable with that at midnight, very different in kind as well as intensity from that produced by the densest fog. Objects are distinctly visible through it at distances of many miles, whether when self-luminous or when instantaneously lit up by lightning. The darkness, then, is simply intense *shadow*, produced by the great thickness and great lateral extension of the cloud-masses overhead. Seen from a distance, the mass of cloud belonging to the storm usually presents a most peculiar appearance, quite unlike any other form of cloud. It seems to boil up, as it were, from below, and to extend through miles of vertical height. The estimated height of its lower surface above the ground varies within very wide limits. Saussure has seen it as much as three miles; and in one case noticed by De l'Isle it may have been as much as five miles. On the other hand, at Pondicherry and Manilla it is scarcely ever more than half a mile. Haidinger gives the full details of an extraordinary case, in which the thundercloud formed a stratum of only twenty-five feet thick, raised thirty yards above the ground. Yet two people were killed on this occasion. Other notable instances of a similar extreme character are recorded.

Careful experiment shows us that the air is scarcely ever free from electricity, even in the clearest weather. And even on specially fine days, when large separate cumuli are floating along, each as it comes near produces a marked effect on the electrometer. Andrews obtained by means of a kite, on a fine clear day, a steady decomposition of water by the electricity collected by a fine wire twisted round the string. Thanks to Sir W. Thomson, we can now observe atmospheric electricity in a most satisfactory manner. I will test, to show you the mode of proceeding, the air inside and outside the hall. [The experiment was shown, and the external air gave *negative* indications.]

On several occasions I have found it almost impossible, even by giving extreme directive force to the instrument by means of magnets, to measure the atmospheric potential with such an electrometer, and had recourse to the old electroscope, with specially long and thick gold-leaves. On February 26th, 1874, when the sleet and hail, dashing against the cupola of my class-room, made so much noise as to completely interrupt my lecture, I connected that instrument with the water-dropper, and saw the gold-leaves discharge themselves against the sides every few seconds, sometimes with positive, sometimes, often immediately afterwards, with negative electricity. Such effects would have required for their production a battery of tens of thousands of cells. Yet there was neither lightning nor thunder, and the water was trickling from the can at the rate of only two and a half cubic inches per minute. Probably had there not been such a violent fall of sleet steadily discharging the clouds we should have had a severe thunderstorm. Falling rain-drops are often so strongly charged with electricity as to give a spark just before they touch the ground. This "luminous rain," as it has been called, is a phenomenon which has been over and over again seen by competent and trustworthy observers. In the *Comptes Rendus* for November last we read of the curious phenomenon of electrification of the observer's umbrella by a light fall of snow, to such an extent that he could draw sparks from it with his finger.

In calm clear weather the atmospheric charge is usually positive. This is very commonly attributed to evaporation of water, and I see no reason to doubt that the phenomena are closely connected. [A few drops of water were sprinkled on a heated crucible, insulated, and connected with the electrometer.]

There can be no doubt that, whatever be the hidden mechanism of this experiment, the steam has carried with it a strong charge of positive electricity, for it has left the rest of the apparatus with a strong negative charge. We will now try that form of the experiment in another way. [High-pressure steam escaping from a little boiler was made to play upon an insulated conductor furnished with spikes, and connected with the electrometer, which then showed a strong positive charge.]

There are many substances which produce on evaporation far greater electric developments than water does, some of positive, others of negative, electricity. By far the most remarkable in this respect to which attention has yet been called is an aqueous solution of sulphate of copper. (*Proc.* R.S.E., 1862.) The smallest drop of this solution thrown on a hot dish gives an intense negative effect—so great, in fact, that it may be occasionally employed to charge a small Leyden jar. But this, like the smaller effect due to water under similar circumstances, is not yet completely explained.

The next striking features are the flashes of lightning which at intervals light up the landscape with an intensity which must in the majority of cases far exceed that produced by the full moon. To the eye, indeed, the flash does not often appear to furnish more than the equivalent of average moonlight, but it must be remembered that it lasts for a period of time almost inconceivably short, and that the full effect of light on the eye is not produced until after the lapse of a considerable fraction of a second. Prof. Swan has estimated this interval at about one-tenth of a second; and he has proved that the apparent intensity of illumination for shorter intervals is nearly proportional to the duration. (*Trans.* R.S.E., 1849.) I can illustrate this in a very simple manner. [Two beams of light were thrown upon the screen by reflection from mirrors, each of which was fixed *nearly* at right angles to an axis. When matters were so adjusted that the brightness of the two illuminated spots was the same, one mirror was made to rotate. The corresponding light spot described a circle about the other, and its brightness became less the larger the circle in which it was made to revolve.] The lightning flash itself on this account, and for the farther reason that its whole apparent surface is exceedingly small, must be in some degree comparable with the sun in intrinsic brilliancy—though, of course, it cannot appear so. The fact that its duration is excessively short is easily verified in many ways, but most simply by observing a body in rapid motion. The spokes of the wheels of the most rapidly-moving carriage appear absolutely fixed when illuminated by its light alone. One can read by its light a printed page stuck on a disc revolving at great speed. But the most severe test is that of Sir Charles Wheatstone's revolving mirror. Seen by reflection in such a mirror, however fast it may be rotating, a flash of lightning is not perceptibly broadened, as it certainly would be if its duration were appreciable.

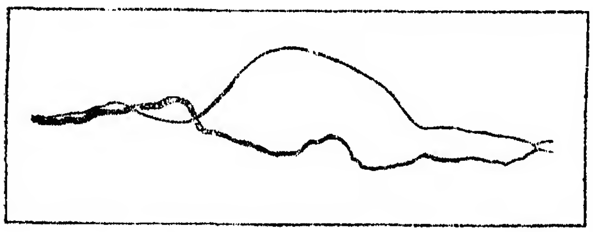
The apparatus which, in our laboratories, enables us to measure the time which light, moving at nearly 200,000

miles per second, takes to pass over a few feet, is *required* to prove to us that lightning is not absolutely instantaneous. Wheatstone has shown that it certainly lasts less than a millionth part of a second. Take this, along with Swan's datum, which I have just given you, and you see that the apparent brightness of the landscape, as lit up by a lightning flash, is *less than one hundred thousandth part* of what it would be were the lightning permanent. We have thus rough materials for instituting a comparison between the intrinsic brightness of lightning and of the sun.

Transient in the extreme as the phenomenon is, we can still, in virtue of the duration of visual impressions, form a tolerably accurate conception of the form of a flash; and in recent times instantaneous processes of photography have given us permanent records of it. These, when compared with photographic records of ordinary electric sparks, bear out to the full the convictions at once forced by appearances on the old electricians, that a flash of lightning is merely a very large electric spark. The peculiar zig-zag form, sometimes apparently almost doubling back on itself, the occasional bifurcations, and various other phenomena of a lightning flash, are all shown by the powerful sparks from an electric machine. [These sparks were exhibited directly; and then photographs of some of them were exhibited.]

The spectroscope has recently given us still more convincing evidence of their identity, if any such should be wanted.

The bifurcations of a flash can puzzle no one who is experimentally acquainted with electricity, but the zig-zag form is not quite so easily explained. It is certainly destroyed, in the case of short sparks, by heating the air. [Photographs of sparks in hot and in cold air were



exhibited. One of each kind is shown in the woodcut. The smoother is that which passed through the hot air. The other passed through the cold air nearer the camera, and is therefore not quite in focus.]

Now heating in a tube or flame not only gets rid of motes and other combustible materials but it also removes all traces of electrification from air. It is possible, then, that the zig-zag form of a lightning flash may, in certain cases at least, be due to local electrification, which would have the same sort of effect as heat in rarefying the air and making it a better conductor.

A remark is made very commonly in thunderstorms which, if correct, is obviously inconsistent with what I have said as to the extremely short duration of a flash. The eye could not possibly follow movements of such extraordinary rapidity. Hence it is clear that when people say they *saw* a flash go upwards to the clouds from the ground, or downwards from the clouds to the ground, they must be mistaken. The origin of the mistake seems to be a *subjective* one, viz., that the central parts of the retina are more sensitive, by practice, than the rest, and therefore that the portion of the flash which is seen directly affects the brain sooner than the rest. Hence a spectator looking towards *either* end of a flash very naturally fancies that end to be its starting-point.

(*To be continued.*)

OBSERVATIONS ON ARCTIC FOSSIL FLORAS WITH REGARD TO TEMPERATURE

THE first feelings of surprise caused by the discovery of remains of warmer-temperate, sub-tropical, and even tropical plants within the Arctic circle, of, geologically speaking, comparatively recent age, have now died away, and we no longer find that their presence there forms so favoured a theme for speculation. The time appears to have arrived when we may critically examine the botanical evidence upon which estimates of the past degree of warmth enjoyed by the Arctic regions have to be formed. The method open to us is very simple: we have, it seems, only to first set aside determinations that are clearly little more than guesses; then ascertain the minimum mean temperature required by the remaining groups of plants to flourish at the present day; and the sum of these temperatures should furnish reliable results for each period.

I am not yet able myself to carry this inquiry beyond the ferns and conifers, but the determinations of these are probably so very much more accurate than those of the higher orders of plants as to comprise most of the safer data, and they are sufficiently numerous for the purpose.

My present remarks are limited to the Komeschichten, a horizon supposed in the "Flora Fossilis Arctica," to represent in Greenland the Urgonian or Neocomian of Central Europe. In this Komeschichten two genera of ferns occur which deserve especial consideration, for Prof. Heer makes use of their presence to infer that at that period the Arctic regions were favoured with a sub-tropical or even tropical climate. These genera are *Gleichenia* and *Oleandra*. The correctness of the determination of the supposed Arctic Oleandra is doubtful, and it is best for the present to place them among the guesses. The very sparse indications of sori are not satisfactory, and there are no less than twelve widely-distinct genera possessing species with approximately the same venation. Oleandra is a small genus with but six species, almost confined to the tropics, but two of them grow in Northern India at altitudes of 6,000 and 7,000 feet.

It is quite otherwise with the remains of *Gleichenia*, for these preserve every characteristic of that genus. But while it is perfectly obvious that these are really fragments of Gleichenias, neither the number of species into which Prof. Heer has divided them, nor the inferences as to climate which he draws from them, can be admitted. He has quite unnecessarily, it seems to me, separated the fragments from the Komeschichten into fourteen species, and to these has added two from the Ataneschichten. The prevailing species, *G. Zippei*, if considered to represent the type in its average size, might be made to embrace eight or ten of them without even then approaching the limits of variation seen in the corresponding existing species. *G. Gieseckiana* receives the rather larger pinnæ and *G. gracilis* the smaller, and many others seem separated on trifling or fancied peculiarities, as *G. acutipennis*, which is merely a small, indistinct fragment, with a few rounded depressions, conjectured to mark sori, but which, from their position on the mid-rib, could not well be such. *Gleichenia* is a particularly variable fern. Berkeley mentions (Introd. to "Crypt. Bot.," p. 516, Fig. 110, *b*) that he had seen at Kew the minute pinnules of one of them expanded to three times its normal length, and the margins unfolded by exposure to a warm damp atmosphere. In two full-grown specimens of *G. dichotoma* from Khasia, in the Kew Herbarium, the longest pinnules respectively are one and nine centimetres in length. The Arctic species are, however, closely represented by *G. glauca* (*G. longissima*, Hook., "Syn. Filicum"), and in this species the pinnules in different plants vary, from a single locality, between 25 and 2 mm. in length. In making species out of fragments of fossil plants the greater or less liability of the living forms to vary should, it seems to me, be kept in mind, and for general convenience the

greatest possible number, if from one locality and horizon, be included together.

There are not wanting altogether, however, indications of other species, and among them *G. rigida*, *G. rotula*, and *G. micromera* seem to be distinct, but the great majority are simply pectinato-pinnatifid, and possess no really distinctive specific characters. In addition to this, fourteen species from one locality and horizon appear a very unlikely number to have existed together, for although the plants are sociable and grow massed together, but few species are ever met with living together in the same vicinity. The whole of America, which is the richest continent in species, contains but nine, the varied lands grouped as the Malayan region but seven, New Zealand five, Australia four, &c.; the total number recognised by Hooker in the "Synopsis Filicum" being but twenty-three. The greatest number growing in a restricted area is in North Caledonia, where there are four; but I am not aware whether these are actually associated together.

These Gleichenias are repeatedly alluded to by Prof. Heer as indicating a tropical nature for the Arctic cretaceous flora, but so far as their presence goes, they by no means imply that a high temperature prevailed. Although no Gleichenia now ranges into high northern regions, they flourish south in the rigorous climates of the Magellan and Falkland Isles, S. lat. 53°, which have an isotherm of less than 45°, and are also found on the high mountains of Tasmania and on the Andes at 10,000 feet, which is, according to Humboldt, the level of gentians and near the limit of arborescent vegetation. The group of Gleichenias from the colder regions of South America all resemble each other in much the same degree as those of the Arctic regions did, and all possess small, hard, rigid, pectinato-pinnatifid pinnæ. Among them are *G. pedalis*, *G. cryptocarpa*, and *G. quadripartita*, all of which, but especially the former, vary considerably, being either long or shortly pectinate. It is a suggestive fact that the existing representative of these Arctic Gleichenias is the only one that still ranges into northern temperate regions, such as China and Japan, while the representative of the English Eocene species is an essentially tropical form.

The Arctic group of Gleichenia appears to have very little affinity with European fossil plants of similar age, except through *G. Zippei*. Heer connects one with *G. comptoniæfolia*, from Aix-la-Chapelle, although there is little discoverable resemblance between them. To do so he has to point out a discrepancy between the drawing and the description, and although he had never seen the specimens, prefers to rely on the drawing which Dr. De Bey now disclaims as incorrect. The Aix-la-Chapelle types are really quite different and more varied, and link them with our own eocene species. This latter is an essentially tropical type, and completely distinct from either the fossil Arctic group or the existing forms from the cold southern latitudes, since it closely approaches *G. dichotoma*, the only type of a well-defined section of the genus, now almost universally distributed over the tropical world.

The Gleichenias seem first to have appeared in the Jurassic, to have passed away from Europe before the close of the Eocene period, and to be now decidedly characteristic of the southern hemisphere—very few species crossing the equator, although the representative of the fossil Arctic species still extends as far north as Japan. It is obvious that we need not, from their presence, assign a very high mean annual temperature to the older cretaceous period in Greenland.

J. S. GARDNER

METEOROLOGY IN JAPAN

WE have read carefully and with great pleasure the *Memoirs* of the Science Department of the University of Tokio, Japan, vol. iii. Part i., which gives the report of the meteorology of Tokio for 1879, by Prof. T. C. Mendenhall. The observations, which are carried on in the west wing of the small observatory attached to the University, were commenced in January 1879, and this is the first report issued by the Observatory. The instruments are from Negretti and Zambra, and, with the exception of the thermometers, they appear to have been placed in suitable positions. The thermometers are mounted outside the north window of the second floor, and are separated from the observing room by glass doors, which are opened for observation. This position of the thermometer is in several respects objectionable, but particularly as it precludes any comparability, beyond a rough one, between the temperature observations at Tokio and at other stations which are or may be established in Japan.

The hours of observation are 7 a.m., 2 and 10 p.m., an arrangement of hours, it may be remarked, which states the mean temperature of the six warmest months of the year about three-fourths of a degree too high, and further does not approximate with the desired closeness to the important diurnal turning-points of the barometric pressure. It is however right to add that it is declared desirable to increase the number of the observations to at least five or six during the day as soon as the necessary arrangements can be made, and to institute a series of hourly observations for approximately determining several of the diurnal curves. An arrangement, if possible to be carried out, for the erection of continuously-recording instruments, would be an important gain to Japan meteorology.

The observations are published *in extenso*, and are illustrated with great fulness by excellent diagrams, which show in a clear manner the main results of the year's observations, the diagrams being lettered and numbered so as to serve for both the English and the Japanese editions which are issued.

The mean pressure for the year at 32° and sea level is given at 29·952 inches, the monthly maximum, 30·093 inches, having occurred in January, and the minimum, 29·809 inches, in August, thus showing a tendency in the atmospheric pressure to be assimilated to the annual march of pressure in the continent adjoining. There having occurred no typhoon during the year, the lowest barometer was only 29·087 inches, which happened on February 23, and the highest, 30·515 inches, on April 21, the range for the year thus being 1·426 inch. The mean diurnal range from 7 a.m. to 2 p.m. is large, being 0·059 inch for the year, regarding which Prof. Mendenhall remarks that "this same relation exists in each set of monthly means with two exceptions." These exceptions are May and September, the ranges for which being, as printed in the means, 0·028 inch and 0·019 inch. On comparing these ranges with those for the other months, they are at once seen to be physically impossible; but by averaging the observations themselves for these months these exceptionally low ranges turn out to be due solely to errors of computation. The true range given by the observations for May and September are 0·047 inch for each month. The exceptionally large range for July, viz., 0·085 inch, is also an error of computation; the true range was only 0·052 inch, the mean range at Tokio being, as in corresponding latitudes of the Atlantic, less in the summer than in the winter months.

The lowest temperature for the year was 24°·1 on January 2 and 7, and the highest 93°·0 on August 15. The temperature fell to or below freezing (32°) on 46 days, 27 of these days being in January, and rose to or above 90°·0 on 12 days, 7 of these days being in July and 5 in August. The mean annual temperature deduced from the 7 a.m., 2 and 10 p.m. observations was 58°·5, and from the maximum and minimum observations 58°·0, the higher temperature of the former being due to the 7 a.m. observations. If this were changed to 6 a.m. the hours of observation

would then be equidistant, which would furnish data for a more exact determination of the mean temperature.

Perhaps the most interesting part of the Report is what relates to the wind which is discussed with no little ability and fulness. The results establish beyond doubt that the wind blows more frequently from N. and N.W. than from any other directions, and that these are especially the directions from which winds of high velocity come. This is strikingly shown by the fact that 75 per cent. of all the high winds which occurred during 1879 came from N. and N.W. The N. and N.W. winds prevail from November to March, and S. and S.E. winds from May to August, the other months being transitional; and with reference to these S. and S.E. summer winds it is clearly shown that they blow with a much less absolute velocity than do the N. and N.W. winds of the winter months.

Of almost equal importance are the facts of the rainfall. The amount for 1879 was 58·98 inches, the rainiest months being May, June, September, and October, and the driest, November, December, January, July, and August. The rainfall is sorted according to the direction of the wind with which it fell; and the highly interesting results are arrived at that the greater number of rainstorms come from N. and N.W., that the heaviest rains come with N.W. winds, and that in no season are the S. and S.E. winds, not even in summer when they are the predominating winds, accompanied with the maximum rainfall as compared with other wind-directions. The rainfall partitioned in percentages according to the winds with which it fell were N. 18, N.E. 9, E. 9, S.E. 5, S. 7, S.W. 3, W. 17, and N.W. 32, there falling thus 67 per cent. of the whole rainfall with N., N.W., and W. winds.

Among the changes it is proposed by Prof. Mendenhall to be introduced are improved hygrometric observations, which were evidently not trustworthy for 1879; observations of earth-temperatures down perhaps to a depth of 40 feet; an extension of the anemometrical observations; observations of variations in the velocity of sound under different meteorological conditions, the data being obtained from the time-gun, which is fired at noon daily; and a systematic investigation of the phenomena of earthquakes.

But what is urgently required in developing the meteorology of Japan is, beyond all question, the establishment of a network of stations over the Islands equipped with trustworthy instruments. The sub-tropical situation of Japan between the largest continent and the largest ocean of the globe is, from a meteorologist's point of view, unique; and the report now under review points to meteorological peculiarities in its climate of the highest interest. A satisfactory statement of its climatic peculiarities is, as our readers are aware, a desideratum; and the information which could not fail to prove of the highest utility to the Japanese, and is certain to cast important lights on the meteorology of Asia and the Pacific, and particularly on the meteorology of this ocean about latitude 33°, south to which the islands extend, can be furnished from no other source than from a network of meteorological stations overspreading Japan.

MINERAL STATISTICS OF VICTORIA

For some years past the yield of gold in the colony has been steadily decreasing. In 1868 the quantity of the precious metal obtained from alluvial deposits amounted to 1,087,502 ounces, and from quartz-veins 597,416 ounces, making in all 1,684,918 ounces of gold. Last year the quantities were respectively—alluvial, 293,310; quartz, 465,637: making a total of 758,947 ounces. The comparatively rapid diminution in the supply from alluvial sources is quite intelligible, as these must necessarily be soonest exhausted, though it is important to observe that in 1879 for the first time for eleven years the return from this source shows a decided advance on that of the preceding year, which is attributed to a better supply of water for sluicing operations, and to the opening up of deep mining ground. It is to quartz-mining, however, that the colony must look for the further development of her gold-fields. There has been a gradual decline in the yield from quartz-mines since 1872, when the amount obtained was 691,826 ounces. But the Secretary for Mines in his recent report speaks hopefully of the probable future of this important industry. Up to the end of 1879 the total quantity of gold raised in Victoria is estimated to have been 48,719,930 oz. 11 dwts., valued at 194,879,722*l*. The proportion of gold in the quartz varies considerably in different districts. Thus, last year at Castlemaine the average yield of each ton of quartz was 5 dwts. 18·45 grs., while in Gippsland it amounted to 1 oz. 2 dwts. 18·66 grs. The quartz of the latter locality is by much the most auriferous in the colony. The decrease in the supply of gold has been accompanied by a falling off in the number of miners. The men who found employment in gold mining in 1874 was 45,151; last year they numbered 37,553, which was an increase, however, of 917 over the number for 1878. The mining population includes an industrious and unpopular contingent of Chinamen, who last year amounted to 9,110, or 528 fewer than in the previous year. Taking the total annual yield of gold and dividing its value among the miners employed, the earnings of an alluvial miner are rated last year at 48*l*. 10*s*. 1½*d*. per annum., while those of the quartz miners are given as 118*l*. 8*s*. 7*d*. Deep mining in quartz reefs continues to make progress, and the mines are becoming every year deeper. Some shafts are now more than 2,000 feet deep. The revenue derived by the colony from the gold districts amounted last year to 15,641*l*. 16*s*. 9*d*., being a slight advance on that of 1878.

PHYSICS WITHOUT APPARATUS[1]

II.

Amongst the elementary principles of mechanics which are capable of easy illustration without special apparatus is that of the centre of gravity. In every solid mass a point can be found such that the resultant of all parallel forces acting on the individual particles passes through it, and such forces balance themselves around this point. The gravitation-force of the earth is exerted towards its centre, but this being 4,000 miles away, the individual forces acting on the separate particles of a body on the earth's surface may be regarded as parallel forces. Hence the centre of the parallel gravitation-forces is termed the centre of gravity. If the centre of gravity be supported, that is to say, if the resultant force be met by an equal and opposite force of resistance, then the body will not fall. The leaning tower of Pisa does not fall because, in the first place, the mortar is strong enough to bind the masonry into a substantial whole, and, in the second place, because the obliquity of the inclination of the tower is not so great as to throw the centre of gravity beyond the supporting base. A vertical plumb-line dropped down from the centre of gravity of the tower would meet the ground inside the base. It is very easy to imitate the leaning tower by taking a common wooden roller and sawing off a piece with oblique ends. The toys which are sold under the name of the Toy Blondin also illustrate the principle of the centre of gravity. A metal figure slides or walks down a stretched string, being kept upright by means of a weight fixed to the end of the rod held in the hand of the figure, thus causing the centre of gravity of the whole to fall below the point of support. A simple way of showing the same thing with improvised material is illustrated in Fig. 3. A couple of forks are stuck into a cork.

[1] Continued from p. 322.

Their weight being considerable, the centre of gravity of the combination is below the cork, and if the cork be placed on the tip of the figure or on the lip of a wine-bottle, it will stand there securely even while the bottle is

Fig. 3.

emptied. M. Tissandier has revived another illustration of the same principle which is capable of evoking roars of laughter at a dinner-table. If a dish of snipe has been served up the head with its long beak may be fixed in a

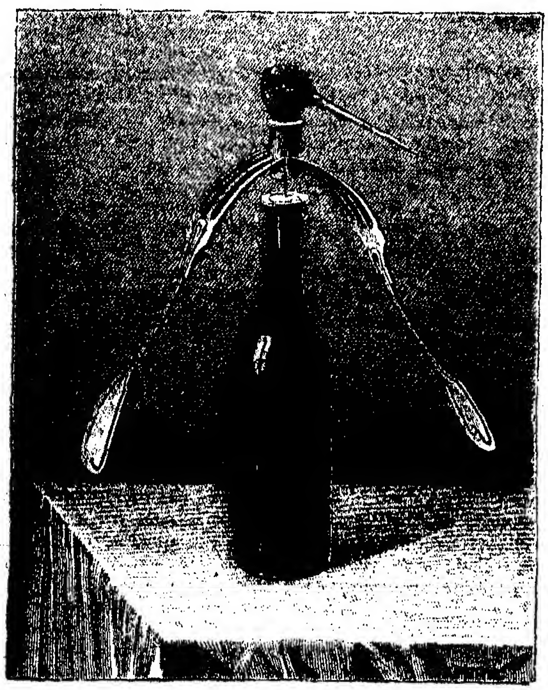


Fig. 4.

cork; and then, two forks being thrust into the sides of the cork and a needle having been fixed into the lower end of it, the cork can be balanced upon a coin laid on the top of a wine-bottle, and can be spun slowly round while the snipe's head nods at the various members of the company in turn, and finally stops opposite one of them (Fig. 4).

A pretty mechanical toy formerly sold in many shops, but now rather rarely met with, is explained upon the principle laid down above. Two small wooden figures with large feet, and holding a couple of poles palanquin-wise between them, are set at the top of a flight of toy stairs. They descend performing summersaults over one another. Fig. 5 shows how the two figures are set at starting. The poles which they grasp are in reality glass tubes plugged at the ends and containing a small quantity of mercury. The figures are themselves made of very light wood, and the quantity of mercury is adjusted to a nicety, so that its position in the tubes determines the position of the centre of gravity of the combination. Fig. 6 shows the position of the mercury in the end *a* of the tube. At this stage of the movement the figure marked R is still standing on the topmost step. The other figure, S, is descending, as shown by the arrow. The position of the figure S, with the feet foremost, is determined by light silk threads which connect the shoulders of R with those of S, and in this position S has the advantage in weight over the counterbalancing mercury at *a*, hence S continues to descend until the tubes have passed the position in which they are level. Once past this position the mercury runs down from *a* to *b* and brings down S firmly on to his feet on the second step. At this juncture the arrangement of the various parts will be that indicated

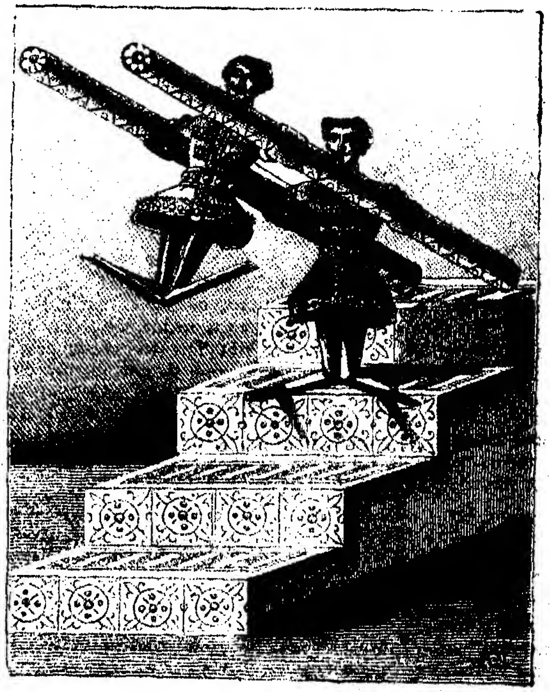

Fig. 5.

in Fig. 7. The hands of S now become the pivot about which the poles can turn and the mercury in *b* is collected right in the bottom of the tube, where it has the greatest leverage. The feet of R (which are

proportionally the heaviest part of him) are near to S, and his centre of gravity is therefore comparatively near to the pivot about which the combination is going to revolve. Hence while *b* sinks, R rises, and as he performs his

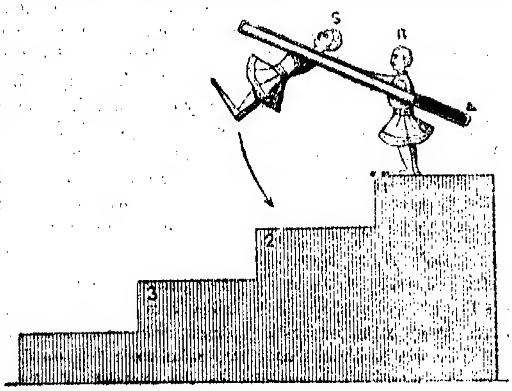

FIG. 6.

flight through the air over the head of S the silken strings gradually bring his feet forward until at last he has turned them forward so much that he has the greater leverage over the counterbalancing mercury at *b* and

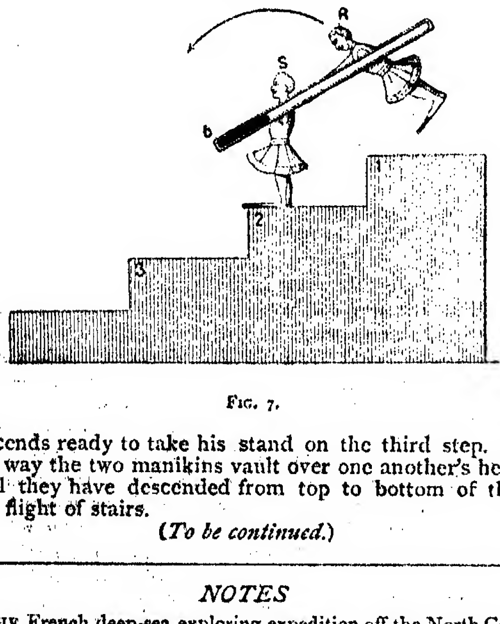

FIG. 7.

descends ready to take his stand on the third step. In this way the two manikins vault over one another's heads until they have descended from top to bottom of their tiny flight of stairs.

(*To be continued.*)

NOTES

THE French deep-sea exploring expedition off the North Coast of Spain in the Bay of Biscay, last month, appears to have been very successful, and to have fully confirmed the great reputation formerly earned by our neighbours in similar undertakings throughout the wide ocean. No less than 103 soundings were taken. The fauna agrees with that which was observed in the *Porcupine* cruise of 1870 along the western coasts of Spain and Portugal; and there are corresponding inequalities in depth. We understand that, with the approval of the French Commission, Dr. Gwyn Jeffreys will give an account of this expedition at the Swansea meeting of the British Association. The Paris report in the *Times* of August 5 is not quite correct.

THE American Association for the Advancement of Science meets this year at Boston, on the same day as our own does at Swansea, August 25. From the Local Committee's circular, which has been sent us, it is evident that a "good time" is in store for those who attend the meeting, and they are likely to be many. It seems to us that the organisation of the American Association is much better than ours, though it will be seen from last week's NATURE that the Swansea Committee have taken great pains to give the British Association an agreeable reception. The Boston Local Committee contains many well-known names, and is subdivided into a Committee-at-Large, Reception Committee (which includes the names of numerous ladies, headed by Mrs. Louis Agassiz), Committees on Finance, Railroads, Hotels and Lodgings, Rooms for Meetings, Mails, Express, and Telegraph, and Excursions. On these committees we find such names as Ralph Waldo Emerson, Asa Gray, Oliver Wendell Holmes, Henry W. Longfellow, A. Graham Bell, A. Agassiz, and many others eminent both in science and literature. The arrangements for excursions and receptions seem admirable, and the *savants* will have a terrible round of pleasure to undergo. Among other provisions by the Local Committee is a daily free public luncheon between the morning and afternoon sectional meetings, for the purpose of keeping the members together. The circular contains all information about hotels and lodgings, receptions, excursions, meetings, &c., and ample provision has been made in the various rooms for experiments and illustrations. The rooms will be connected by telephone with each other, with the hotels, and with the general telephone circuit of Boston and Cambridge. Indicators in each of the sectional rooms, as well as in the secretary's room and in the hotel selected for head-quarters, will show at any moment what papers are under discussion in each of the sections. Among the public addresses to be given during the meeting are those of the retiring president, Prof. G. F. Barker, the vice-president of Section A, Prof. Asaph Hall, and the vice-president of Section B, Mr. Alexander Agassiz.

THE Annual Meeting of the British Medical Association was opened at Cambridge on Tuesday, under the presidency of Prof. Humphry.

THE Institution of Mechanical Engineers had a very successful meeting last week at Barrow-in-Furness. Every facility was afforded the members for inspecting the many objects of engineering interest in Barrow and its vicinity. The papers read were all of more or less technical interest.

ON Thursday last the Anthropological Congress was opened at Berlin in the presence of the Crown Prince and Princess of Germany and of many distinguished literary and scientific men. Prof. Virchow delivered an eloquent speech. Dr. Schliemann afterwards gave an account of his discoveries and excavations. On Monday a banquet was given in honour of Dr. Schliemann and Prof. Nordenskjöld, who, on Tuesday, were entertained by the Crown Prince.

IN connection with the vote for the British Museum on Monday there was some talk as to the organisation of that institution and of the new Natural History Museum. Mr. Walpole spoke hopefully of the early transference of all the collections destined for the South Kensington buildings, while Mr. Story-Maskelyne, tenderly remembering his former colleagues, advocated the erection of houses for the officials. There was a good deal of vague and unsatisfactory talk about the distribution of duplicates to provincial museums. This is evidently a matter that requires clearing up, and it might be well to take means to decide once for all what are duplicates and what would be the best method of disposing of them. Mr. M'Cullagh Torrens thought there was great room for reform in the method of appointing the Trustees of the British Museum, who are far from being representative; there should, he thinks, be a larger infusion of the scientific element among them.

A CORRESPONDENT sends us some notes as the result of a visit to the Belgian National Exhibition at Brussels. The total

extent of the ground is 300,000 square metres, and the area covered by the palace 70,000. The number of exhibitors is 7,000, or more than one for each 1,000 inhabitants in a population of about 6,000,000. Two of the pavilions are occupied by the two principal telephonic companies, who are competing at Brussels, Antwerp, and Verviers, where rival central offices have been built, and are besieged by a crowd of experimenters. The number of tickets sold at the gate is about 10,000 a day, which is considered a success. It was attempted to establish a captive balloon on the model of the large Giffard captive balloon on a reduced scale, the rope being only 300 metres long instead of 500, and the volume 8,400 cubic metres instead of 25,000. But in spite of this diminution the balloon refused to go up, the hydrogen having been mixed with a large quantity of common air. The Belgian balloon has been disinflated, and fresh efforts will be made to fill it with better gas, but success is considered rather doubtful. Except this disappointment, which it shares with Berlin, Vienna, and New York, where attempts to start a captive balloon failed, everything is going on remarkably well at Brussels. It is difficult to give a brief description of all the objects worthy of notice in this wonderful display of Belgian enterprise and skill. In the engine hall a facsimile of the first locomotive constructed on the continent has been placed. It bears the date of 1835, and an inscription shows it was made by Cockerill for the Belgian Government Railway. One of the wonders of the Exhibition is the collection of models of mining, showing all the incidents of underground workings and living. Scientific societies and Government exhibit complete collections of the mineral and vegetable kingdoms within the limits of Belgian territory. Every provincial Government is an exhibitor, and also the various Central Government Departments. The Belgian Photographic Society has organised a very good display. The Brussels Observatory has sent a model of van Rysselberghe's self-registering meteorograph. This apparatus is in operation at the Brussels Observatory, in Antwerp, at Ostend, and at Arlon. When the Belgian Observatory is moved to a new situation at some distance from the city, all these instruments will be connected with it by a special telegraph wire, so that the physicists of the Meterological Office will write their predictions in a room where they will be able to watch the development of meteorological phenomena all over their native country. An electrical railway has been established in the gardens, and is working all day long with perfect regularity. The number of waggons is three, each of them carrying six passengers, with a velocity of 3 metres per second, to a distance of 300 metres, for 3*d*. The locomotive, of which the weight is 800 kilogs., carries a Gramme machine, worked by another machine, which is stationary. There is also in another part of the city a so-called International Exhibition, but this, although opened in state by the King, is merely a private speculation, without having any special feature or deserving any particular notice.

SIR WILLIAM HARCOURT stated in the House of Commons the other day that it is hoped that the work of the Cambridge University Commissioners will be completed before the Christmas Vacation.

PROF. MENDELEEF is at present in the Caucasus. He intends to visit Vladikavkaz, Tiflis, Batoum, and Poti, whence he proposes to proceed to Kertch to inspect the sources of petroleum.

THE ladies continue to keep well to the front in the University of London Examinations. In the first division of the first B.Sc. examination the fourth on the list is Miss Sophia Bryant. The other five ladies are well up in this division, there being none so low as the second. In the first division of the first B.A. Examination the second on the list is Miss Catherine Eyre Anelay.

GREAT activity prevails at the Meudon aëronautical school, where the French Government has established extensive works for the construction of a large number of war balloons. Each of these, 10 metres in diameter, will be made of silk, varnished by a process invented in 1794. The valve is to be made of metal, and the shape will be quite spherical. Not less than forty of them will be sent to the several French armies for the purpose of making captive or free ascents when required. Of these more than half have been already constructed. The construction of furnaces for the preparation of pure hydrogen has not begun yet. The warehouse is large enough to contain inflated balloons, which can find exit by the roof. All the men and officers (except one) belong to the corps of Military Engineers. All the works for building directing balloons have been stopped.

THE *Daily News* Naples correspondent writes that Prof. Silvestri wrote from Catania on July 15 that since his report on May 1 last about the eruption of ashes from Mount Etna he has observed many other interesting phenomena. On May 16 and 17 last some slight shocks of earthquake were felt on the east side of Mount Etna, especially in the district of Acireale. About a month later the shocks commenced again and were repeated on several consecutive days—that is on June 15, 16, 17, and 18. The motion was undulating. About two days before these manifestations a new and very active phase of mud eruptions set in at Paterno, on the south-east of Etna. Two craters opened, which violently ejected gaseous matter with abundant torrents of mud, more consistent than usual, and of a higher temperature (140 degrees Fahrenheit), which, accumulating in the basins in large masses, finally broke through all barriers, overflowed and destroyed the adjoining fields, and buried several mills and farmhouses. In this eruption Prof. Silvestri noticed an abundant development and pressure of gaseous matter, of such force that it produced oscillations strong enough to tear up the old lava, forming rents out of which the gas rushed with the noise of a boiler letting off its steam. Coincident with these phenomena clouds of vapour issued from the eruptive fissure of last year, confirming the opinion formed by the Professor before —namely, that this fissure, lying between the two principal craters of 1879 and the great central one, had not been blocked with lava, but was still in communication with the central eruptive axis, for vapour, mixed with ashes which fell all over the cone, also issued from the central crater. This activity continued during several days, and still continues with decreased intensity, seen from Catania in the shape of dense clouds covering the whole summit of Etna in a clear sky. Changes have taken place which have entirely altered the form of the central crater. The old ravine, which formerly crossed the crater and made two-thirds of it into an ample and easily accessible basin, a natural laboratory for the study of the products of the volcano, now exists no longer. The central crater, from the effects of violent commotions, has crumbled, and, with part of its sides and the high point whence it was formerly possible to enjoy the sunrise, has been precipitated into the ravine, diminishing the height of the mountain by about 40 feet, while the circumference of the crater has become wider by half a kilometre. The general destruction of the old sides has in a certain way rejuvenised the crater, which has regained its characteristic form of a funnel, at the bottom of which is now the eruptive mouth.

A LETTER from San José de Guatemala, dated July 2, to the *Panama Star and Herald*, says:—"At 3 a.m. on June 29 the volcano Fuego suddenly became active, throwing out vast showers of fire and cinders, with great darts of flame shooting up from 350 feet to 500 feet above the mouth of the crater. The whole country to the east and south was magnificently illuminated. At 3.40 a.m. two streams of lava could be seen running down the sides of the volcano, one to the south and east, the

other to the westward. Dense masses of steam and smoke rose from the courses of the lava streams, as the shrubbery and foliage were burnt. The river Guacalate rose suddenly, and its waters were quite warm. Fuego continued to belch fire until daylight, by which time the whole northern horizon, looking from San José, was dark with the smoke from the volcano. The lava streams continued in view until 4.30 a.m. The first grand column of fire rose at least 500 feet in height, solid and smooth, and then the top, expanding, opened out like an umbrella, the sparks coruscating like those from a brilliant rocket. The pulsations of flame during the first two hours of the eruption were about 50 seconds apart, strong and regular. The eruption was less active until, at 7.30 p.m. on July 1, a column of flame rose to a height, probably, of 150 feet or more. At the hour of writing Fuego smokes away steadily."

A REMARKABLE thunderstorm is reported as having occurred on July 24 last at Moylough, county Galway, Ireland. The storm, which was very vivid and accompanied by a most destructive fall of enormous hailstones, lasted about an hour and a half. One of the strongest discharges took place in a field about a mile from Moylough Church. The spot is described as presenting on a large scale an appearance like that of a sheet of cardboard that has been pierced by the discharge of a battery of Leyden jars. A long branching furrow, upturned as if by a plough, was found, a deep hole being bored at each end of six terminal branches, the earth round the holes being raised as if pushed up from below. Tufts of grass were scattered thirty and forty yards from the place.

MR. W. BRANKSTON RICHARDSON, writing from 61, Sutherland Gardens, Maida Vale, sends the following dog-story to the *Times*:—"Concurrently with the forty days' fast of the misguided American doctor, another fast has been in progress in our own country, for the truth of which I myself can vouch. A friend of mine who lives in Devonshire left home some weeks since on a series of visits to his friends in distant parts of the country. A few days after he left his servants wrote him that a favourite Skye terrier was missing. My friend, after every search had proved fruitless, considered that the dog had been stolen. On his return home, after an absence of one month and five days, he unlocked the library, the doors and windows of which had been bolted and barred during his absence, and to his astonishment the missing dog crept out into the light, a living skeleton and totally blind. He was well cared for, and has now quite recovered his health and sight. But his existence was wonderful. He had had no food and no water, and had not gnawed the books or obtained sustenance from any source whatever."

IT is at present too early to offer an opinion as to whether "Brook's Popular Botany: comprising all the Plants, British and Foreign, most useful to Man in Medicine, Food, Manufactures, and the Garden," is likely to answer to its title, since so much depends on its completeness. In the two numbers which we have at present received the letterpress seems fairly accurate, if not scientifically precise; but the illustrations are on too small a scale, and altogether wanting in detail. The publication is at all events cheap enough.

THE City of Nancy has instituted at its own expense a competition among aëronauts. A premium of 80*l*. has been offered to the aëronaut who on an ascent made from Nancy shall have made the best observations. MM. Eugène Godard and Duruof have entered the lists.

IN the beginning of September a statue erected to Pascal by ublic subscription will be inaugurated at Clermont. The principal address will be delivered by M. Bardoux, ex-Minister of Public Instruction, and member for Clermont.

EVERY year the laureates of the Municipal Schools of Paris travel during their holidays at the expense of the Municipality. The pupils of the Turgot School will visit Chambéry, those of the Lavoisier School, Havre, and those of the Colbert School, Chambéry. The pupils of the J. B. Say School will go to Clermont-Ferrand and witness the inauguration of Pascal's statue.

M. MAURICE KOECHLIN of Mulhouse, although born deaf and dumb, has passed successfully his examinations for baccalaureat at Rouen. He was educated by M. Hugentobler, director of an institution for such unfortunate persons. This young man is only sixteen years old, and his wonderful success has created quite a sensation.

THE Sixth Annual Report of the Yorkshire College for 1879-80 speaks with satisfaction of the progress of that institution. Instruction is now given in fourteen distinct subjects by twelve professors, lecturers, and instructors, aided by nine assistants. The number of students had increased to 142 from 113 of the previous year; there were besides 52 medical and 148 occasional students.

THE additions to the Zoological Society's Gardens during the past week include two Lesser Black-backed Gulls (*Larus fuscus*), British, presented by Mr. Beazley; a Horned Lizard (*Phrynosoma cornutum*) from Texas, presented by Mr. Luiz de Tavaris Ozorio, a Red-handed Tamarin (*Midas rufimanus*) from Surinam, two Russ' Weaver Birds (*Quelea russi*) from West Africa, deposited; a Servaline Cat (*Felis servalina*), a Coquetoon Antelope (*Cephalophus rufilatus*) from West Africa, a White-cheeked Capuchin (*Cebus lunatus*) from Brazil, four Brown Capuchins (*Cebus fatuellus*) from Guiana, two Swainson's Lorikeets (*Trichoglossus novæ-hollandiæ*) from Australia, an Anaconda (*Eunectes murinus*) from Demarara, purchased; a Mesopotamian Fallow Deer (*Cervus mesopotamicus*), a Gaimard's Rat Kangaroo (*Hypsiprymnus gaimardi*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

COMETS OF SHORT PERIOD.—Faye's comet was detected by Mr. Common at Ealing, with his large reflector, on August 2, in the position given by Dr. Axel Möller's ephemeris. The theoretical intensity of light at this date was 0·078, which rather exceeds that at the first and last observations at the appearance in 1850-51. The comet was very small and extremely faint when the sky was not quite black. The perihelion passage does not take place until January 22, 1881, but although long visible, the faintness of the comet will prevent its being well observed at any time with ordinary telescopes. Since its last appearance in 1873, when only four observations were secured, the effect of perturbation has been to lengthen the period 56·5 days, and to retard the arrival at perihelion by 38 days, the main part of this perturbation having been produced by Jupiter in 1875.

Prof. Oppölzer has published an ephemeris of Winnecke's comet from elements brought up to the next perihelion passage (December 4). The track of the comet will be so unfavourable that it is very doubtful if observations can be obtained at this return. If the comet be glimpsed at all, it is most likely to be during the month following December 20, for which period, that nothing may be wanting on his part, Prof. Oppölzer has given an accurately-calculated ephemeris, which he thinks will indicate the position within two minutes of arc. The three returns in 1858, 1869, and 1875 were connected, taking into account the perturbations by Jupiter and Saturn, and Herr A. Palisa determined the effect of the same planets (first-power perturbations) from 1875 to December 1, 1880. The effect of a resisting medium was likewise included, Prof. Oppölzer having, as we lately recorded, found evidence of its sensible influence on the motion of this comet, unless a correction be applied to the received mass of Jupiter, which seems hardly admissible to the extent required.

Encke's comet will again arrive at perihelion about the first week in November, 1881, after which no one of the comets of short period will be due until January, 1884, but before that time it may be anticipated that the comet of 1812 will have

arrived in these parts of space. A search for this body with the aid of Prof. Winnecke's sweeping ephemerides is desirable forthwith, the length of the revolution not appearing to be determinable within very narrow limits from the observations of 1812, and there being no other recognised appearance.

IS η CYGNI A VARIABLE STAR?—Writing in September, 1842, Sir John Herschel drew attention to this star, which he said appeared to have increased very considerably in magnitude since the date of Piazzi's observations. In 1842 it was "the principal star in the neck of the Swan, and of nearly the fourth magnitude, very conspicuous to the naked eye, and making in fact the only very distinctly seizable point between *Albireo* in the beak and the bright star γ in the body."

Piazzi, who observed the star nineteen times in right ascension and eleven times in declination, calls it 6·7 m. D'Agelet had estimated it 4·5 on July 29, 1783, and 5 on September 17, 1784; Lalande, 5 on August 12, 1793, and 4 on July 14, 1797; Bessel in his zone 436 on September 8, 1828, calls it 3 m. (!); Argelander and Heis, 4·5. Thus Piazzi's estimate appears to be lower than in the case of any other modern observer, but it is to be noted that Flamsteed reckoned the star no higher than the *sixth* magnitude.

η Cygni seems to deserve some attention at the hands of observers of the variable stars.

GEOLOGICAL NOTES

GEOLOGY OF BELGIUM AND THE NORTH OF FRANCE.—M. Mourlon of Brussels has just published a work devoted to the general geology of Belgium. It describes the formations in chronological series, and is illustrated with maps, sections, and plates of the microscopic structure of rocks. A useful feature in it is a full bibliography of Belgian geology brought up to date. The new Government Geological Survey of Belgium has just published three sheets of maps, with sections, and explanatory notices. The maps, on a scale of $\frac{1}{20000}$, are printed in chromolithography and on a novel plan. The ordinary topographical features—roads, fences, trees, houses, &c., are printed in different colours, according to the tertiary formation lying underneath. Thus the Wemmelien (Eocene) areas are at once recognisable by an orange topography, the Oligocene tracts by one in slate colour and the Anversian (Miocene) by one in crimson. The quaternary deposits overlying these formations are expressed by broad tints of colour. The maps are accompanied by "Notices Explicatives," which in the case of the Hoboken and Contich sheets appear as a well-printed 8vo pamphlet of 256 pages, and a sheet of superficial sections on a scale of $\frac{1}{20000}$ for length and $\frac{1}{1000}$ for height. The country delineated and described lies on the low ground drained by the Escaut and Rupel, where, as little can be seen at the surface, a large series of borings has been made. The work has been accomplished by the Baron O. van Ertborn, with the co-operation of M. Cogels. Prof. Gosselet of Lille has just issued the first fasciculus of an essay on the geology of the North of France and the neighbouring regions. It deals with the palæozoic formations, and is accompanied with an atlas of plates of fossils, maps, and sections. No one is so competent as M. Gosselet to describe the older formations of that district which he has so sedulously studied for many years. His volume will be welcomed not only by students in Belgium and the North of France, but by geologists in other countries, who will find in it an admirable *résumé* of all that is known on this subject up to the present time, and references to the more important original memoirs where fuller information can be had.

THE RIGHT OF PRIORITY IN PALÆONTOLOGICAL NOMENCLATURE.—M. Gosselet, in a communication to the Société Géologique du Nord, calls attention to the great inconveniences which arise from the multiplication of names for the same species. He suggests the establishment of an international tribunal for judging of the value of each new species, and for registering it, with its name and the exact date of its publication. He thinks that the expenses of the journal of such a commission would be easily met by the subscriptions of scientific men, and that the duties of the commissioners would not be heavy, as they would need to be consulted only occasionally in doubtful cases, the ordinary routine work being performed by a secretary. As illustrations of the evils of the present system, or, rather, want of system, he cites the history of some Spirifers.

GEOLOGICAL SURVEY OF NEW JERSEY.—Mr. George H. Cook, State Geologist of New Jersey, has issued his unpretending but useful Annual Report for 1879. It contains a record of the development of the mineral industries of the State for last year, and is accompanied with a good map, on which are delineated the various soils as distributed over the area. The iron-bearing rocks of the Archæan series extend from the north across New Jersey, and for several generations iron has been worked in this State. It is chiefly magnetic ore, and is searched for by means of the compass-needle, the attraction of which is noted. The commercial depression which began in 1873 has told heavily on the iron manufacture in the State. Of 200 mines and localities for ore only thirty have been kept in operation during the whole period of depression. There are now hopeful indications however of a revival of the trade. In the midst of information about building-materials, soils, mines, water-supply, and other topics, the writer of the Report continues to find a place for occasional interesting geological facts. His chapters are likely to be of much service to his fellow-citizens, who, it is pleasant to learn, show their appreciation of these Annual Reports, of which many of the former volumes are out of print.

GEOLOGICAL SURVEY OF ALABAMA.—The Geological Survey of this State is very modestly equipped. Its director, Prof. Eugene A. Smith, issues Annual Reports, which show, as minutely as the resources at his command will allow, the geological structure and economic resources of the different counties of the State. But he cannot make bricks without straw. It is short-sighted policy to require a Geological Survey to be made, and to equip it so economically that it cannot efficiently perform its work. In a country where the mineral resources remain in great measure undeveloped, it would be a wise expenditure of public funds to furnish means for making cuttings or borings where the crop of a seam of coal or vein of ore might be revealed at a short distance below the surface.

CENTRAL ASIAN GEOLOGY.—We find in the last number of the *Izvestia* of the Russian Geographical Society information as to the geological structure of the tracts to be crossed by the Southern Central Asian Railway. Altogether it is a flat and dry desert, covered with recent alluvial formations; the land becomes hilly only in the Mugojar Mountains. At Orenburg, and as far as Mertvyia Soli, there appear Trias sandstones and clays, which cover the Permian limestones, and gypsum with salt-springs (Sletskaya Zaschita). In the neighbourhood of Khanskiy Post we find a formation which probably will have an importance for the railway, namely, the Jura, which contains coal. At Ak-tube the shores of Teres-bvutak, Yakshi, and Djaman-kargal Rivers are craggy, and consist of Permian and Trias rocks. The Mugojar Mountains are formed of pretty green and red jades, and the Djaman-tau Mountains of an augitic porphyry of syenite and granite; gneiss and mica-slate cover the granite on the eastern slope. A kind of fine white clay, being a product of the trituration of rocks, is found at the foot of the Mugojar Mountains on both slopes, and large accumulations of gravel in the form of mounds appear at a short distance from the mountains to the east. The Karakorum steppe affords a series of mounds of sand mostly covered with vegetation and often with very old trees. These mounds are usually motionless, only those which are quite devoid of vegetation (such being exceptional) are set in motion during heavy storms. Altogether the structure of the steppe appears thus: At the base a sandstone, probably Tertiary, horizontally stratified; above this, a clay with gypsum borrowed by former watercourses, and above it the sandy mounds. Water is found at a small depth. Sandstone and clays forming low elongated terraces, and belonging possibly to the Jurassic formation, appear in the neighbourhood of Kara-tougay on the Syr-daria River.

GEOLOGY OF GENEVA.—The Geological Map of the Canton of Geneva, on the scale of 1 to 25,000, together with a "Geological Description of the Canton," in two volumes, by Prof. Alphonse Favre, have been published under the auspices of the Geneva Agricultural Society—the map a year ago, and the "Description" only now. The map is well printed with eight colours very agreeable to the eye, and sufficiently transparent not to obstruct the topographical details. As to the geological value of this work, the name of M. Favre is a sufficient warrant. The learned professor has spent no less than twenty-seven years in the study of the formations of his Canton. The "Description" consists of four parts. The first gives general notions in geology; the second contains a detailed description of the formations of the Canton, namely, the Molasse, the glacial and the post-glacial deposits

with numerous analyses of soil which give to this part a great importance for agriculture. The third part deals with erratic blocks as to their composition and origin; the fourth part describes subsoils, and contains a description of Lake Leman.

JURASSIC ROCKS OF THE ALTAI MOUNTAINS.—According to the researches of M. Schmalhausen, noticed in the *Memoirs* (*Troudy*) of the St. Petersburg Society of Naturalists, vol. x., the fossils of the Kouznetzk Carboniferous basin in the Altai Mountains, which fossils were described until now as palæozoic by Göppert in Tchikhatcheff's "Travels," by Eichwald, and by Heinitz in Cotta's "Altai," are identical with the Jurassic (Bathonian) plants which Heer has recently described in the Jurassic Flora of Eastern Siberia and Amour. M. Schmalhausen describes them as *Phyllothera*, *Asplenium whitbiense tenuis*, *Pterophyllum inflexum*, *Podozanistes lanceolatus*, Lindl., *Brachyphyllum*, and *Czekanowskia rigida*, Heer.

MIOCENE FLORA.—In his work, "Die Miocene Flora von Sakhalin," just published by the St. Petersburg Academy of Sciences, Prof. Schmidt describes 74 species of plants he has discovered, of which 43 were formerly known in other countries, and 31 are new; 27 are identical with Arctic Tertiary plants, 25 with Swiss, 18 with those of Alaska, and 21 with those of North America. The eighteen Alaska species are the most common of the Sakhalin Miocene flora, which circumstance, as well as the intermediate characters of the Tertiary flora of Kamchatka, is a new argument in favour of Asia, having formed, with America, one continent at this geological period. It is important to observe that the Tertiary flora of Sakhalin has more likeness to that of Greenland, of Spitzbergen, and of Switzerland, than to that of Central Siberia; thus, out of the eighteen species of Tertiary plants discovered by M. Lopatin on the banks of the Choulym River (not far from Krasnoyarsk), none were found among the Miocene fossils of Sakhalin, whilst the Tertiary flora of the southern shores of Lake Baikal is very like that of Sakhalin and of Alaska. To explain these differences Prof. Schmidt supposes that the fossil plants which are all described by Heer as Miocene ought to be considered as belonging to an older substage, all the more that the Sakhalin plant-beds are very intimately connected with the marine chalk which they concordantly cover.

CHEMICAL NOTES

THE influence of sewage on potable waters is again being discussed. Herr R. Emmerich—in *Bied. Centralblatt*—makes an original contribution to the subject. He has for a long time daily drunk from a half to one litre of water from one of the Munich brooks which receives sewage of every kind; he has satisfied himself that there were cases of typhoid in some of the houses which drained into the brook. No bad effects having followed the consumption of this beverage, Herr Emmerich invites other experimenters to pursue investigations similar to his own! The same observer, however, finds that sewage water produces death in rabbits when injected subcutaneously in quantities of from 6 to 60 c.c., rabbits of a similar size being killed by the injection of 200 c.c. of distilled water. The injection of the residue from the evaporation of 500 c.c. of sewage water produced strong convulsions and death in rabbits. He proposes that suspected water may be examined by injecting 40 to 80 c.c. under the skin of a full-grown rabbit; if no rise of temperature greater than 1° occurs, or if death does not quickly follow the injection, the water would probably be uninjurious to human beings drinking it.

CITRIC acid has been formed synthetically by Grimaux and Adam. The process, which is described in the *Comptes rendus*, consists in forming dichloracetonic acid $CH_2Cl—COH\left<\begin{matrix}CO_2H\\CH_2Cl\end{matrix}\right.$ from symmetrical dichloracetone, itself produced from glycerin through the intermediate stage of dichlorhydrin. By saponifying, by means of hydrochloric acid, the sodium salt of dichloracetonic acid, citric acid is produced; this synthesis confirms the generally accepted structural formula of citric acid.

DOUBT as to the elementary nature of sulphur is expressed by Th. Gross because of recent experiments wherein he claims to have produced a black, nonoxidisable, chemically indifferent substance by heating perfectly pure sulphur with linseed oil, dissolving the product in sulphuric acid, and precipitating by sulphuretted hydrogen.

THE influence of very small quantities of foreign substances in modifying processes of chemical change is a subject of much interest to the chemist, although as yet no full explanation has been given of this class of phenomena. In the course of his researches at high temperatures Victor Meyer has given one or two instances of such reactions. Thus he finds that ferric chloride, aluminium chloride, and zinc chloride are decomposed with evolution of chlorine at much lower temperatures when the vapour-density apparatus is previously filled with nitrogen gas than when no foreign gas is present. Meyer cannot trace any connection between the temperature, or amount of decomposition, and the chemical nature of the foreign gas.

THE long-protracted discussion between Berthelot and Wurtz regarding the dissociation of the vapour of chloral hydrate appears at length to be closed; Berthelot admits in the *Comptes rendus* that the vapour is partly dissociated at 100°, and that if the pressure is small the dissociation is probably complete.

AN interesting experiment, and one likely to lead to further results, is described by Berthelot in the *Comptes rendus*. He finds that such unstable compounds as ozone, hydrogen peroxide, &c., are not affected by sonorous vibrations of the rapidity of 100 and 7,200 per second.

M. MEUNIER claims, in *Comptes rendus*, to have produced spinel crystals, and thinks he has also produced periclase and corundum by the action of steam on aluminium chloride, at a red heat, in presence of magnesium.

AMONG other results accruing from V. Meyer's recent determinations of vapour densities is the addition of six or eight substances to the small list of gaseous metallic compounds. From the densities, and analyses, of these compounds the following numbers may be deduced as representing the *smallest possible valency* of the element placed opposite each number:—Arsenic, 2; cadmium, 2; copper, 2; iron, 4; indium, 3; tin, 2; zinc, 2. The formula of stannous chloride is shown by Meyer to be Sn_2Cl_4 at about 700°, but $SnCl_2$ at 900°. Hence the valency of tin varies at different temperatures.

IN the last number of the *Berliner Berichte* an attempt is made by Wiebe to trace a connection between the atomic weights of elements and the molecular weights of carbon compounds, and the coefficients of expansion of the same substances. He shows that for many elements the ratio between the reciprocal of the number obtained by multiplying the atomic weight of an element into the mean coefficient of cubical expression from 0° to 100°, and the heat required to raise unit weight of the same element from absolute zero to the melting-point, is a nearly constant number. For elements crystalising in the regular system the mean value of the constant is 2·6; other elements show considerable divergences. For certain classes of carbon compounds the following equation is shown to hold: $\frac{A \cdot \alpha}{d} \cdot T = n.$ const., where A = molecular weight, α = mean cubical expansion from 0° to 100°, d = density of liquid compound, T = absolute boiling-point, and n = number of atoms in the gaseous molecule of the compound. The constant for the fatty acids and ethereal salts is from 3·1 to 3·8.

IN the *Proceedings* of the Asiatic Society of Japan R. W. Atkinson gives the results of his analyses of several Japanese porcelain clays; these results show that the opinion of H. Wurtz, viz., that Japanese porcelain is prepared from decomposed felspathic rocks alone, without admixture of kaolin, is not generally correct. Many of the clays analysed by Atkinson contained from 54 to 59 per cent. of silica, with 26 to 32 per cent. of alumina; others again contained from 73 to 79 per cent. of silica. In the clays exhibited in the Philadelphia Exhibition Wurtz found only one containing less than 74·5 per cent. of silica.

IN a series of papers by Nilson, and by Nilson and Pettersson, in the last number of the *Berliner Berichte*, important additions are made to our knowledge of the rarer earth metals. The existence of ytterbium seems proved. The atomic weight of this metal is 173 (mean of seven closely-agreeing determinations), assuming the formula of the oxide to be Yb_2O_3. The chief reasons for this formula are the isomorphism and general analogy of the sulphates of ytterbium, erbium, and didymium; the close analogy between the selenite of ytterbium and the selenites of metals which form oxides of the formula M_2O_3, and the molecular heat and molecular volume of Yb_2O_3 compared with the same constants for the group M_2O_3.

REASONS are given for adopting the formula of scandium oxide as Sc_2O_3, and the atomic weight of scandium is determined to be 44·0 (mean of four closely-agreeing results). Scandium is undoubtedly identical with Mendelejeff's ekabor.

THE specific heat of beryllium has been determined by Nilson and Pettersson. Between 0° and 100° the specific heat is 0·4246; between 0° and 300°, 0·5060. These chemists have likewise made a new determination of the combining weight of beryllium, and find it to be 4·55, which is a very little less than the number found by previous observers. They think that the atomic weight of beryllium is undoubtedly 13·65, and not 9·1, as generally supposed; oxide of beryllium is therefore Be_2O_3, and this metal is not to be placed, in Mendelejeff's system, as the first member of the magnesium group. Neither can beryllium form the first member of the aluminium group, as suggested by Lothar Meyer. Nilson and Pettersson detail many facts which lead them to regard beryllium as the first member of the group of cerite and gadolinite metals, which comprises the metals, Be, Sc, Y, La, Ce, Di, Tr, Y_α, Y_β, Soret's x, Er, Tu, Yb. The paper contains many most important chemical and physical data concerning the salts of the metals of this group.

FROM the specific heats of the oxides of beryllium, scandium, gallium, indium, and aluminium, the specific heat of oxygen in combination is deduced by Nilson and Pettersson as being 2·3 to 3·1; the mean specific heat of oxygen in combination is 4·0; the oxides named are therefore somewhat anomalous.

THE "molecular volume," *i.e.*, $\frac{\text{molecular weight of gas}}{\text{sp. gr. of solid}}$, of the various molecules of water of hydration has been recently shown by Thorpe and Watts to vary in the magnesium group of sulphates; Nilson and Pettersson obtain nearly the same number (8·5) as representing the mean volume of each water-molecule in the sulphates of yttrium, erbium, and ytterbium; but a somewhat larger number (11·5) for the mean volume in the sulphates of cerium, lanthanum, and didymium.

PHYSICAL NOTES

IN liquids small particles often show dancing motions under the microscope, and similar motions have been attributed to dust-particles in air, and accounted for by the shock of molecules with the particles. In a recent paper treating fully of the movements of very minute bodies (*Münch. Ber.*, 1879, p. 389) Herr Nägeli calculates from data of the mechanical theory of gases as to the weight and number and collisions of molecules, the velocity of the smallest fungus-particles in the air that can be perceived with the best microscopes, supposing a nitrogen or oxygen molecule to drive against them. It is, at the most, as much as the velocity of the hour-hand of a watch, since these fungi are 300 million times heavier than a nitrogen or oxygen molecule. The ordinary motes would move 50 million times slower than the hour-hand of a watch. Numbers of the same magnitude are obtained for movements of small particles in liquids. In both cases a summation of the shocks of different molecules is not admissible, as the movements are equably distributed in all directions. Herr Nägeli therefore disputes the dancing motion of solar dust-particles, and attributes the Brownian molecular motion to forces active between the surface-molecules of the liquid and the small particles; but he does not say how he conceives of this action.

THE absorption of heat-rays by powders has been lately investigated by Herr van Deventer (*Inaug. Diss. Leid.*, 1879, p. 78, or *Wied. Beibl.*, 6) without use of any binding material. Under a copper cube kept at 100° was brought a thermo-element consisting of a brass plate, on the lower side of which was soldered a piece of bismuth and antimony (parallelopiped shape). On the plate was strewn the powder to be examined. A second similar element, with thermo-element lampblacked, served for control. Briefly, the results were these: (1) Powdered substances in the same physical state have different absorptive power; (2) this depends on the thickness of the absorbing layer: each powder has its maximum absorption layer; (3) quite comparable values for the absorption cannot be bad, as the thickness of the powder layer cannot be exactly determined; (4) the divergences proved in Tyndall's results with different binding materials are attributed to his not having taken into account the maximum emission layer; (5) whether the binding material affects absorption, and if so, how, can be demonstrated by the author's method (the element being painted over with the liquid holding the powder in suspension): but experiments are here wanting; (6) the author's series of powders arranged according to absorption is quite different from Tyndall's emission series.

DR. PULUJ observes that if an electric radiometer is worked for some minutes and then the circuit is broken, a reversed motion is immediately set up, which continues for four or five minutes with an enormous rapidity. This he explains by assuming that there are really two actions tending to produce rotation: the electric reaction between the vanes and the molecules, and the heating of the metallic side of the vanes; that these two actions oppose one another, but that at small pressures, such as the high vacua, the electrical forces are in excess. When however they are brought to an end the heat-forces assert themselves, producing the opposite rotation.

FROM recent experiments (described in *Wied. Ann.*, No. 7) Herr Heitz concludes that the kinetic energy of the electric current in 1 cubic millimetre of a copper conductor, traversed by a current of unit electromagnetic density, is less than 0·008 milligramme-millimetre. As the kinetic energy is equal to half the mass multiplied by the square of the velocity, the mass of the positive electricity in 1 cub-mm. is $< \frac{0·008 \text{ mg.}}{v^2}$. *E.g.*, if $v = 1$ mm., 10 mm., &c., the mass of the positive electricity $<$ 0·008 mg., $<$ 0·00008 mg., &c. The limits here assigned, however, are exceeded where the densities of the electricity in the materials used are as their conductivities. (The experiments were made both with straight wires and with spirals, the former giving the more reliable results.)

THE results of theory regarding stationary vibrations of water are, in a recent paper (*Wied. Ann.*, No. 7) by Herr Kirchhoff and Herr Hansemann, compared with those of experiments in which a prismatic glass vessel, whose vertical cross-section consisted of two straight lines meeting at a right angle and equally inclined to the vertical, formed part of a pendulum, and was vibrated by electromagnetic means about that angle as axis. In the *Journal de Physique* (June) M. Lechat studies the surface vibrations of a liquid in a rectangular vessel, a small vertical rod having been adjusted to any point of the surface, and vibrated in the direction of its length by an electro-magnetic arrangement. The resultant forms were thrown on to a screen by means of a reflected beam of light.

IN a recent paper to the Belgian Academy (*Bull.*, No. 5) Abbé Spée contends that the spectral line D_3, with wave-length about 588, observed in the chromosphere and protuberances, and assigned to a hypothetical body, helium, which some suppose to have a still more simple molecular constitution than hydrogen, probably belongs in reality to this gas. As to its non-reversibility, he considers that at a very small distance from the chromosphere the solar hydrogen may be so far cooled as to be comparable to that which we manipulate, and so, unable to extinguish waves which it can no longer produce, just as a stretched cord loses the property of vibrating in sympathy if its tension have been altered.

PURSUING his researches on the welding of solid bodies by pressure, M. Spring has subjected to various strong pressures (up to 10,000 atm.) more than eighty solid pulverised bodies; this was done in vacuo, and in some cases at various temperatures. The results are highly interesting. All the crystalline bodies proved capable of welding, and in the case of bodies accidentally amorphous the compressed block showed crystalline fracture; crystallisation had been brought about by pressure. Softness favours the approximation of the particles and their orientation in the direction of the crystalline axes. The amorphous bodies, properly so called, fall into two groups, one of substances like wax (*ciroid* bodies), which weld easily, the other of substances like amorphous carbon (*aciroid* bodies), which do not weld. The general result is that the crystalline state favours the union of solid bodies, but the amorphous state does not always hinder it. M. Spring says the facts described do not essentially differ from those observed when two drops of a liquid meet and unite. Hardness is a relative, and one may even say subjective, term. Water may appear with a certain hardness to some insects, and if our bodies had a certain weight we should find the pavement too soft to bear us. Again, prismatic sulphur is changed by compression to octahedric sulphur; amorphous phosphorus seems to be changed to metallic; other amorphous bodies change their state, and mixtures of bodies react chemically if the specific volume of the product of the reaction is smaller than the sum of specific volumes of the reacting bodies. In all

cases the body is changed into a denser variety, whence may be inferred that the state taken by matter is in relation to the volume it is obliged to occupy under action of external forces. This (M. Spring points out) is merely the generalisation of a well-known fact. Some curious results are deduced from it. The researches described have important bearings on mineralogy and geology.

MR. R. CROWE of Liverpool communicates to the *British Journal of Photography* an account of some attempts to photograph a landscape by the aid of lightning-flashes. A gelatine plate, requiring by day an exposure of two seconds, was exposed from 10.15 p.m. to 10.45 p.m., during which time there were 120 brilliant flashes and about half as many minor ones. Most of these were in a horizontal direction, and five or six of then were imprinted on the negative. A perpendicular flash which struck a church-tower half a mile away was rendered with extraordinary sharpness and brilliancy. The surrounding objects, in spite of the long exposure, were but feebly impressed; whence Mr. Crowe argues that though the light of a flash of lightning is of a very actinic character, there still is not sufficient volume of light to illuminate a landscape or building to allow a successful photograph to be taken. Mr. Crowe further suggests that an attempt should be made to photograph, for scientific purposes of reference, the varied forms assumed by lightning at different times and in different countries.

GEOGRAPHICAL NOTES

NEWS has been received from Zanzibar that Capt. Carter and Mr. Cadenhead, of the Belgian Exploration Expedition, have been killed by the chief "Wrambo." This is probably the chief Mirambo, who formerly caused so much trouble to explorers between Zanzibar and Lake Tanganyika, but of whom Mr. Stanley gives so good a report in his last work. It was Capt. Carter who was so successful in the introduction of Indian elephants into Africa.

THE August number of the Geographical Society's *Proceedings* contains Mr. im Thurm's paper on his journey in British Guiana, already noticed in our columns, but the principal feature this month is of course the paper on Kuldja by Major F. C. H. Clarke, R.A., a well-known military writer on Eastern affairs. After a useful historical sketch, Major Clarke deals successively with the geography, orography, rivers, communications, towns, population, climate, vegetable products, and minerals of the region, and furnishes much interesting information, collected with evident care. This paper is followed by an account of M. Severtsoff's journey in Ferghana and the Pamir, from a translation by M. Alexis Lomonossoff, of the Russian Geographical Society. The geographical notes furnish information respecting the East African Expedition, the climate of Matabele-land, the recent observations of Dr. Matteucci in Kordofan, and Dr. Gerhard Rohlfs' account of the Jofra oasis. After notes on American Arctic expeditions and the position of the Crozet Islands, we have Mr. Whymper's account of his ascent of the famous Antisana mountain in South America, and lastly Mr. A. Forrest's own narrative of his journey through North-Western Australia. Two maps are given with the present number, one of British Guiana, which is very acceptable, and the other of the Kuldja district and the Russo-Chinese frontier in Turkistan.

WITH the August number of their *Herald* the Baptist Missionary Society publish a map of Equatorial Africa, which, though presumably not laying claim to scientific accuracy, is of interest as showing what an immense region can be reached by means of the River Congo and its affluents. The map is intended to illustrate the scheme which Mr. Arthington has sketched out for the application of his last munificent donation to the Society. The geographical part of this great task consists in the exploration of the Nkutu and Ikelemba Rivers, the two principal tributaries of the Congo from the south, after passing Stanley Pool, and the opening of a route towards Lake Albert, along the Mbura River, which enters the Congo above Stanley's Arawimi.

M. C. E. DE UJFALVY left Paris in July to undertake a new and important journey in Central Asia. He goes in the first instance to Orenburg, and thence to Tashkend, where he hopes to arrive at the end of next month. He contemplates staying the winter at Samarkand, and will commence his explorations next spring. His programme is an extensive one, and embraces a considerable part of the Southern Pamir region. In the course of his labours he will visit the Upper Zarafshan valley, Karategin, Wakhan, Shignan, Badakshan, and probably Afghanistan. The return journey will, if possible, be made through Persia and the Caucasus.

NEWS has arrived in Paris that a French mission has reached Segon Sokkova and has been well received by King Ahmadan. M. Soleillet, who is on his way to Senegal, is not a member of this expedition, and will proceed by another route to the same city.

THE *Weimar Gazette* states that Dr. Gerhard Rholfs is about to set out for Abyssinia, accompanied by Dr. Stecker, who will attempt a new exploration in Central Africa.

IT is stated that a fifth Belgian Expedition is about to start for Africa, intended to reinforce the expedition on the Congo under Mr. Stanley. It will be commanded by Lieut. Braconnier.

THE August number of *Petermann's Mittheilungen* contains an exhaustive article by Dr. Behm on the Island of Rodriguez, accompanied by a very clear map. Bernhard v. Struve discusses the question of an inland trade-route through Siberia. An excellent hydrographical article, with a large-scale chart, on the Lower Weser from Bremen to Bremerhaven, is contributed by Oherbau-Director L. Franzius of Bremen. The results of the various East African International Expeditions are described. The researches of the Danish schooner *Ingolf* in the seas around Iceland in 1879 are described by H. Wichmann.

THE London Missionary Society have received intelligence of the safe arrival of their new Tanganyika Expedition at Zanzibar on May 29. The party is composed of the Revs. A. J. Wookey and D. Williams, with Dr. Palmer as medical assistant. When the last mail left, an efficient leader and some of the head-men had already been engaged, and they hoped to start for the interior early in July.

THE Church Missionary Society are sending out further reinforcements for their Nyanza mission. The Rev. P. O'Flaherty, an able Oriental scholar, who was an interpreter on Lord Raglan's staff in the Crimean war, left for Zanzibar early in July, and will probably accompany the Waganda chiefs on their journey back to Lake Victoria. Mr. W. E. Taylor, of Hertford College, Oxford, who has been trained as a medical missionary, and Mr. A. J. Biddlecombe have, we believe, just started for East Africa, and will in the first instance join Mr. Copplestone at Uyui.

L'Exploration for August 5 contains some interesting extracts from the letters of Col. Prejevalsky, describing the difficulties he had to encounter in attempting to reach Lhassa, in which he was foiled. The intrepid Colonel has evidently succeeded in making considerable natural history collections.

THE STRUCTURE AND ORIGIN OF CORAL REEFS AND ISLANDS[1]

DARWIN'S THEORY.—During the voyage of the *Beagle* and subsequently, Mr. Darwin made a profound study of coral reefs, and has given a theory of their mode of formation which has since been universally accepted by scientific men.

Darwin's theory may be said to rest on two facts—the one physiological, and the other physical—the former, that those species of corals whose skeletons chiefly make up reefs cannot live in depths greater than from 20 to 30 fathoms; the latter, that the surface of the earth is continually undergoing slow elevation or subsidence.

The corals commence by growing up from the shallow waters surrounding an island, and form a fringing reef which is closely attached to the shore. The island slowly sinks, but the corals continually grow upwards, and keep the upper surface of the reef at a level with the waves of the ocean. When this has gone on for some time a wide navigable water channel is formed between the reef and the shores of the island, and we have a barrier reef. These processes have but to be continued some stages further, when the island will disappear beneath the ocean, and be replaced by an atoll with its lagoon where the island once stood.

According to this simple and beautiful theory, the fringing

[1] Abstract of paper read at the Royal Society of Edinburgh by Mr. John Murray. (Published by permission of the Lords Commissioners of the Treasury.)

reef becomes a barrier reef, and the barrier reef an atoll by a continuous process of development.

Object of the Present Paper.—Prof. Semper,[1] during his examination of the coral reefs in the Pelew group, experienced great difficulties in applying Darwin's theory. Similar difficulties presented themselves to the author in those coral-reef regions visited during the cruise of the *Challenger.*

The object of the present paper is to show, *first*, that, while it must be granted as generally true that reef-forming species of coral do not live at a depth greater than 30 or 40 fathoms, yet that there are other agencies at work in the tropical oceanic regions by which submarine elevations can be built up from very great depths so as to form a foundation for coral reefs; *second*, that while it must be granted that the surface of the earth has undergone many oscillations in recent geological times, yet that all the chief features of coral reefs and islands can be accounted for without calling in the aid of great and general subsidences.

Nature of Oceanic Islands and Submarine Elevations.—It is now known that, with scarcely an exception,[2] all oceanic islands other than coral atolls are of volcanic origin. Darwin, Dana, and others have noticed the close resemblance between atolls and ordinary islands in their manner of grouping as well as in their shapes. In a previous paper the author pointed out the wide distribution of volcanic *débris* over the bed of the ocean in tropical regions, and the almost total absence of minerals, such as quartz, which are characteristic of continental land.[3] There is every reason for believing that atolls are primarily situated on volcanic mountains, and not on submerged continental land, as is so often supposed.

The soundings of the *Tuscarora* and *Challenger* have made known numerous submarine elevations: mountains rising from the general level of the ocean's bed, at a depth of 2,500 or 3,000 fathoms, up to within a few hundred fathoms of the surface. Although now capped and flanked by deposits of Globigerina and Pteropod ooze, these mountains were most probably originally formed by volcanic eruptions. The deposits in deep water on either side of them were almost wholly made up of volcanic materials.

Volcanic mountains situated in the ocean basins, which during their formation had risen above the surface of the water, would assume a more or less sharp and pointed outline owing to the denuding action of the atmosphere and of the waves, and very extensive banks of the denuded materials would be formed around them. Some, like Graham's Island, might be wholly swept away, and only a bank with a few fathoms of water over it be left on the spot. In this way numerous foundations may have been prepared for barrier reefs and even atolls.

Those volcanoes which during their formation had not risen above the surface of the sea (and they were probably the most numerous) would assume a rounded and dome-like contour,[4] owing to the denser medium in which the eruptions had taken place, and the deposits which had been subsequently formed on their summits.

In order to clearly understand how a submarine mountain, say half a mile beneath the sea, can be built up sufficiently near the surface to form a foundation on which reef-forming corals might live, it is necessary to consider attentively the

Pelagic Fauna and Flora of Tropical Regions.—During the cruise of the *Challenger* much attention was paid to the subject. Every day while at sea tow-nets were dragged through the surface waters; and while dredging they were sent down to various depths beneath the surface. Everywhere life was most abundant in the surface and sub-surface waters. Almost every haul gave many calcareous, siliceous, and other Algæ; great numbers of Foraminifera and Radiolaria, Infusoria, Oceanic Hydrozoa, Medusæ, Annelids; vast numbers of microscopic and other Crustacea, Tunicates, Pelagic Gasteropods, Pteropods, Heteropods, Cephalopods, Fishes, and fish-eggs; larvæ of Echinoderms, and of many of the above creatures, &c.

Most of these organisms live from the surface down to about 100 fathoms.[5] In calm weather they swarm near the surface, but when it is rough they are to be found several fathoms beneath the waves. They are borne along in the great oceanic currents which are created by the winds, and meeting with coral reefs, they supply the corals on the outer edge of the reefs with abundant food. The reason why the windward side of a reef grows more vigorously appears to be this abundant supply of food, and not the more abundant supply of oxygen, as is generally stated. The *Challenger* researches showed that oxygen was particularly abundant in all depths inhabited by reef-forming corals.

When these surface animals die, either by coming in contact with colder water or from other causes, their shells and skeletons fall to the bottom, and carry down with them some organic matter which gives a supply of food to deep-sea animals. The majority of deep-sea animals live by eating the mud at the bottom.

An attempt was made to estimate the quantity of carbonate of lime in the form of calcareous Algæ, Foraminifera, Pteropods, Heteropods, Pelagic Gastropods, in the surface-waters. A tow-net, having a mouth 12½ inches in diameter, was dragged for as nearly as possible half a mile through the water. The shells collected were boiled in caustic potash, washed, and then weighed. The mean of four experiments gave 2·545 grammes. If these animals were as abundant in all the depth down to 100 fathoms as they were in the track followed by the tow-net, this would give over 16 tons of carbonate of lime in this form in a mass of the ocean one mile square by 100 fathoms.[1]

Bathymetrical Distribution of the Calcareous Shells and Skeletons of Surface Organisms.—Although these lime-secreting organisms are so abundant in tropical surface waters, their cast-off shells and skeletons are either wholly or partially absent from by far the greater part of the floor of the ocean. In depths greater than 3,000 fathoms we usually met with only a few shells of Pelagic Foraminifera of the larger and heavier kinds; a few hundred fathoms nearer the surface they became more numerous, and we got a few of the smaller kinds and some Coccoliths and Rhabdoliths. At about 1,900 or 1,800 fathoms a few shells of Pteropods and Heteropods are met with; and in all depths less than a mile we have a deposit in which the shell and skeletons of almost every surface organism is to be found. In the equatorial streams and calms the calcareous Algæ, Pelagic Foraminifera, Pteropods, and Heteropods are more abundant in the surface waters than elsewhere; and it is in these same regions that we found their dead shells at greater depths than in the deposits of other parts of the ocean. Another circumstance influences the bathymetrical distribution of these surface shells. When there is a complete and free oceanic circulation from the top to the bottom, these dead shells are found at greater depths in the deposits than where the circulation is cut off by submarine barriers.

The agent by which these shells are removed is, as Sir Wyville

[1] *Zeitschr. für Wissen. Zoologie*, vol. xiii. p. 563.

[2] New Zealand, New Caledonia, and the Seychelles have primitive rocks, if these can be regarded as oceanic islands. Some of the islands between New Caledonia and Australia may have primitive rocks, and the atolls in these regions may be situated on foundations of this nature.

[3] *Proc.* Roy. Soc. Edin., 1876-77, p. 247.

[4] Scrope on "Volcanoes," chap. viii.

[5] The Challengeridæ, and many of the other members of Hæckel's new order *Phæodaria*, certainly live deeper, as we never got them in the tropics except when the net was sent down to a depth of 200 or 300 fathoms.

[1] Among the varieties of Foraminifera recognised by Mr. Brady in the *Challenger* collections, the following have a Pelagic habitat.

Pulvinulina Menardii.	*Hastigerina pelagica.*
,, *canariensis.*	*Orbulina universa.*
,, *crassa.*	*Globigerina bulloides.*
,, *Micheliniana.*	,, *æquilateralis.*
,, *tumida.*	,, *sacculifera* (hirsuta).
Pullenia obliquiloculata.	,, *dubia.*
Sphæroidina dehiscens.	,, *rubra.*
Candeina nitida.	,, *conglobata.*
Hastigerina Murrayi.	,, *inflata.*

It is the dead shells of these Pelagic Foraminifera which chiefly make up the calcareous oozes of the deep sea. The living shells of all the above varieties swarm in the tropical and sub-tropical waters near the surface. It is especially in the region of the equatorial calms that the largest and thickest shelled specimens are found. As we go north or south into colder water they become smaller, and many varieties die out. In the surface-waters of the Arctic and Antarctic regions, only some dwarfed specimens of *Globigerina bulloides* are met with. The author is unable to agree with Dr. Carpenter and Mr. Brady in thinking that these Pelagic Foraminifera also live on the bottom. This question was made the subject of careful investigation during the cruise. The shells from the surface and from the bottom were compared at each locality, and it was found, by micrometric measurement, that surface specimens were as large and as thick-shelled as any average specimens from the soundings. It is quite unlikely that the same individuals should pass a part of their lives in the warm sunny surface-waters, at a temperature of from 70° to 80° F., and another part in the cold dark waters two or three miles beneath, at a temperature of 30° or 40° F. The geographical distribution of these Pelagic forms over the bottom coincides exactly with the distribution of the same forms on the surface, that is to say, both on the surface and on the bottom the distribution is ruled by surface-temperature. No specimens of these Pelagic varieties were ever obtained from the bottom with the shells filled and surrounded with sarcode. Whereas creeping and attached forms (like Truncatulina, Discorbina, Anomalina, and some Textulariæ) were taken in this condition in almost every dredge. These last-mentioned forms, which we know live on the bottom, have a distribution quite independent of surface-temperature.

Thomson suggested, carbonic acid. Analysis shows that carbonic acid is most abundant in sea-water, and especially so in deep water. Pteropod and Heteropod shells are very much larger than the Foraminifera, yet are very much thinner; and hence, for the quantity of lime contained in them, they present a much greater surface to the action of the sea-water. This seems to be the reason why all large and thin shells are first removed from the deposits with increasing depth, and not the fact that some shells are composed of arragonite and some of calcite, as has been suggested.

There is a continual struggle in the ocean with respect to the carbonate of lime. Life is continually secreting it and moulding it into many varied and beautiful forms. The carbonic acid of ocean-waters attacks these when life has lost its hold, reduces the lime to the form of a bicarbonate, and carries it away in solution. In all the greater depths of the ocean these surface shells are reduced to a bicarbonate either during their fall through the water or shortly after reaching the bottom.

In the shallower depths—on the tops of submarine elevations or volcanoes—the accumulation of the dead siliceous and calcareous shells is too rapid for the action of the sea-water to have much effect. Long before such a deposit reaches sufficiently near the surface to serve as a foundation for reef-forming corals, it is a bank on which flourish numerous species of Foraminifera, Sponges, Hydroids, deep-sea Corals, Annelids, Alcyonarians, Molluscs, Polyzoa, Echinoderms, &c. All these tend to fix and consolidate such a bank, and add their shells, spicules, and skeletons to the relatively rapid accumulating deposits. Eventually coral-forming species attach themselves to such banks, and then commences the formation of

Coral Atolls.—Mr. Darwin has pointed out that "reefs not to be distinguished from an atoll might be formed"[1] on submerged banks such as those here described. However, the improbability of so many submerged banks existing in the open ocean caused him to reject this mode of formation for atolls. As here stated, recent deep-sea investigations have shown that submerged banks are continually in process of formation in the tropical regions of the ocean, and it is in a high degree probable that the majority of atolls are seated on banks formed in this manner.

Mr. Darwin has also pointed out that the corals on the outer margin of a submerged bank would grow vigorously, whilst the growth of those on the central expanse would be checked by the sediment formed there, and by the small amount of food brought to them.[2] Very early in the history of such an atoll, and while yet several fathoms submerged, the corals situated on the central parts would be placed at a disadvantage, and this would become greater and greater as the coral plantations approached the surface. When the coral plantation was small there was a relatively large periphery for the supply of food to the inner parts, and also for the supply of sediment; and hence in small atolls the lagoon was very shallow, and was soon filled up. For the same reasons coral islands situated on long and narrow banks have no lagoons. An atoll one mile square has a periphery of four miles. In an atoll four miles square—the periphery increasing in arithmetical progression and the area as the square—we have for each square mile only a periphery of one mile over which food may pass to the interior, and from which sediment is supplied for filling up the lagoon.

With increasing size, then, the conditions become more and more favourable to the formation of lagoons, and as a consequence we have no large or moderate sized coral islands without lagoons. Tow-net experiments always showed very much less Pelagic life (food) in the lagoon waters than on the outer edge of the reef. The lagoon becomes less favourable for the growth of all the more massive kinds of coral as the outer edge of the reef reaches the surface, and cuts off the free supply of ocean-waters. Many species of corals die.[3] Much dead coral, coral rock, and sediment is exposed to the solvent action of the sea-water. Larger quantities of lime are carried away in solution as a bicarbonate from the lagoon than are secreted by the animals which can still live in it; the lagoon thus becomes widened and deepened.[4]

On the other hand a vigorous growth and secretion of lime takes place on the outer margins of the reef; and when the water outside becomes too deep for reef-forming corals to live, these still build seawards on a talus of their own *débris*:—the whole atoll expands somewhat after the manner of a fairy ring.

[1] "Coral Reefs," p. 118.

[2] "Coral Reefs," p. 134.

[3] There are no living corals or shells in some small lagoons, the waters of which become highly heated, and in some cases extremely saline.

[4] Complete little Serpula-atolls, with lagoons from 3 to 50 feet in diameter, and formed in this way without subsidence, were numerous along the shores of Bermuda.

It is not necessary to call in disseverment of large atolls in order to explain the appearances presented in the Great Maldiva group of atolls.[1] The coral fields rising from very many parts of these extensive submarine banks form atolls. The marginal atolls have from the first the advantage of a better supply of food. They elongate in the direction of the margin of the bank where the water is shallower than to seaward. Many of these marginal atolls have coalesced, and as this growth and coalescence have continued, a large part of the food-supply has been cut off from the small atolls situated towards the interior of the bank. Ultimately a large atoll-like Suadiva atoll would be formed. The atolls in the interior would be perhaps wholly removed in solution, and the atoll-like character of small marginal but now coalesced atolls would be wholly or partially lost by the destruction of their inner sides.[2] A study of the charts shows all the stages in this mode of development.

In the case of the Lakadivh, Caroline, and Chagos archipelagos we have submarine banks at various stages of growth towards the surface, some too deep for reef-forming species of coral, others with coral plantations, but all submerged several fathoms, and scattered amongst these some of the oldest and most completely-formed atolls and coral islands. It is most difficult to conceive how these submerged banks could have been produced by subsidence, situated as they are in relation to each other and with respect to the perfectly-formed atolls, barrier or fringing reefs of the groups.

It is a much more natural view to regard these atolls and submerged banks as originally volcanoes reaching to various heights beneath the sea, and which have subsequently been built up to and towards the surface by accumulations of organic sediment and the growth of coral on their summits. It is a remarkable fact that in all coral atolls which have been raised several hundred feet above the sea, the base is generally described as composed of solid limestone, or "of various kinds of coral evidently deposited after life had become extinct."[3] This base is probably often made up of such a rock as that brought by the missionaries from New Ireland, and described by Prof. Liversidge,[4] as composed chiefly of Pelagic foraminifera, the same as those taken by the *Challenger* in the surface waters of the Pacific.

Microscopic sections of a rock taken from 50 feet below sea-level at Bermuda show that a deposition of carbonate of lime is going on. The small shells are filled with, and the broken pieces of shells and corals are cemented by, calcite. The wells in coral islands rise and fall with the tide, so that the whole atoll is filled like a sponge with sea-water. This water is very slowly interchanged, and by the solution of the smaller and thinner particles becomes saturated, and a deposition of lime follows. In this way we may explain the absence of many of the more delicate shells from some limestones.[5]

Barrier Reefs.—During the visit of the *Challenger* to Tahiti a careful examination was made of the reefs by dredging, sounding, &c., in a steam pinnace, both inside and outside the reefs. Lieutenant Swire, of the *Challenger*, made a careful trigonometrical survey of the profile of the outer reefs on six different lines; and while associated with him in this work the author was indebted to that officer for many valuable suggestions.

A ledge ran out from the edge of the reef to about 250 yards, where we got a depth of from 30 to 40 fathoms. It was covered with a most luxuriant growth of coral bosses and knobs.

Between 250 and 350 yards from the edge of the reef there was generally a very steep and irregular slope; about 100 fathoms was got at the latter distance, and the angles between these last-mentioned distances often exceeded 45 degrees. The talus here appeared to be composed of huge masses and heads of coral, which had been torn by the waves from the upper ledge and piled up on each other. They were now covered with

[1] Mr. Darwin's application of his theory to this group—where the disseverment of large atolls is called in, and a destructive power attributed to oceanic currents, which it is very unlikely they can ever possess—has often been considered unsatisfactory.

[2] "In speaking of Bow Island, Belcher mentions the fact that several of its points had undergone material change, or were no longer the same when visited after the lapse of fourteen years. These remarks refer particularly to islets situated within the lagoon. I could myself quote many instances of the same description."—"Wilkes' Exploring Expedition," vol. iv. p. 271.

living Sponges, Alcyonarians, Hydroids, Polyzoa, Foraminifera, &c.[1]

From 350 to 500 yards from the edge of the reef we had a slope with an angle of about 30°, and made up chiefly of coral sand. Beyond 500 yards the angle of the slope decreased till we had at a distance of a mile from the reef an angle of 6°, a depth of 590 fathoms, and a mud composed of volcanic and coral sand, Pteropods, Pelagic and other Foraminifera, Coccoliths, &c.

In the lagoon channel the reefs were found to be fringed with living coral, and to slope downwards and outwards for a few feet, and then plunge at once to a depth of 10 or 16 fathoms. Many portions of these inner reefs were overhanging, and at some places overhanging masses had recently fallen away. Everywhere much dead coral rock was exposed to the solvent action of the sea-water. The reefs of Tahiti are at some places fringing, at other places there is a boat passage within the reef, and at Papiete there is a large ship channel with islets within, and the outer edge of the reef is a mile distant from the shore. The island itself is surrounded with a belt of fertile low land, frequently three or four miles wide; this shows that the island has not in recent times undergone subsidence; there are indeed reasons for supposing it has recently been slightly elevated. Everything appears to show that the reefs have commenced close to the shore and have extended seawards, first on a foundation composed of the volcanic detritus of the island, and afterwards on a talus composed of coral *débris* and the shells and skeletons of surface organisms.[2]

The lagoon channel was subsequently slowly formed by the solvent action of the sea-water thrown over the reefs at each tide, and the islets in the lagoon channel are portions of the original reef still left standing. The reefs have extended outwards from the island and have been disintegrated and removed behind in the same way as the atoll has extended outwards after reaching the surface.

Where reefs rise quite to the surface, and are nearly continuous, we find relatively few coral patches and heads in the lagoons and lagoon channels. Where the outer reefs are much broken up, the coral growths in the lagoon are relatively abundant. Where the water was deep and the talus to be formed was great, the outward growth has been relatively slow,[3] and the disintegrating forces in the lagoons and lagoon channels gaining in the struggle, the reefs would become very narrow, and might indeed be broken up. This, however, would admit the oceanic waters and more food, and growth would again commence on the inner as well as the outer sides of the still remaining portions. In the great barrier reef of Australia, where the openings are numerous and wide, the reefs have a great width. Where the openings are few and neither wide nor deep (as in lat. 12° 30') the reefs are very narrow and "steep to"—on their inner side.

At the Admiralty Islands, on the lagoon side of the islets on the barrier reefs, the trees were found overhanging the water, and in some cases the soil washed away from their roots. It is a common observation in atolls that the islets on the reefs are situated close to the lagoons. These facts point out the removal of matter which is going on in the lagoons and lagoon channels.

Elevation and Subsidence.—Mr. Darwin has given many reasons for believing that those islands and coasts which have fringing reefs had recently been elevated, or had long remained in a state of rest. Throughout the volcanic islands of the great ocean basins the evidence of recent elevations are everywhere conspicuous. Jukes has given most excellent reasons for believing that the coast of Australia fronted by the barrier reef, and even the barrier reef itself, have recently been elevated.[1] Dana and Conthouy have given a list of islands in almost every barrier reef and atoll region which have recently been elevated.[2]

This is what we should expect. Generally speaking, all the volcanic regions which we know have in the main been areas of elevation, and we should expect the same to hold good in those vast and permanent hollows of the earth which are occupied by the waters of the ocean. It must be remembered that probably all atolls were seated on submarine volcanoes. Areas of local depression are to be looked for in the ocean basins on either side of and between groups of volcanic islands and atolls, and not on the very site of these islands. This is what the deep-sea soundings show if they show any depression at all. Subsidence has been called in in order to account for the existence of lagoons and lagoon channels, and the narrow bands of reef which inclose these; but it has been shown that these were produced by quite other causes—by the vigorous growth of the corals where most nourishment was to be had, and their death solution and disintegration by the action of sea-water and currents[3] at those parts which cannot be, on account of their situation, sufficiently supplied with food.

All the chief and characteristic features of barrier reefs and atolls may indeed exist with slow elevation, for the removal of lime from the lagoons and the dead upper surface of the reefs by currents, and in solution by rain and sea-water, might keep pace with the upward movement.

The most recent charts of all coral reef regions have been examined, and it is found possible to explain all the phenomena by the principles here advanced; while on the subsidence theory it is most difficult to explain the appearances and structures met with in many groups, for instance, in the Fiji islands, where fringing reefs, barrier reefs, and atolls all occur in close proximity, and where all the other evidence seems to point to elevation, or at least a long period of rest. In instances like the Gambier group the reefs situated on the seaward side of the outer islands would grow more vigorously than those towards the interior; they would extend in the direction of the shallower water, and ultimately would form a continuous barrier around the whole group. The distinguishing feature of the views now advanced is that they do away with the great and general subsidences required by Darwin's theory,[4] and are in harmony with Dana's views of the great antiquity and permanence of the great ocean basin, which all recent deep-sea researches appear to support.

Summary.—It was shown (1) that foundations have been prepared for barrier reefs and atolls by the disintegration of volcanic islands, and by the building up of submarine volcanoes by the deposition on their summits of organic and other sediments.

(2) That the chief food of the corals consists of the abundant Pelagic life of the tropical regions, and the extensive solvent action of sea-water is shown by the removal of the carbonate of lime-shells of these surface organisms from all the greater depths of the ocean.

(3) That when coral plantations build up from submarine banks they assume an atoll form, owing to the more abundant supply of food to the outer margins, and the removal of dead coral rock from the interior portions by currents and by the action of the carbonic acid dissolved in sea-water.

(4) That barrier reefs have built out from the shore on a foundation of volcanic *débris* or on a talus of coral blocks, coral sediment, and Pelagic shells, and the lagoon channel is formed in the same way as a lagoon.

(5) That it is not necessary to call in subsidence to explain any of the characteristic features of barrier reefs or atolls, and that all these features would exist alike in areas of slow elevation, of rest, or of slow subsidence.

In conclusion it was pointed out that all the causes here appealed to for an explanation of the structure of coral reefs are proximate, relatively well known, and continuous in their action.

[1] This ledge and steep slope beyond where a depth of 30 or 40 fathoms was reached, was characteristic of a large number of atoll and barrier reefs, and seemed due to wave action. Experiments had been made with masses of broken coral, and it was found that these could (on account of their rough and jagged surface) be built up into a nearly perpendicular wall by letting them fall on each other. A talus formed in water deeper than 40 fathoms, where there was little, if any, motion, would be different from one formed on land. In the latter case the disintegrating forces at work always tended to set the talus in motion; in the former case everything tended to consolidate and to fix the blocks in the positions first assumed. A removal of lime in solution would take place from the blocks forming this steep slope, but except in very deep water this would not be sufficient to check the outward extension of the reef.

[2] A dredging in 155 fathoms, close to the barrier reef of Australia (between it and Raine Island), gave a coral sand, which was, I estimate, more than two-thirds made up of the shells of surface animals.

[3] Hence in barrier reefs, where the depth outside is very great, we find the reefs running closer to the shore than where the depth is less, and consequently the talus to be formed is smaller.

[3] Very strong currents run out of the entrances into lagoons and lagoon channels, and when the tow-net was used in these entrances it showed that a large quantity of coral detritus was being carried seawards.

[4] "We may conclude that immense areas have subsided, to an amount sufficient to bury not only any formerly existing lofty table-land, but even the heights formed by fractured strata and erupted matter."—"Coral Reefs," p. 190.

The author expressed his indebtedness to all his colleagues, to Prof. Geikie, to the Hydrographer and officers of the hydrographic department, and in a special manner to Sir Wyville Thomson, under whose direction and advice all the observations had been conducted.

Challenger Office, 32, Queen Street, Edinburgh.

THE JAMIN CANDLE

A NEW system in addition to those already prominent in the extensive field of electric lighting is shortly to be introduced into this country in the form of a candle devised by the well-known French electrician M. Jamin. This invention brings with it a considerable reputation, and how far this may be justified we shall probably soon have the opportunity of judging.

It has not yet had a trial in England, and until this is done we can only rely on the results of experiments, apparently of a not very exhaustive or conclusive character, which have taken place in Paris, and which must be accepted with a considerable amount of reservation.

The following description of the new candle is that given by M. Jamin himself in his paper to the French Academy of May 31, 1880:—

"I have had the honour to submit to the Academy during its sitting of March 17, 1879, the principle of a new electric burner.

"I have since succeeded in constructing a practical lamp, which I will describe. It rests on a slate base, which can be fixed into the globes or lanterns, according to the requirements of the decorations, and which supports at the base a gutter of copper, wide, but not very thick, in order to avoid shadows, and at the top is a gutter of soft iron, intended to be magnetised and to attract a movable armature or plate. The alternating current of a Gramme machine passes first through a wire of thin copper folded round the gutter some fifteen or twenty times, and which constitutes the directing circuit. In the middle of this frame and in the same plane are placed the candles or pairs of carbon rods between which the electric arc is to play. There are three, but a larger number can be inserted if the lighting is to be prolonged. Each carbon rod is inserted in a metal socket, in which they stand vertically, point downwards, and are retained in this position by means of a spring.

"The working offers no difficulties and demands no skill. There is no insulating material between the carbons. Those on the right are fixed and vertical; those on the left, hang freely from hinges; the tops of their supports are conected by a small bar, which gives them a movement in common; the armature is attached by a lever to this bar, which it pushes towards the left by its weight, which brings the carbons together until one of them touches its companion. It is to be remarked that the contact will only be made in one of the candles, the longest, or the one whose points hang nearest together; that one will be lighted.

"The electric current, after having traversed the directing circuit, arrives simultaneously at the movable carbons, and can return indiscriminately by the three fixed carbons; it passes between those which touch, and lights them. Immediately the magnetism is made the armature is attracted, the three couples of carbons spring apart at the same time, two remaining cold, and the arc being established in the third. As long as there is any matter to burn it continues maintained at the points by the action of the directing current, and necessarily returning to it if any foreign cause should drive it away. When the current stops the armature falls back, and the contact is re-established; if it passes through again, the carbons are relighted, and spring apart as at first. Thus the lighting is automatic, instantaneous, and renewable at will.

"When the first candle is consumed, another must succeed it. For this purpose the left carbon-holder, which remained fixed, is jointed at the top and can be displaced, not in the plane of the frame, but perpendicularly. It is pushed by a spring, R, which tends to force it away, but it is kept vertical by a wire, D, bent round like a hook at its end, and which slides tightly in a receptacle where a spring presses it. When the combustion of the candle has brought the arc up to this point, the wire is melted, the carbon-holder is released, the two carbons spring suddenly apart, and the arc is extinguished, but immediately relights in the neighbouring candle. The change is so rapid that the action is hardly perceptible, and the other lamps in the same circuit are not at all affected.

"Besides, it must be remarked that this substitution of a fresh candle for the one consumed only happens every two hours, that the wire is only melted at its extremity, that it is sufficient to cut off the point to bend it again and to draw it a little further from its receptacle, when new carbons are to be inserted, and that it serves for a great number of times. One of the greatest inconveniences of electric lighting is the possible sudden extinction of one of the lamps, which immediately causes that of the other candles in the same circuit, although they may be in good condition. Ours are very little subject to this danger, but it must, however, be foreseen and remedied. For this purpose one of my pupils has devised a system, the description of which would be too long. Its effect is (1) to open, at the moment of accident, a secondary circuit, which continues the current across the faulty candle; (2) to replace the extinguished lamp by an equal resistance, which leaves the others in the condition in which they were at first.

"This addition is very important, as it permits of our lighting many or few candles without changing their brilliancy.

"To sum up, our lamp contains many essential qualities. It lights and relights itself as often as required; it only requires one circuit for all the neighbouring candles; it replaces automatically those which are entirely consumed, by new carbons; it employs no insulating material which might alter the colour of the flame; and it requires no preliminary preparation of the carbons, which considerably diminishes the expense. If at first it underwent, like all others, variations of brilliancy that were owing, not to the construction, but to the defective preparation of the carbons, these variations have disappeared since, thanks to M. Carré, to whom so much is already due, and who has just given to his carbons the necessary solidity."

In the summer of 1878 the writer, in conjunction with Mr. McEniry, carried out a series of experiments with various forms of electric candles for Mr. Robert Sabine; the result is embodied in his provisional specification of November 27, 1878, part of which runs as follows:—

"My third improvement in regulating the distance between the carbon electrodes of a regulator or lamp consists in taking advantage of the well-known fact that parallel conductors attract or repel each other according as the currents in them go in the same or in opposite directions. For this purpose I place the carbons vertically side by side, one of them being fixed and the other balanced over a fulcrum or centre. The frames carrying the two carbons form portions of the common electric circuit in such a way that when the current circulates the parallel portions of the balanced frame (which carries the movable carbon) are deflected and the carbons separated. The degree of deflection of the flame depending upon the current, it follows that, should from any cause the electromotive force in the circuit increase, the frame is thereby deflected more, and the electric arc is correspondingly increased in length, which reduces the current again and maintains the light more steadily than when the carbons are placed immovably side by side without any such adjustment."

It is presumed by the writer that M. Jamin's paper to the French Academy of March 17, 1879, explaining the principle of his new candle, was the first public notice of it, and it will be therefore clearly seen that the part of the apparatus which he claims as particularly his own, viz., the directing frame, is in reality due to Mr. Sabine, and that while giving every credit to M. Jamin for independence of thought, it is only in common justice to Mr. Sabine that he should receive the merit of an idea which, in the words of a very flattering notice of the origin of Jamin's candle in a recent number of *La Lumière Electrique*, constitutes an elegant application of Ampère's laws.

Mr. Sabine's arrangement is also of a more simple nature than the candle just described, for it not only regulates the arc but separates the carbons without the aid of magnetism, and this could be as easily accomplished for a combination of three candles as for one.

It is probable that this latter candle was never constructed beyond the experimental stage, but that it could be put into a very simple and practical form is obvious.

Having thus shown that the two systems are identical, we will turn our attention to the consideration of the claims of this particular form of candle as now perfected and brought forward by M. Jamin.

It is questionable whether the surrounding frame of wire is as efficacious as we are led to believe, but that it exerts a certain influence on the electric arc is beyond doubt; but whether this favours the light or acts detrimentally by blowing and expanding the arc remains to be proved. Again, the fact of burning an

electric candle point downwards cannot be claimed as anything new, for the candles of Mr. Wilde have been successfully used in this position and without any directing frame. This latter, being of fine wire, must offer a considerable resistance to the current, and cannot be overlooked. It is claimed as an advantage in this system that the leading wires used are of the smallest description even for considerable distances, but the same may be said of any other system where the current-producing machine has a very high electromotive force. The size of wire for the circuit is not dependent upon any particular form of candle or regulator, but upon the current-producing strength of the machine employed for working the system.

The automatic lighting and re-lighting of the Jamin candle shows no advance over the means employed by others, nor does the insertion of a resistance in the place of an extinguished lamp constitute anything new. In any construction of candle where the two carbons are separated by the action of magnetism (one carbon being movable and attached to an armature influenced by an electro-magnet) it is impossible to keep the distances of the carbons apart always constant. Any variation in the current produces a corresponding variation in the magnetism which affects the movable carbon, this being especially the case in using alternating currents where the carbon must necessarily be in a continual state of vibration from the rapid changes of polarity.

Those candles of the Jablochkoff type are free from such a fault, owing to both carbons being made quite rigid by the insulating material between them, and the distance apart, therefore, being invariable throughout the whole length, which conduces greatly to the steadiness of the arc.

It is probable that the brilliancy of the light may be increased by burning the candle point downwards, but it must consume more rapidly than when in the reverse position, as the arc would tend to warm the carbon rods throughout their length. It is however certain that improvements will be made, and that probably this system will eventually compete favourably with others already established, although at present it is difficult to see much advantage over such candles as Wilde's, Rapieff's, &c.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, August 2.—M. Edm. Becquerel in the chair.—The following papers were read:—On the preparation of chlorine, by M. Berthelot. The formation of the brown soluble compound (preceding the liberation of chlorine) requires not only chlorine and manganese, but a considerable excess of hydrochloric acid; it is a perchlorised chlorhydrate of manganese.—On heats of combustion, by M. Berthelot. This relates to the agreement between Thomsen's results and his own.—Synthesis of hexamethyl benzine and of mellic acid, by MM. Friedel and Crafts.—On human walking, by M. Marey. With his odograph he proves that the step is longer in mounting than in descending for an unburdened man than for one carrying a load, for one with very low-heeled, than for one with high-heeled shoes, for one with a thick sole prolonged slightly beyond the foot than when the sole is short and flexible. It seems as though the heel might be lowered indefinitely with advantage, but soles must not be elongated beyond a certain limit, nor made quite rigid. Sometimes (as in ascending) the length of the step is increased, and the rhythm retarded; at other times (as in more rapid walking) the step both lengthens and is accelerated.—Report on the interoceanic canal project. (Second Part.) M. de Lesseps' documents are approved.—On the gallicolar phylloxera and *Phylloxera vastatrix*, by M. Laliman.—M. Zazareff described a battery in which electricity is produced by passage of a solution of glycerine, under pressure, through a mixture of coke and anthracite.—On the theory of sines of superior orders, by M. Farkas.—Researches on the electric effluvium (silent discharge), by MM. Hautefeuille and Chappuis. M. Thenard's apparatus (with alternative discharges) is well fitted to show the rain of electric fire in various gases. Fluoride of silicium gives the best effects; nitrogen comes next; hydrogen and chlorine also present the phenomenon.—Researches on batteries, by M. D'Arsonval. He indicates two methods of obviating the chemical action which goes on in batteries with two liquids when the circuit is open. The first consists in use of animal charcoal, substituted *e.g.* for the sand in a Minotto battery; the second, in using, as a depolariser, a liquid which gives a precipitate by its mixture with the liquid which attacks the zinc (there are many ways of doing this; and the author mentions some). In the latter case the diaphragm is rendered impermeable by means of a conducting and electrolysable precipitate.—On the optical properties of mixtures of isomorphous salts, by M. Dufet. Let N be the index of the mixed salt, n and n' those of the components, p and p' the numbers of equivalents of the two salts; then $N = \frac{pn + p'n'}{p + p'}$. This law is demonstrated, at least, for sulphates of the magnesian series.—Influence of temperature on the distribution of salts in their solutions, by M. Soret. The concentration of the heated part diminishes, that of the cold increases. The difference grows with the original concentration, and nearly in proportion. In the series of the alkaline chlorides the difference is greater (for the same concentration), the higher the molecular weight of the salt. The phenomenon seems to have no relation to solubility of the salt.—On the rise of the zero point in mercury thermometers, by M. Crafts. This rise (through heating) is quicker and greater in crystal thermometers than in those of glass without oxide of lead; it is quicker at first, and tends to a limit (with heating at fixed temperature). The zero point becomes fixed at the new height, when the instrument is kept at ordinary temperature and the thermometer becomes more stable.—Development, by pressure, of polar electricity, in hemihedral crystals with inclined faces, by MM. Jacques and Curie.—On the pyridic bases, by M. de Coninck.—On the heats of combustion of some substances of the fat-series, by M. Louguinine.—Identity of acute experimental septicæmia with the cholera of fowls, by M. Toussaint.—Formation of new races; researches in comparative osteology, on a race of domestic oxen observed in Senegambia, by M. de Rochebrune. The animal—a zebu—is specially distinguished by a conical nasal horn.—Action of poison on cephalopoda, by M. Yung. The effects of curare, strychnine, nicotine, &c., are described.—On a hailstorm at Paris on July 30, 1880, by M. Ferrière.—On determination of crystallisable sugar in presence of glucose and dextrine, by M. Pellet.

Vienna

Imperial Academy of Sciences, July 1.—The following, among other papers, were read:—Development and formation of the glands of the stomach, by Prof. Toldt.—Tuberculosis, by Prof. Heschl.—On the absorption of radiant heat in gases and vapours, by Herr Lecher and Herr Pernter.—On an optical property of the cornea, by Prof. Fleischl.

COLOURS IN ART

A Handbook for Painters and Art Students on the Character and Use of Colours, their Permanent and Fugitive Qualities, and the Vehicles proper to Employ. Also Short Remarks on the Practice of Painting in Oil and Water-Colours. By W. J. Muckley. (London: Baillière, Tindall, and Cox, 1880.)

THAT a book for the instruction of artists as to the composition and purity of their pigments is much needed can hardly be denied. The difficulty, however, in writing such a book is very great; for it must either be very incomplete or contain a large amount of matter which but very few artists can understand. And no one is competent to write such a book but he who has some knowledge of painters' manipulations and a very good knowledge of chemistry; to drop the chemistry and take upon faith what has been written about the purity and nature of pigments, is hardly the method which should be adopted, and the person who does it is not likely to be a very safe guide to the artist, although he may give very many useful hints, and state much that is true. To treat of colours properly their composition must be described and the adulterations to which they are liable should be explained, which cannot be done without a certain amount of chemistry and chemical terms, and if the persons who read a book on pigments know nothing about chemistry, how can they be benefited by it? And this is difficulty number two. How is it to be overcome? Why, simply by artists learning something of chemistry? There is no other way for it. A book so incomplete as that under consideration is very misleading, because a person after reading it will know but little more about pigments than when he began. Of what use is it to know that cadmium yellow is a "sulphide of the metal cadmium," and that "emerald green is a preparation of copper," unless it be known that the elements which compose each have a decided liking for changing places, and that if these pigments are brought into contact the change will assuredly take place to the entire destruction of the tint of both of them? The real truth of the matter is that until artists will consent to become, to a certain extent, students of science, they will never get out of their difficulties, and if they will consent to this, to some of them we fear derogatory task, they will find that there is more help for them from science than they imagined: chemistry will lead to physics, and then for the first time perhaps many of them will learn what colour is, and what light and shade *really* are, and new views will burst upon them, and new methods of using their pigments will become necessary, and then pictures will be resplendent with nature's tints, and transparency will replace opacity, and nature will have some chance of being fairly represented. There are many artists who are scientific men, and there are others to whom nature has given special powers; and these show by their works that they understand or appreciate the true nature of colour and of light and shade. Look at Mr. Brett's sea-pieces (he is a scientific man of note), they are bright, luminous, and true to nature, although they may not please painters of the old school, one of whom once, when asked what he thought of one of this artist's pictures, was heard to say he did not like rocks. As an illustration of one who lays no claim to be a scientific man, take Mr. Herbert's painting of *Moses* in the House of Lords, where bodies of the colour nearly of the sandy back ground stand out from it without any tricks, with all the vivid distinctness of a stereoscopic picture.

To those who know nothing of chemistry what directions can be given for the use of paints which in themselves are stable, but which cannot be mixed with certain others? It would take a huge volume to record all the cases in which they could be used, and to note all the contingencies which might arise to influence them, and yet a little sound chemical knowledge would make the matter easy and brief. Good champagne is a good and wholesome wine, and good old port is a nectar fit for the gods, and hock and claret are cooling drinks which, with their fragrant bouquets, appeal to the imagination: all are good and wholesome; but mix them all in the same stomach at a great feast, and what will be the result, at least in most cases? Vermilion is a good and safe pigment, so is cadmium yellow, and so is emerald green; but mix them all together, and what will happen? Keep the emerald green and the cadmium apart by some hard and quick-drying vehicle, and all will be well; allow a day's interval to elapse between taking the champagne and hock, and port and claret, and no inconvenience will be experienced.

It is very refreshing to read from the pen of Mr. Muckley the warning which he gives to artists to restrict the number of colours which they employ. It is to the use of bright and new tints with which the French colour-makers tempt our artists that much of the evil complained of is due, and moreover the adulteration practised abroad, but rarely in this country, has added to it. Mr. Muckley has divided pigments into "permanent colours" and "useless pigments." Speaking of "whites," he very justly recommends zinc white as being permanent, but then he speaks of "flake white" as permanent, but confesses that it loses "its opacity by age," and that "impure air and sulphuretted hydrogen turn white lead" (*i.e.* flake white) "to a dirty brown in a short time." One would hardly rank this among permanent colours. Amongst yellows he mentions "lemon yellow" as not altogether trustworthy. Now lemon yellow is chromate of baryta, and, like all other chromates, is liable to reduction by organic matter, and then, as it becomes reduced, its tint changes to green. Although he ranks this pigment among "permanent colours" he does so with a caution; why then place it in this list? "Aureolin" is also included in it; but very grave doubts are entertained of its stability in oil by many artists. It certainly resists the action of alkalies fairly well.

"Naples yellow," a pigment which portrait and figure painters have a great affection for, is now a compound made in imitation of the old paint, which consisted of antimony and lead; it was usually some time ago made with white lead tinted with some yellow pigments. If made with zinc white and cadmium, as Mr. Muckley asserts, there is not much danger in using it.

Amongst the "useless pigments" which are said to be "stable" it should be remarked that the whites, "Blanc

d'Argent or silver white," "London and Nottingham white," are both white lead, and therefore subject to the same influences as "flake white." "Scheele's green," which is an arsenite of copper, can hardly be called a "stable" colour, "but unnecessary."

"Semi-transparent colours." Amongst these is placed "cremintz white." Why this should be it is difficult to understand, if flake white is to be ranked among permanent colours, for cremintz white is white lead produced by precipitation.

"Prussian blue" is spoken of as not being durable; it is quite certain that it stands well sometimes, but that its hue does often fade. This must surely cause a reflecting mind to ask himself how this can be? The colour is so beautiful and useful to the artist that some effort should be made to prevent its total expulsion from his palette, and here we have an instance of the importance of chemical knowledge to the artist. It is impossible in this place to go into the question; it is however manifest if a pigment stands well at one time but not at another that it must be mixed, in the latter case, with something which does not agree with it. Now this is true; from its composition prussian blue is affected by anything which will change the state of oxidation in which part of its constituent iron is held. Terra verte, for example, is, or ought to be, an earth tinted with the protoxide of iron; if this is mixed with prussian blue it will in time change the condition of the oxide of iron in the prussian blue, and therefore its colour. In concluding these remarks on pigments treated of in Mr. Muckley's book one feels great pleasure in being able to state that with the few exceptions noticed there is nothing incorrect, only one feels how terribly wanting it is in completeness when a thoroughly scientific treatment of the subject is required. One of the points which artists have to guard against is adulteration of pigments; now this is a thing of constant occurrence, where cheap colours are bought, but in this work nothing is said about this important matter. However well an artist may select his paints, impurities in one or two of them may upset all his calculations and render of no value a work which might, if sound, represent a considerable sum of money. From the present position of art in this country this is probably the most touching way of putting it. It would be well, in a future edition, if Mr. Muckley would attend to this, and give some simple methods by which the impurities could be detected.

It is as important to the artist that he should understand the nature of the vehicles with which he paints as the composition of his pigments, and here one wishes that Mr. Muckley had gone more into detail, and that he had given reasons why such substances as maguilps, mastic, sugar of lead, &c., are so very objectionable. The reason why pictures crack is because two or more media are used which dry differently; if the vehicle employed is homogeneous there is no fear of cracking. Maguilp is made by mixing linseed oil with mastic varnish, and mastic varnish is gum mastic dissolved in turpentine. When these are mixed together the turpentine goes to the oil and leaves the mastic in a jelly-like condition; the whole mass is then rubbed up together, and in proportion as the mixture is more or less complete so will the vehicle be more or less liable to crack, because it is made up of substances which take different times in drying. All maguilps are bad; here Mr. Muckley is right, and he is also right in advising the use of amber varnish and of good copal varnish tempered with nut (better with poppy) oil. No better media can be used than these, but the picture must be painted from first to last with one of them, whichever the artist selects, but the amber is the best. Six years ago the then Professor of Chemistry at the Royal Academy urged Messrs. Winsor and Newton to get amber varnish made, and that firm did so, therefore amber varnish has been to be had for that space of time, and several artists of distinction, viz., Mr. Brett, Mr. Vicat Cole, R.A., and others, have painted with it to their entire satisfaction; nor have they complained that it is too dark to mix with their lighter colours. When a picture is perfectly hard which has been painted with this vehicle, no better varnish can be used, when required, than amber varnish properly applied, that is, in as thin a coat as possible. Mr. Muckley speaks of mastic varnish blooming, but he does not tell us why it does so. It is because the substance is hygroscopic, and taking up moisture is the cause of blooming, therefore it should never be used. All driers, as he says, are unnecessary, they are all ruinous to pictures; under certain conditions crystallisable driers crystallise out and make the picture spotty. It would have been much more satisfactory if Mr. Muckley had treated this part of his subject at greater length and with greater minuteness; it is evident that he is quite competent to do so. Copal is a name used by varnish makers for several kinds of gum, and some of the cheap varnishes do not contain any of the better or harder gum. The kind used for artists' varnishes is what is termed a fossil gum, and is found largely at Zanzibar; it is almost, if not quite, as hard as amber, and almost intractable. The best copal varnishes sold by the best artist colourmen are, as a rule, made from this gum, and can be obtained from them with confidence. It is however pleasing to learn that so conscientious and respectable a firm as Messrs. Mander Brothers of Wolverhampton have undertaken to manufacture vehicles "in accordance with the old formulæ supplied by the author." There is no need whatever to use sandrac, it is very brittle and unmanageable.

In the work before us "turpentine" is spoken of as being, in conjunction with colours, "detrimental to their permanence." Turpentine, which is distilled with water from coniferous trees, oxidises and forms a resin, this it does most readily in the presence of moisture and sunlight. If then turpentine be kept free from moisture, in a well-corked bottle, in the dark, this will not happen, and the way to keep it free from moisture is to put into it lumps of quicklime or fused chloride of calcium; when so treated it may be used with safety. One does not like to have so old a friend banished without saying a word in his defence. The suggestion made to use oil of lavender is a very good one, but it need not displace turpentine, but both must not be used together.

"The conditions under which a painter commenced his education in former times were totally different from what they are now." It would be better for art if they were the same, though perhaps not better for art regarded as a trade. The paintings of the old masters certainly beat most of the modern works in this country, both in merit and durability. Mr. Muckley's remarks on this point are

very good; one only wishes that he had treated this part of his subject more fully.

The chapter on "Mixing and Nature of Colours" is not as complete as it should be, from the almost entire absence of chemical illustrations, which on such a subject are invaluable. One remark, however, which often occurs in this book is most admirable. "The painter should always make an effort to use as few colours as possible, and they should be of the most permanent kind."

On damage to oil-paintings by gas and damp, it is stated that painter's canvas is usually prepared by first covering one side of it with a coat of whiting, to which glue size has been added. This is hardly a correct statement of the method employed by the best firms. The canvas is treated with size rubbed in with long knives, in the jelly form, it is then scraped off as bare as possible. This is done to protect the canvas from the disintegrating effects of the oil used in the preparation of the surface, for oil oxidises and speedily rots canvas, and therefore a coat of oil paint would not be, as stated, a protection to the back of prepared canvas: better use paraffin, which does not oxidise. Space will not allow a further notice of the concluding chapters of this work. One or two points, however, seem to require remark. "If darkening of a picture is due to some chemical action in the colours themselves, which is not unfrequently the case, the original condition of the work cannot be restored." If the darkening be due to the action of sulphuretted hydrogen or white lead, the whiteness can be restored by washing with peroxide of hydrogen.

In the directions given for painting the walls of the painting-room it is advised to use prussian blue, and the vehicle to be employed is spoken of as distemper colour. prussian blue is immediately decomposed by lime or chalk, and therefore cannot be used with these materials.

On the whole, one feels great pleasure in recommending this book as useful to art students. As has been before stated, it is matter for regret that parts of it have not been more fully treated, and at the same time it must be observed that, as regards scientific questions involved in the composition of pigments and on their action on one another, as well as the adulterations with which they are contaminated, the subject is almost wholly untouched, and we must look for some further treatise to illustrate and explain these points, either from Mr. Muckley or from some other author.

A VISIT TO ETNA

Un Viaggio all' Etna. Del Prof. Orazio Silvestri, di Firenze, Presidente del Club Alpino Italiano a Catania. (Torino: Ermanno Loescher, 1879.)

THE Italian Alpine Club has branches in all the principal cities of the kingdom, and a good deal of useful work is done every year by its members. The work before us is designed not only for the benefit of the Club, but to foment and foster a greater taste among Italians for exploration, by setting before them a history of their most famous mountain, and detailing the very varied incidents to be met with in a journey to its summit. The book is divided into eight chapters, and is furnished with an appendix, which contains a list of the principal monticules on the slopes of Etna, with their altitude and position; the altitude of the principal towns on and around the mountain; and (to prevent imposition) the tariff established by the Catanian branch of the Alpine Club for the ascent of the mountain, and for visiting points of interest on its flanks.

The population of the mountain is rapidly increasing. In 1871 it amounted to 314,092, divided between thirty-nine cities, towns, and villages. The largest of these—Catania—contains 84,397 inhabitants; the smallest—S. Agata di Battiati—507.

The first chapter of the "Viaggio" carries the traveller from Turin to Naples, from Naples to Messina, and from Messina to Catania. The passing glimpses of Vesuvius and Stromboli are described, and the beautiful coast scenery between Messina and Catania, which embraces the Capo di Taormina, one of the most picturesque spots in Europe. The second chapter describes the ascent as far as Nicolosi, the last village on the route to the summit. In its immediate neighbourhood are the Monti Rossi, formed during the eruption of 1669, which is described at some length.

Starting from Nicolosi (Chapter III.), the traveller passes over the lava of 1537, and presently enters the *Regione Selvosa;* he notes the numerous groups of monticules scattered in various directions, rests at the Casa del Bosco, 235 metres higher than Vesuvius; and later on continues his journey through a region in which the vegetation becomes more and more sparse until he arrives at the Casa Inglese, near the foot of the great cone. Here the author bursts out into an "Inno alla Natura" improvised by the poet Mario Rapisardi on the occasion of his visit to the summit, and of which the following is a specimen:—

> "Sorridi a noi, sorridi,
> O Dea! sia che de l'Etna
> T'amiamo oggi invocar,
> O dai pietrosi lidi,
> Ove fuggente e pavido
> Scagliossi il poveretto Aci nel mar."

About two o'clock in the morning the traveller leaves the Casa Inglese for the summit (Chapter IV.). The severe climb up the cone of cinders (angle from 32° to 35°) is attended by some difficulty of respiration, both from the rarity of the atmosphere, and the presence of volcanic exhalations. The phenomena preceding sunrise are described, the gradual illumination of the scene, and the projection of the shadow of the mountain over Sicily. An account of the appearance of the great crater concludes this chapter. A description of the eastern flank of Etna and the Val del Bove furnishes the matter for the two succeeding chapters. The geology of the mountain is herein discussed; specially the theory of two axes of eruption, warmly supported by Lyell and other geologists.

After resting a night at Giarre, the traveller visits the eruptive craters of 1865, passing by the villages of S. Giovani and S. Alfio, and through the wood of Carpinetto, which contains the celebrated *Castagno del Cento Cavalli.* A detailed account of the eruption of 1865 which was minutely studied by Prof. Silvestri, is given in this part of the book (Chapter VII.). The last chapter is a very comprehensive one. It takes the reader completely round the northern, western, and southern flanks

of the mountain, by way of Randazzo, Bronte, Adernò, Paterno, and Monte Ste. Anastasia, and so back to Catania. Reflections on the results of the journey are concluded by a perfervid peroration, in which the author reminds us that from the top of Etna we may see nearly the whole of that beautiful island which the ancient poets symbolised as "La bionda e leggiadra figlia di Cerere e del sole," and the moderns yet more happily as "la fulgida perla dell' Italico diadema circondata da tre puri zaffiri; il Tirreno, il Jonio, l'Africano" . . .

The book is not illustrated, but it contains a clear and very accurate map of Etna, reduced from that of von Waltershausen, and with the addition of the eruptions subsequent to 1843. Prof. Silvestri's style, while it is accurate and precise from the scientific standpoint, is never dull or lagging. He carries his reader with him, and excites a genuine enthusiasm, which all who know him can well understand. G. F. RODWELL

OUR BOOK SHELF

Methods and Theories for the Solution of Problems of Geometrical Construction, Applied to 410 Problems. By Julius Petersen.

Text-book of Elementary Plane Geometry. By the same. (London: Sampson Low, 1880.)

SOME months since we noticed Prof. Petersen's "Theorie der algebraischen Gleichungen," and now we desire to draw attention to two more works by the same writer. The former, in its Danish garb, appeared so long ago as the year 1866, and having been tried and found to be a successful text-book, the author naturally desired to offer his work to a wider circle of geometers and students. The "Methods" has been rendered also into French; it is "an attempt to teach the student how to attack a problem of construction." Solutions in most cases are merely indicated, the following up the author's remarks being left to the student or teacher. The first chapter treats of "Loci" (method of similitude and inverse figures); the second of "Transformation of the Figures" (parallel translation, replacing, and revolution around an axis); the third of "The Theory of Revolution," with an appendix on systems of circles and on the possibility of solving a given problem by the straight edge and pair of compasses. It is a work of considerable merit. The "Text-book" we do not value so highly, though there are points of interest and novelty about it also; it contains besides 228 geometrical exercises. We hail Prof. Petersen as a valuable coadjutor in the work of improving geometrical teaching, and shall be glad if his little books meet with a fair measure of acceptance in this country. We could point out what we consider blemishes, but in the main commend both books. The respective translators (both, we presume, Danish students) have done their part intelligently, and English students will have no difficulty in understanding the language, though they may not be able to master the matter.

Practical Chemistry. The Principles of Qualitative Analysis. By W. A. Tilden, D.Sc. (Longmans and Co., 1880).

OF making books on practical chemistry there is no end. If it were necessary that another should be added to the list, the publication of this little book by Dr. Tilden has surely removed the necessity.

There is no special feature to be noted in this book; it is clearly and accurately written, and proceeds on the well-beaten paths. The adoption of a general table printed on strong paper and protected by cloth backing is to be commended.

It is, we think, doubtful whether anything is to be gained by attempting to teach mere outlines of the methods for analysis of mixtures; a more thorough grounding in qualitative analysis may, as a rule, be given by limiting the student's work for some time to simple salts—which is not such an extremely easy branch of analysis as may at first sight appear; then proceeding to mixtures of metals with one metal only in each group; then to mixtures of various metals of the same group; and lastly to complex mixtures.

The detection of acids—even of a simple acid—is made, as is usual in elementary text-books, to appear a much less difficult undertaking than it really is.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

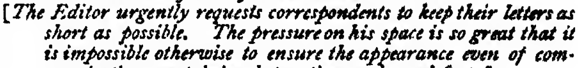
A Rotatory Polarisation Spectroscope of Great Dispersion

I HAVE just had an opportunity of trying, on a fine aurora, an instrument for measuring the wave-length of monochromatic light in terms of quartz-rotation of its plane of polarisation. My apparatus is, as yet, very roughly put together, so that I got no measurements of any value, but to-night's experience has shown me that the method, while simple in application, is capable of very great accuracy.

The construction of the instrument will be easily understood from the anexed rough sketch. The course of the light is with the arrows. N is a Nicol, S an adjustable slit, L a lens at its focal distance from S, Q a plate of quartz cut perpendicularly to the axis, P a double-image prism, and E a small direct-vision spectroscope, which may be dispensed with when absolutely monochromatic light is to be examined.

When the instrument is properly adjusted by daylight the two images of S formed by P are parts of a straight line, so that E gives two spectra side by side. These are crossed by dark bands, which are numerous in proportion to the thickness of Q, and which move along the spectra as N is made to rotate.

In observing a bright-line spectrum the slit is to be made as wide as possible, subject to the condition that no two of the



differently-coloured images shall overlap. We have thus a pair of juxtaposited rectangles for each of the bright lines, and the angular positions of N, when the members of the several pairs are *equally bright*, are read off on a divided head. I find by trial that a division to 2° is quite sufficient.

A *first* set of readings is taken with a plate Q (permanently fixed in the instrument) 5 or 6 millimetres thick. Then an additional plate of quartz 100 millimetres or more thick is introduced between Q and L, and a *second* set of readings is taken. From the readings with the thin plate we find approximately the positions of the spectral lines, and the more exact determination is obtained from the readings with the thick plate.

This is the chief feature of the instrument. The actual error of any one reading is not more than 2°, but when a thick plate is used the whole rotation may be from ten to twenty or even thirty circumferences. By thus increasing the thickness of the quartz plate *very* little additional loss of light is incurred, while the inevitable error forms a smaller and smaller fraction of the whole quantity to be measured.

The graduation of the instrument is to be effected by very careful measurements upon a hydrogen Geissler tube, and comparison with the known wave-lengths of the hydrogen lines.

An observer furnished with this instrument (which is not much larger than a pocket spectroscope) and with a long rod of

quartz, will be able to make measurements of any required degree of accuracy.
P. G. TAIT

The Club House, St. Andrews, N.B., August 12

Dimorphism of "Nature" on June 17

WITH reference to the statement in an editorial note in NATURE, vol. xxii. p. 317, that one statement of mine "does not accord well" with another, I must request to be allowed to show that this observation is incorrect.

I was told by a friend on July 27 (five weeks after the event) that there had been apparently two issues of NATURE of June 17, and that Prof. Allman was intending to write to NATURE quoting the uncorrected issue (which was unfortunately the one which had been supplied to him) in support of his statement, in NATURE, vol. xxii. p. 218, which I had declared to be a misconception (NATURE, vol. xxii. p. 241), viz., that I differed from him as to the existence of a marginal canal in the new medusa. Accordingly I wrote on July 28 to the editor, requesting him to state, "if necessary," that there had been two issues, and expecting that this explanation would be inserted immediately after Prof. Allman's letter, published in NATURE, vol. xxii. p. 290. The explanation was not, however, given, and it was left to me to write my letter of two days later date (July 30), which was published in NATURE, vol. xxii. p. 316. I had in that two days interval "ascertained" by further evidence that there were actually two issues of No. 555 of NATURE, and my "great surprise" was due to the fact that the editor of NATURE should have allowed Prof. Allman's letter to appear without offering any explanation of the direct opposition between his quotation and mine—the cause of which was well known at the printing office of NATURE.

It is thus clear that my letter of July 30 is consistent with my letter of July 28.
E. RAY LANKESTER

[We willingly give space to the above letter, and, accepting the interpretation of the former one which Prof. Lankester now gives us, we regret having made the observation to which Prof. Lankester alludes. We may further add that the insertion of the reference to the letter in question was due to an oversight.—ED.]

Magnetic and Earth-Current Disturbance

IT may be of interest to point out that a magnetic disturbance has just been experienced at the Royal Observatory greater in magnitude than any that has occurred for some years.

On August 11, at 10.30 a.m., active disturbance suddenly commenced, and continued until midnight, accompanied, as usual, by the exhibition of earth currents. The magnets were then generally quiet until about noon of August 12, when disturbances of still greater magnitude began to be shown, continuing till 6 a.m. of August 13. During the latter period the variations in the magnetic declination and horizontal force were frequent and large, especially between noon and 4 p.m., and between 7 and 9 p.m. Between noon and 4 p.m. there was also a considerable increase of vertical magnetic force. During the whole period, from noon of August 12 to 6 a.m. of August 13, earth-currents were continuous and strong, and especially strong at those times at which the magnets were most disturbed.

It seems well at the present time to warn telegraph engineers, and especially those concerned in the laying of submarine cables, that disturbances of the character of that described above may now become not unfrequent as compared with the quietness of recent years. I may perhaps be permitted here to refer to a short paper, "Note on Earth-Currents," to be found at p. 214 of vol. viii. of the *Journal* of the Society of Telegraph Engineers, as containing information on the question of magnetic disturbances and earth-currents, probably not without interest at this time.
WILLIAM ELLIS

Royal Observatory, Greenwich, August 14

P.S.—During the evening and night of August 13–14 large magnetic disturbances again occurred, accompanied as before by strong earth-currents.

Aurora Borealis and Magnetic Storms

THE epoch of grand auroras and magnetic storms has again returned, as was evident from the fine displays seen here on the evenings of the 11th and 12th, and these are as usual accompanied by an increase in the number and size of the sun-spots, and in the development of the solar prominences. The aurora on the 11th was grand, but that which followed it on the 12th recalled vividly the magnificent displays of 1869, 70, and 71.

On the 12th my attention was first called to the phenomenon at 10h. 25m. p.m., when the northern horizon was skirted by a bright white haze terminating in an ill-defined arch, from which sprang a large number of broad streamers stretching towards the zenith. The bank of white light on the horizon extended from about 15° E. of N. to 45° W. of N., and some of the streamers attained an altitude of fully 60° or 70°. The brilliancy of the individual streamers was varying rapidly, but there was little variety in the character of the phenomenon.

At 10h. 30m. the brightest streamer was 3° W. of N. Ten minutes later this brilliant white band of light had moved gradually westward, and was some 25° W. of N., when it faded away. Some streamers were still more W. of N., and others again were slightly E. of N.

At 10h. 46m. there was nothing remaining of the aurora except a cloudy whiteness in the north, the rest of the heavens being a deep blue. A minute later streamers were again appearing.

At 10h. 56m. a very bright streamer formed 2° E. of N., and then a similar band of light appeared 5° W. of N., followed in rapid succession by other streamers 10°, 20°, and 45° W. of N., each streamer fading away before the succeeding one became very bright.

At 11h. 0m. a single narrow band of intense white light stretched from the horizon towards the zenith, passing through Cor Caroli.

At 11h. 7m. the light in the N. and N.N.W. again brightened up, but there was no further appearance of streamers.

The magnetic storm that accompanied the aurora of the 12th was one of the most violent ever recorded at this observatory, and was very similar in character to the magnificent storm of 1869.

On the evening of the 11th the magnetic needle was very irregular in its movements, but it was only towards midday of the 12th that the storm really began. The oscillations from the beginning were very rapid and extensive. The first great movement began at 11h. 34m. a.m., and between 12h. 18m. and 12h. 24m. the declination magnet moved 1° 6′ 45″ eastward. It then returned westward, and at 1h. 4m. the reading had increased by 1° 18′ 13″. Between 7h. 9m. and 7h. 29m. p.m. the needle moved 59′ 18″ eastward, when it attained its minimum; it then returned quickly towards the west, and after a double sweep it reached its maximum at 8h. 13m., the change of declination in 46m. being 1° 27′ 23″.

The oscillations of the V.F. magnet were as great as those of the declination. The chief maximum occurred at 3h. 40m. p.m., and there were three decided minima at about 10 p.m. midnight and 2 a.m., the two latter of which were lost from the oscillation being too great to be recorded on the photographic cylinder, and the first showing a change of 1·9 inch of ordinate in 5m.

The variation of the H.F. magnet was very large, but not so remarkable as that of the V.F.

On the 13th the magnetic storm continued greatly to disturb all the magnets, but it was less violent than on the preceding day.

Stonyhurst Observatory, August 15
S. J. PERRY

THERE was a beautiful display of the aurora here last night. Between ten and eleven o'clock the streaks extended from the horizon to the zenith. The colour was principally pale blue, but a reddish tinge was occasionally discernible. I observed what I thought was a lateral movement of some of the streaks. A bright spot suddenly made its appearance to the westward of a small black cloud, seemed to move slowly eastward and disappear. There was a slight breeze from the east at the time, but I do not think that the clouds were moving sufficiently rapidly to account entirely for the phenomenon.
J. A. B. OLIVER

Springburn, Glasgow, August 13

A FINE display of aurora was visible here on the night of Thursday, August 12, about 10.30. White streamers, stretching vertically from the horizon nearly to the zenith, occupied the north-west segment of the heavens from the pole to Arcturus. There was a narrow bank of cloud along the horizon, and I thought at first that the streamers might be shadow-phenomena from the sun; but the hour was too late, and the rapid variations of form and

intensity were characteristic of aurora, which is not very common at this season of the year, I think. F. T. MOTT

Birstal Hill, Leicester, August 13

WE had a fine aurora here last night (11th). There was a bright bank of uniform glow till 11 p.m., when it suddenly broke into streamers, some of which reached 40° or 45° in height, the glow extending along 100° or 120° of the horizon. There was no colour, and by midnight it had all faded out.

Whitby, August 12 B. W. S.

Height of the Aurora

I SHALL be glad if you will allow me the use of your columns to point out that there is really less uncertainty about this element than is usually supposed, and that there are two methods of measuring auroral heights which give accordant results. The first is that based upon the measurements of the altitude and amplitude of auroral arches, and which gives the results mentioned by Mr. Rand Capron. That these results should have so wide a range is probably owing to the fact that they proceed upon an assumption which may or may not be correct, viz., that the arch is part of a circle having the magnetic pole for its centre. Still the mean result from this method would seem to be reliable, especially if care were taken to exclude doubtful measurements from the list. Possibly we may assume that this method gives a height not far from 100 miles for the ordinary arch. I speak particularly of the white auroral arch with or without uncoloured streamers that forms, I suppose, 95 per cent. of the auroral phenomena visible in this country. These arches are formed for the most part over a portion of the earth considerably to the (magnetic) north of these islands, but occasionally they would seem to be formed over our heads. Mr. Capron in his work on "Auroræ and their Spectra" mentions one such instance, though he appends no explanation of the phenomenon, but in the course of ten years' observations I have myself seen three such arches. Indeed they are perfectly well known to observers in Scotland and the north of England, though I have never seen them in the south. As early as the year 1843 the height of these zenithal arches had been trigonometrically computed from observations made in different localities in Britain, with the result of proving them to be at an uniform height of 70 to 74 miles above the earth.[1] There is much less liability to error in these results than in the determination of the height of a meteor, and a single pair of satisfactory observations will yield a value within one or two miles of the actual elevation.

That auroral arches are ever formed much below this limit I beg leave to doubt. I am aware of the accounts which would place them between the eye and natural objects, but such assertions are far from having the weight of accurate measurements, and I have yet to find a case of a supposed low aurora, the evidence of which is above criticism.

I do not wish to assert that the streamers at right angles to these arches may not be frequently visible at a *less* height, just as they undoubtedly reach to a much *greater* elevation in the region where the auroral crown is formed. But to fix either the superior or inferior limit is precisely one of those questions which we can have no hope of solving by direct measurement, since the length of the streamer varies with the force of electric discharge. This is shown by the fact that in an active aurora some streamers extend only a short distance from the arch, while others will climb up to the vanishing point, or crown.

To carry these remarks so as to include the question of coloured auroræ would oblige me to trespass more upon your space than I am willing to do on this occasion.

Orwell Park Observatory, Ipswich JOHN I. PLUMMER

Fire-Ball

ON the evening of the 12th a very brilliant fire-ball fell at 8h. 30m. G.M.T. It was first observed at an elevation of about 25° above the E.S.E. horizon, and its path was inclined at an angle of about 35° to the horizon. It was lost in the mist near the south horizon. There was no explosion or noise of any kind. The daylight was still fairly strong, and yet the light of the meteor was very dazzling. S. J. PERRY

Stonyhurst Observatory, August 15

[1] I give these figures from memory, as I have no library at hand to which to refer, but I have no doubt that they are strictly correct. Mr. Capron may perhaps find some information on the point in the published works of the late Prof. Phillips, who was one of the observers engaged in these investigations about the date I have named, or they may be verified upon the first appearance of a zenithal arch.

Atmospheric Phenomenon

A CURIOUS phenomenon was observed here after sunset the night before last, and again in a less degree last night.

Looking across from this point to the position of the sun at and after setting, the line of sight crosses about three miles of sea, then about the same distance or rather less of projecting high ground, and beyond that many miles of sea again. On Tuesday (10th) the sun set in a hot haze, and half an hour after there appeared on the edge of the projecting land what looked like tongues of flame fifteen to thirty minutes in height, lasting from two to four seconds each, and then disappearing in different places, sometimes half a dozen at a time. At the same time there was more or less of a flickering light along the whole line of projecting land.

My first impression was that it was an optical illusion, and the second that a moor was on fire behind the ridge, and that these were points of flame. The first was negatived by the fact that four others beside myself (two of them with very keen sight) saw the lights independently in the same places; and the second by the gradual fading of the light as the evening became darker, the "tongues" retaining pretty much their relative brightness to the general glow until both faded out.

The day had been extremely hot, and the evening was sultry, with motionless air. I imagine the appearance was due to irregular refraction, arising from heated currents of air from the cooling land, and that the circumstance of the *slice* of land with its currents occurring between the two stretches of homogeneous air over the sea allowed the effect to be seen without being masked, as it would have been had there been intervening land. But I never saw it before, and don't remember to have seen it described. B. W. S.

Whitby, August 12

Intellect in Brutes

INSTINCT apart, cases of intelligence in animals are very numerous, of the affections still more numerous. Comte was of opinion that the affections were even more highly developed in animals than in men. The dog will lay down life for the man he loves, the horse will do so likewise. We have all heard of Greyfriars Bobby, if that be the creature's name. But instances crowd on the memory. A few years back, during a heavy gale, a sweep of the spanker-boom drove the master of a Leith and London smack into the sea. Instantly the ship's dog bounded in after, and, sustaining the drowning man, both passed grandly into the eternities together. I have known cats who let themselves into the dwelling-house at pleasure, and at least three dogs who were wont to deposit the pennies given them on the counter of some baker or pastry-cook in return for values received. I used to meet on the highway a dog who rode behind his master's groom. The hardest trot never seemed to discompose his seat. Even birds—not merely trained birds—sometimes display singular attainments. I knew a lady who had a singing duck, but being one day at a loss for a couple, she sacrificed the songstress to make up a pair. One wishes that she had displayed a little more humanity; as also a clergyman, not a hundred miles from where I sit, who ordered a goose that had evinced the warmest attachment to be slain by reason of the poor bird having followed him on the occasion of paying a visit into a friend's drawing-room.

When a boy I used to spend many a holiday at a farmer's house in the County Armagh. I there experienced great kindness, enjoying myself as much as was well possible in the open air, the garden, and the stubble fields. Besides human beings, I had numerous playmates too in the kine, swine, dogs, fowl, horned cattle, and horses about the place, and indeed was never tired in observing their modes of living and acting. The great house-dog used often to play with a large hog. They alternately chased and faced one another till the hog's chaps would froth again actually with the excitement of the sport. At first I supposed that the pig did not like it, but in this I was mistaken. One day a strange dog, an immense brute, made his appearance, and attacked the house-dog, who was evidently getting the worst of it, when who should come to the rescue but the hog, who instantly jumped on the strange dog's back, assailing him at the same time with hoof and tooth. Placed thus between two fires, the stranger beat a speedy retreat, leaving the friends complete masters of the situation.

I think I was about ten years old when my parents went to reside at a place called Fairlawn, situated on a gentle eminence a few miles from the mutually contiguous towns of Moy and

Charlemont. Facing the house, a stone's throw or two in front of the lawn, was a river called the Tall, which ran into the close-at-hand Callan, which again ran into the Black Water, which, in turn, emptied itself into that immense puddle which bears the name of Lough Neagh. The waters of Lough Neagh, unable, by reason of the obstructions in the Lower Bann, to escape rapidly enough into the sea, swell up and cause backwater in the rivers I have named, and others as well. The result is the periodic flooding of thousands and tens of thousands of acres of valuable land, to the immense prejudice of the occupants and country at large. The Tall, I should observe, was banked or dyked up on both sides. In some places, however, the dyke had given way, so that at flood-time—and it was flood-time at the period I speak of—the waters of the Tall were awash with those of the flooded meads on both sides. There was further a rapid current in the Tall, and before it merged into the Callan the stream had to pass under the arch of a bridge which it filled to the crown. In fact the battlements themselves were nearly covered, and the country, as far as the eye could reach from the position which I at the moment occupied at the foot of the lawn, wore the aspect of a sea. At this precise juncture two horses, whilom occupants, I presume, of the then flooded meads, were to be seen slowly wading in the direction of the Tall. The green summit of the dyke was for the most part visible, and upon this the poor brutes mounted, in quest, I suppose, of some outlet. They had not gone very far when, owing to the treacherous footing, one of the horses lost his balance and fell, rolling over and over into the Tall. He swam on bravely, the other horse stretching down at intervals a sympathising muzzle, making indeed repeated efforts to escape, but falling back each time into the surging current. I was alone, surveying the transaction, from which I never removed my eyes, with the deepest interest. All at once the horse that was on the dyke, keeping pace at a sort of half-trot with the other, burst into a hand-gallop, and when he had got sufficiently beyond his struggling comrade, bounded himself into the Tall. Swimming briskly onwards for a few fathoms, he then made his way out through what he must have seen beforehand was a practicable breach in the dyke, followed on the instant by his friend, evading, not a moment too soon, the submerged bridge, where they would have otherwise inevitably gone under. So long as my eyes could follow them they dashed onwards at a gallop, throwing up their exultant heels and flourishing their tails across the flooded meadows. It is now many years since I beheld this astonishing spectacle, which my memory recalls as freshly as if it had happened yesterday, awakening, as I think it is well calculated to do, serious reflections in regard of our mysterious associates and the wondrous Power which has called them into being, and now sustains them and ourselves alike in this transitory state which we term life. HENRY MACCORMAC

Belfast, August

Radiation.—A Query

IN Baily's experiments with the torsion-rod and two leaden balls weighing 380½ pounds each, it was found that the radiation of heat from the leaden masses affected the vibrations of the torsion-rod. These masses were thereupon gilded, and the torsion-rod protected by a gilt box covered with thick flannel, and the disturbing influence overcome. How did radiation affect the motion of the torsion-rod? F. G. S.

"On a Mode of Explaining the Transverse Vibrations of Light"—The Expression "Radiant Matter"

WITHOUT wishing at all to underrate the apparent difficulty noticed by your New Zealand correspondent, Mr. J. W. Frankland (NATURE, vol. xxii. p. 317) in regard to my paper under the above heading (NATURE, vol. xxi. p. 256), as it would be against the interests of truth to do so; I may nevertheless call his attention to a letter of mine (NATURE, vol. xxi. p. 369), where an attempt is made to meet the difficulty in question. The point is to account for the circumstance (admitting that it is rendered necessary by physical evidence) that the velocity of propagation of gravity must, at least, be very much greater than that of light. I will merely confine myself here to recapitulating one of the main conclusions in a somewhat different form, viz., it appears to be necessary to look to a separate medium for gravity, or (more accurately) to *one* medium with particles of two grades of dimensions; the one set of particles having very minute mass, and consequently enormous velocity, and concerned in the effects of gravity; the other set, of much greater mass and slower velocity, concerned in the phenomena of light. It will, I think, be so far tolerably evident that if the *number* of the more minute set of particles be comparatively very great, the pressure produced by them would be correspondingly great, and therefore these particles would be mainly (*i.e.*, almost exclusively, if their number were sufficiently great)[1] concerned in producing gravity. On the other hand, on account of the extreme velocity of these particles, they could not apparently be appreciably concerned in the phenomena of light, since the molecules of gross matter would vibrate among them without appreciable resistance. For it is a well-known dynamical fact that the resistance opposed to the motion of a body in a medium *diminishes* as the velocity of the particles of the medium increases. It may be worth observing perhaps that this idea of three grades of dimensions in matter (viz. gross matter, light-carrying matter, and gravific matter) appears to be an old one. Thus a book was published in 1827 by Dr. Blair, formerly Regius Professor of Astronomy in the University of Edinburgh, entitled "Scientific Aphorisms" (to which my attention was called by Prof. Tait), where the idea of three grades of dimensions in matter is set forth, and a theory of gravity very similar to that of Le Sage expounded. Also M. Prevost ("Deux Traités de Physique mécanique") expresses, I believe, the view that matter exists fundamentally in three grades of magnitude.

It may be rather a curious fact to notice that if the theory, that the æther consists merely of finely sub-divided matter in the ultra-gaseous state, light being regarded as a vector property carried off by the atoms in their passage through the open structure of the vibrating molecules of gross matter, as suggested by the late Prof. Clerk Maxwell, article "Æther," new edition of the "Encyclopædia Britannica" (*i.e.*, with range of free path greater than planetary distance, NATURE, vol. xxi. p. 256),[2] should ultimately turn out to be substantially true; then the term "radiant matter," employed by Mr. Crookes in connection with his experimental researches, would have its practical application in nature on a large scale—or light would be actually propagated by "radiant matter." If, on an examination of the theory in that spirit of good-humoured impartiality representing entire freedom from the predilections of any school of thought (the best guarantee of truth)—the difficulties attaching to it should not be considered insurmountable; then it may be worth remarking that the theory, without violating in the least the essential principles of the firmly-established undulatory theory, contains nevertheless (in its corpuscular essence) *one* of the ideas of Newton; so that it would appear that the latter might not have been entirely wrong, nor the upholders of the opposite view completely right, but that a partial reconciliation of their rival ideas might be possible. S. TOLVER PRESTON

London, August 10

Earthquake in Smyrna

ACCOUNTS are freely coming forward, but they are of popular interest, seismological details being scanty. I must premise that in in 1862 I took great interest in promoting Abyssinian wells in Smyrna, and that large numbers were put down. When the French Company built the quay the new works there were similarly supplied, and the result has been that for some years the surface and pipe-wells in the parallel Marina and Frank Streets have been wanting in water.

Within a few hours after the earthquake it was noticed that both classes of wells, say 600 feet from the sea, were freely supplied with water. This fact appears to me deserving of record.

It is said that the earthquake was most felt near the Greek Cathedral of St. Photius, at the Three Corners in Frank Street. It was here the ground opened in the last century earthquake and swallowed up two men, as I heard by tradition; and I always walked across the churchyard in full remembrance.

Of late years some kind of a landslip took place on Mount Pagus, or the Castle Hill, where Alexander the Great fell asleep.

[1] It may be worth noting in connection with this that (according to a principle developed by Sir W. Thomson, *Phil. Mag.*, May, 1873) it appears that if the "elastic rigidity" of the *larger* particles were such that they suffered no appreciable diminution of velocity at rebound from gross matter, they would not be appreciably concerned in the effects of gravity (even if their number were comparable to that of the smaller set of particles).

[2] Also previous papers by the present writer (on the same subject)—*Phil. Mag.*, September and November, 1877, February, 1878, April and May, 1880.

In this new earthquake springs are said to have burst out on the side of Mount Sipylus. HYDE CLARKE

32, St. George's Square, S.W., August 9

New Biological Term

IN writing certain parts of a book on water-beetles, I find myself frequently desirous of indicating briefly but emphatically that some particular genus I may be mentioning consists of only a single species. If we take a rational or theoretical view of classification rather than an empirical one, it must be admitted that a genus consisting of only one species is almost as great an anomaly as a species that should consist of a single individual; and a special term to indicate the fact would be desirable. Mr. Pascoe has suggested to me that the expression "monotypical genus" meets the want: but I am not satisfied with this, for in the first place it is a phrase, not a word; and in the second place the use of the "typical" interferes with concentration of thought by the introduction of an alien suggestion. I therefore propose to use either the word "autogenus" or the word "monogenus" for the purpose, and on the whole prefer the former. Perhaps some one else may be able to suggest a better term, and I shall be very glad of an expression of opinion on the point.

Thornhill, Dumfriesshire D. SHARP

Depraved Taste in Animals

YOUR correspondent, Mr. Nicols, draws attention this week to what he terms the "depraved taste" for tobacco exhibited by several individuals of that species of Phalangistidæ known as the koala.

Whilst in Australia some years ago I myself remarked the same propensity amongst numerous *wild* specimens of the *Pharcolarctos cinereus*, in an abandoned tobacco clearing not far from my residence, and, like Mr. Nicols, I also observed that no ill effects seemed to follow the consumption of the tobacco by the Koalæ. Now since the Phalangistidæ I had the opportunity of observing were perfectly wild, I cannot agree with Mr. Nicols that their taste for tobacco is a depraved one, although the desire for spirits which he mentions is of course decidedly unnatural.

These observations induced me to make several analyses of the Victorian tobacco, with the result of isolating an hitherto undiscovered vegetable alkaloid. A detailed account of my various experiments is contained in a paper read by me before the Melbourne Medical and Chemical Society, and printed in the fourteenth volume of the Society's *Transactions*.

Firing a Tallow Candle through a Deal Board

WILL the writer of "Physics without Apparatus" be good enough to specify the conditions of success for the above experiment? C. J. WOODWARD

Birmingham and Midland Institute, August 9

[Set up a ½-inch or ⅞-inch plank of deal in the ground. It should be 6–8 inches wide. Ram small charge of gunpowder into gun with wad. Select a *dip* candle just fitting bore; cut down to about 5 inches long, with flat end. Be very particular *to ram it down well*; for if there is air space between it and the wad there is risk of bursting gun. Take care that the rest of barrel is cleared of bits of tallow. Fire at say 3 yards from plank. If you don't miss aim, there will be a hole *torn*, about 2 inches in diameter.—The WRITER of "Physics without Apparatus."]

$\sqrt{-1}$ must send his name and address.

THUNDERSTORMS[1]

II.

BEFORE I can go farther with this subject it is necessary that I should give some simple facts and illustrations connected with ordinary machine electricity. These will enable you to follow easily the slightly more difficult steps in this part of our subject which remain to be taken.

Since we are dealing mainly with *motion* of electricity, it is necessary to consider to what that motion is due. You all know that winds, *i.e.* motions of the air, are due to differences of pressure. If the pressure were everywhere the same at the same level we should have no winds. Similarly the cause of the motion of heat in a body is difference of temperature. When all parts of a body are at the same temperature there is no change of distribution of heat. Now electricity presents a precisely analogous case. It moves in consequence of difference of *potential*. Potential, in fact, plays, with regard to electricity, a part precisely analogous to the *rôle* of pressure, or of temperature, in the case of motions of fluids and of conducted heat. Now the power of an electrical machine may be measured by the utmost potential it can give to a conductor. The greater the *capacity* of the conductor the longer time will be required for the machine to charge it; but no electricity passes between two conductors charged to the same potential. Hence the power of a machine is to be measured by using the simplest form of conductor, a sphere, and finding the utmost potential the machine can give it. It is easily shown that the potential of a solitary sphere is directly as the quantity of electricity, and inversely as the radius. Hence electricity is in equilibrium on two spheres connected by a long thin wire when the quantities of electricity on them are proportional —not to their surfaces, nor to their volumes, as you might imagine—to their radii. In other words, the capacity is proportional to the radius. This, however, is only true when there are no other conductors within a finite distance. When a sphere is surrounded by another concentric sphere, which is kept in metallic connection with the ground, its capacity is notably increased, and when the radii of the spheres are nearly equal the capacity of the inner one is directly as its surface, and inversely as the distance between the two spheres. Thus the capacity is increased in the ratio of the radius of one sphere to the difference of the radii of the two, and this ratio may easily be made very large. This is the principle upon which the Leyden jar depends.

It is found that the work required to put in a charge is proportional to the square of the charge. Conversely, the damage which can be done by the discharge, being equal to the work required to produce the charge, is proportional to the square of the charge, and inversely to the capacity of the receiver. Or, what comes to the same thing, it is proportional to the square of the potential and to the capacity of the conductor directly. Thus a given quantity of electricity gives a greater shock the smaller the capacity of the conductor which contains it. And two conductors, charged to the same potential, give shocks proportional to their capacities. But in every case, a doubling of the charge, or a doubling of the potential, in any conductor, produces a fourfold shock.

The only other point I need notice is the nature of the distribution of electricity on a conductor. I say *on* a conductor, because it is entirely confined to the surface. Its attractions or repulsions in various directions exactly balance one another at every point in the *substance* of the conductor. It is a most remarkable fact that this is always possible, and in every case in one way only. When the conductor is a single sphere the distribution is uniform. When it is elongated the quantity of electricity per square inch of its surface is greater at the ends than in the middle; and this disproprotion is greater the greater is the ratio of the length to the transverse diameter. Hence on a very elongated body, terminating in a point, for instance, the electric density—that is, the quantity per square inch of surface—may be exceedingly great at the point while small everywhere else. Now in proportion to the square of the electric density is the outward pressure of the electricity tending to escape by forcing a passage

[1] Abstract of a lecture, delivered in the City Hall, Glasgow, by Prof. Tait. Continued from p. 341.

through the surrounding air. It appears from experiments on the small scale which we can make with an electrical machine, that the electric density requisite to force a passage through the air increases under given circumstances, at first approximately as the square root of the distance which has to be traversed, but afterwards much more slowly, so that it is probable that the potential required to give a mile-long flash of lightning may not be of an order very much higher than that producible in our laboratories.

But from what I have said you will see at once that under similar circumstances an elongated body must have a great advantage over a rounded one in effecting a discharge of electricity. This is easily proved by trial. [The electric machine being in vigorous action, and giving a rapid series of sparks, a pointed rod connected with the ground was brought into the neighbourhood, and the sparks ceased at once.] In this simple experiment you see the whole theory and practical importance of a lightning conductor. But, as a warning, and by no means an unnecessary one, I shall vary the conditions a little and try again. [The pointed rod was now insulated, and produced no observable effect.] Thus you see the difference between a proper lightning-rod and one which is worse than useless, positively dangerous. There is another simple way in which I can destroy its usefulness, namely, by putting a little glass cap on the most important part of it, its point, and thus rendering impossible all the benefits it was originally calculated to bestow. [The pointed rod was again connected with the ground, but furnished with a little glass cap. It produced no effect till it was brought within four or five inches of one of the conductors of the machine, and then *sparks* passed to it.] You must be strangely well acquainted with the phases of human perversity if you can anticipate what I am now going to tell you, namely, that this massive glass cap, or *repeller*, as it was fondly called, was only a year or two ago taken off from the top of the lightning-rod employed to protect an important public building. [The repeller was exhibited. It resembled a very large soda-water bottle with a neck much wider than the usual form.] From the experiments you have just seen it must be evident to you that the two main requisites of an effective lightning-rod are that it should have a sharp point (or, better, a number of such points, lest one should be injured), and that it should be in excellent communication with the ground. When it possesses these, it does not require to be made of exceptionally great section; for its proper function is *not*, as is too commonly supposed, to parry a dangerous flash of lightning: it ought rather, by silent but continuous draining, to prevent any serious accumulation of electricity in a cloud near it. That it may effectually do this it must be thoroughly connected with the ground, or (if on a ship or lighthouse) with the sea. In towns this is easily done by connecting it with the water mains, at sea by using the copper sheathing of the ship, or a metal plate of large surface fully immersed. Not long ago a protected tower was struck by lightning. No damage was done in the interior, but some cottages near its base were seriously injured. From a report on the subject of this accident it appears that the lower end of the lightning rod was "jumped" several feet into the solid rock! Thus we see, in the words of Arago, how "False science is no less dangerous than complete ignorance, and that it *infallibly* leads to consequences which there is nothing to justify."

That the lightning-rod acts as a constant drain upon the charge of neighbouring clouds is at once proved when there is, accidentally or purposely, a slight gap in its continuity. This sometimes happens in ships, where the rod consists of separate strips of metal inlaid in each portion of the mast. If they are not accurately fitted together, a perfect torrent of sparks, almost resembling a continuous arc of light, is seen to pass between them whenever a thunderstorm is in the neighbourhood.

I cannot pass from this subject without a remark upon the public as well as private duty of having lightning-rods in far greater abundance than we anywhere see them in this country. When of proper conducting power, properly pointed, properly connected with the ground and with every large mass of metal in a building, they afford absolute protection against ordinary lightning—every single case of apparent failure I have met with having been immediately traceable to the absence of one or other of these conditions. How great is their beneficial effect you may gather at once from what is recorded of Pietermaritzburg, viz., that till lightning-rods became common in that town it was constantly visited by thunderstorms at certain seasons. They still come as frequently as ever, but they cease to give lightning-flashes whenever they reach the town, and they begin again to do so as soon as they have passed over it.

A knight of the olden time in full armour was probably as safe from the effects of a thunderstorm as if he had had a lightning-rod continually beside him; and one of the Roman emperors devised a perfectly secure retreat in a thunderstorm in the form of a subterraneous vault of iron. He was probably led to this by thinking of a mode of keeping out missiles, having no notion that a thin shell of soft copper would have been quite as effective as massive iron. But those emperors who, as Suetonius tells us, wore laurel crowns or sealskin robes, or descended into underground caves or cellars on the appearance of a thunderstorm, were not protected at all. Even in France, where special attention is paid to the protection of buildings from lightning, dangerous accidents have occurred where all proper precautions seemed to have been taken. But on more careful examination it was usually found that some one essential element was wanting. The most common danger seems to lie in fancying that a lightning-rod is necessarily properly connected with the earth if it dips into a mass of water. Far from it. A well-constructed reservoir full of water is *not* a good "earth" for a lightning-rod. The better the stonework and cement the less are they fitted for this special purpose, and great mischief has been done by forgetting this.

A few years ago the internal fittings of the lighthouse at Skerryvore were considerably damaged by lightning, although an excellent lightning-rod extended along the whole height of the tower.

The real difficulty in these situations, exposed to tremendous waves, lies in effecting a permanent communication between the lightning-rod and the sea. But when this is done the sea makes far the best of "earths."

When a lightning-rod discharges its function imperfectly, either from insufficient conducting power or because of some abnormally rapid production of electricity, a luminous brush or glow is seen near its point. This is what the sailors call St. Elmo's Fire, or Castor and Pollux. In the records of mountain climbing there are many instances of such discharges to the ends of the alpenstocks or other prominent pointed objects. One very remarkable case was observed a few months ago in Switzerland, where at dusk, during a thunderstorm, a whole forest was seen to become luminous just *before* each flash of lightning, and to become dark again at the instant of the discharge.

Perhaps the most striking of such narratives is one in the memoirs of the Physical and Literary Society of Edinburgh, on Thunder and Electricity, by Ebenezer McFait, M.D.

The destructive effects of lightning are familiar to all of you. All the more ordinary effects can easily be reproduced by the help of Leyden jars on a small scale. How small you may easily conceive when I tell you that a three-foot spark is considered a long one, even from our most powerful machines, while it is quite certain that lightning flashes often exceed a mile in length, and sometimes extend to four and five miles. One recorded observation,

by a trustworthy observer, seems to imply a discharge over a total length of nearly ten miles.

When a tree is struck by a violent discharge it is usually split up laterally into mere fibres. A more moderate discharge may rupture the channels through which the sap flows, and thus the tree may be killed without suffering any apparent external damage. These results are usually assigned to the sudden vaporisation of moisture, and the idea is probably accurate, for it is easy to burst a very strong glass tube if we fill it with water and discharge a jar by means of two wires whose extremities are placed in the water at a short distance from one another. The tube bursts even if one end be left open, thus showing that the extreme suddenness of the explosion makes it act in all directions, and not solely in that of least resistance. When we think of the danger of leaving even a few drops of water in a mould into which melted iron is to be poured, we shall find no difficulty in thus accounting for the violent disruptive effects produced by lightning.

Heated air is found to conduct better than cold air, probably on account of the diminution of density only. Hence we can easily see how it is that animals are often killed in great numbers by a single discharge, as they crowd together in a storm, and a column of warm air rises from the group.

Inside a thundercloud the danger seems to be much less than outside. There are several instances on record of travellers having passed *through* clouds from which, both before and after their passage, fierce flashes were seen to escape. Many remarkable instances are to be found in Alpine travel, and specially in the reports of the officers engaged in the survey of the Pyrenees. Several times it is recorded that such violent thunderstorms were seen to form round the mountain on which they were encamped, that the neighbouring inhabitants were surprised to see them return alive.

Before the use of lightning-rods on ships became general great damage was often done to them by lightning. The number of British ships of war thus wholly destroyed or much injured during the long wars towards the end of the last and the beginning of the present century is quite comparable with that of those lost or injured by gales, or even in battle. In some of these cases, however, the damage was only indirectly due to lightning, as the powder magazines were blown up. In the powder magazine of Brescia, in 1769, lightning set fire to over 2,000,000 lbs. of gunpowder, producing one of the most disastrous explosions on record.

A powerful discharge of lightning can fuse not only bell wires, but even stout rods of iron. It often permanently magnetises steel, and in this way has been the cause of the loss of many a good ship; for the magnetism of the compass-needles has been sometimes destroyed, sometimes reversed, sometimes so altered that the compass pointed east and west. And by the magnetisation of their steel parts the chronometers have had their rates seriously altered. Thus two of the sailor's most important aids to navigation have been simultaneously rendered useless or, what is worse, misleading; and this, too, at a time when, because of clouds, astronomical observations were generally impossible. All these dangers are now, however, easily and all but completely avoidable.

A very singular effect of lightning sometimes observed is the piercing of a hole in a conducting-plate of metal, such as the lead-covering of a roof. In such a case it is invariably found that a good conductor well connected with the ground approaches near to the metal sheet at the part perforated.

(To be continued.)

HUMAN HYBERNATION

DR. TANNER is scarcely off the field when another physiological wonder breaks out in the form of a sleeping girl of Grambke, near to Bremen. This young lady lies, it is said, in a profound slumber night and day, resting on her left side and never asking for food, but swallowing liquid food when it is put into her mouth. The trance lasts an average of fifty days, during which time she is pale, but does not lose in weight. Her sleep is not cataleptic in the proper sense of the term, inasmuch as she is sufficiently conscious to swallow, and presents none of the indications of death. She merely sleeps. Instances of this kind are not so uncommon as those of true catalepsy, though some of them are sufficiently remarkable. In the *Transactions* of the Royal Society Dr. W. Oliver has recorded the history of an extraordinary sleeping person named Samuel Chilton of Tinsbury, near Bath, who, on May 13, 1694, being then "of robust habit of body, not fat, but fleshy, and a dark brown hair," happened, without any visible cause or evident sign, to fall into a very profound sleep, out of which no art used by those who were near him could rouse him until after a month's time; then he rose of himself, put on his clothes, and went about his business of husbandry as usual; slept, could eat and drink as before, but spoke not one word till about a month after. In 1696, on the 9th of April, this youth fell off to sleep again, and although a heroic apothecary, Mr. Gibbs, bled him, blistered him, cupped him, and scarified him, he slept on for seventeen weeks, waking up on August 7, not knowing he had slept above a night, and unable to be persuaded he had lain so long, until going out into the fields he found everybody busy getting in the harvest, and then remembered very well that when he fell asleep they were sowing of the barley and oats which he now saw ripe and ready to be cut down. For six weeks of this sleep he had fasted, but after he awoke he went to work in his ordinary way, and continued to work until August 17, 1697, when, after complaining of shivering and cold in his back, and vomiting once or twice, he fell into one of his long sleeps once more, and being visited by Dr. Oliver and many others, was subjected to further bleeding and extremely sharp treatment indeed, but without being roused. So he lay sleeping until November 19, when he awoke, said he "felt very well, thank God," ate some bread and cheese, and dropping off still another time, slept on until the end of January, 1698, and "then waked perfectly well, not remembering anything that happened all this while." He was observed to have lost flesh, but only complained of being pinched by the cold, and presently fell to husbandry as at other times. The known phenomenon that is nearest to this is hybernation in some of the inferior animals; but it is worthy of remark that the persons affected take food unconsciously when it is offered them, the lower nervous centres seeming to remain in a continued state of activity.

PHYSICS WITHOUT APPARATUS[1]

III.

THE laws of the behaviour of liquids, their pressure and their flow, are very readily demonstrated without special apparatus by the aid of simple articles of everyday use. First amongst the laws of liquid pressure comes the all-important principle that the pressure exerted by a liquid at any point is proportional to the depth, below the surface, of the point under consideration. This pressure is exerted upwards or downwards according to circumstances. We can show first a case of pressure exerted in an upward direction. Take the glass chimney of a lamp, that of a paraffin-lamp will answer, though the straighter form of chimney used in an Argand or a Silber lamp is preferable. Cut out with a pair of scissors a circular disk of stout cardboard, and attach a thread to it by means of a drop of sealing-wax. Provide yourself also with a deep dish of water. Such a glass trough as is

[1] Continued from p. 345.

used for a drawing-room aquarium will answer capitally for this purpose; but if no deep glass vessel is available, a pan or tub of stone-ware or of tin-ware will serve the purpose. The disk of card should be pressed against the lower end of the lamp-chimney (as in Fig. 8) by pulling up the thread through the glass tube. If it is then lowered into the water in the glass trough, the upward force of the water outside pressing up against the card disk will keep it against the end of the lamp-glass. The deeper it is plunged the more tightly is it pressed up against the end of the tube, for the pressure of the liquid becomes greater and greater as the depth of the disk below the surface is increased. A case of downward pressure is even more simply shown. Take the lamp-chimney in your hand and hold it vertical as before, and fix to the lower end another disk of card, this time fixing it to the bottom of the glass by means of soft bees'-wax or of a little stiff tallow. Now pour in some water from above. At first the disk is held on by the wax, and you may pour in water until the chimney is perhaps half full. But as you go on pouring in water the

FIG. 8.

depth of the water inside gets greater and greater, and the pressure exerted by the column of liquid becomes also greater, until the adhesive force of the wax is overcome, and the water bursts off the card and rushes out. This second experiment may be combined with the first one, as is shown in Fig. 8. After having lowered the empty lamp-chimney closed by the card disk into the trough of water, slowly pour in water into the inside. As long as the level of the water *outside* is higher than that of the water inside, the outer pressure upwards will be greater than the inner pressure downwards; but as soon as enough water has been poured in to raise the inner level to that outside, the internal and external pressures will be equal, and when a few more drops are added inside the card will be forced away. The fact that liquid pressure depends upon the height of the column of liquid that is pressing, is made familiar to us in the arrangements for supplying our houses with water; for when the cistern is at the top of the house we find that on opening a tap in a lower storey the water rushes out with very great force, so grea', perhaps, that we cannot

FIG. 9.

possibly stop it with our hand, however tightly we press it against the mouth of the tap.

FIG. 10.

Another important law of liquid pressure, not so easy of illustration without apparatus, is the famous principle

of Pascal, that when a liquid is put into a closed vessel, and then subjected at any point to a pressure, this pressure is transmitted equally in all directions. If the vessel be a strong one and provided with two movable pistons, a large and a small one, the area of the large piston being many times as great as that of the small one, any pressure exerted upon the small piston to the liquid will be transmitted equally over equal amounts of surface, and hence the total pressure on the large piston will be many times as great as the original force, just in proportion as its area is greater than that of the small piston. This is, in fact, the principle applied in the hydraulic press of Bramah and in the hydraulic machinery of Sir W. Armstrong, by which heavy bridges, dock-gates, and elevators are set in motion. The writer of this article, when sore-pressed to devise an experimental illustration of the principle of the hydraulic press, contrived the following arrangement. The lid of a coffee-pot was removed and a piece of sheet-indiarubber was tied tightly over the open top. Into the spout a piece of lead-pipe about six feet long was inserted, firmly fixed with sealing-wax, and then turned up vertically. The pot was filled with water, and a heavy book placed upon the top. Water was poured into the lead tube until it was filled up to the top. A column of water six feet high affords a pressure of nearly three pounds per square inch, and this, exerted over the whole area of the rubber-covered top, gave a sufficient total pressure to raise the heavy book.

The air also possesses weight, and exerts a pressure which may be upwards or downwards according to circumstances. Let a wine-glass or a tumbler be filled full of water and a thin card laid upon the top of it, so that bubbles of air are excluded. Now invert the whole, pressing the card lightly on to the glass during the operation, to prevent accidents, and it will be found (see Fig. 9) that the water will remain in the wine-glass, and will not fall out. In fact the pressure of the air upwards against the card is much more than sufficient to counterbalance the downward pressure of the water in the wine-glass.

Most of the experiments upon the pressure of the air require, however, the aid of an air-pump for their performance. With the air-pump a large variety of interesting properties of the air can be demonstrated, which otherwise cannot be shown. A few, however, do not require the aid of this instrument. The effect of the external pressure of the air in raising the level of a liquid in a tube from which the air has been partially exhausted, thereby reducing its pressure, can be shown by sucking with the mouth at the top of a glass tube, the lower end of which dips into the liquid in question. Thus it is possible to suck up mercury to a height of fifteen inches into a tube; for the lungs are strong enough to reduce the air in the tube to about half the ordinary pressure. If a glass tube of sufficient length were available it would be possible to suck up water in it to a height of about sixteen or seventeen feet; for a column of that height would be sufficient to counterbalance the difference between the inside and outside pressures.

The rising of a liquid into a space from which the air has been partially removed may also be illustrated in the following pretty way. Take a small bit of card and let it float upon the surface of water in a shallow dish. Upon it place a few shavings of wood and light them with a match; or place a small red-hot coal upon it, and on this sprinkle a little brimstone to burn. Then quickly invert over the blazing mass a wine-glass or a tumbler, as in Fig. 10. As the shavings or the brimstone, as the case may be, burn away, they withdraw the oxygen of the air inclosed in the space above, until only the nitrogen (about four-fifths of the whole) remains. The gases inside, therefore, will not exert so great a pressure as before, and consequently the pressure of the air outside will force the water to rise in the glass as the remaining gases cool down to the temperature at which they were at first.

(*To be continued.*)

ON THE ABSORPTION BANDS IN CERTAIN COLOURLESS LIQUIDS

[Preliminary Notice]

HAVING occasion to examine the absorption spectra produced by considerable thicknesses of alcoholic solutions of certain cobalt salts, we were led accidentally to observe that alcohol alone gave a very distinct band, and afterwards, on examining water, found that it also, when a column of six feet was used, gave a very distinct absorption band in the orange, a little on the less refrangible side of D. By graphical interpolation we find the centre of this band to be about 600, and that the band extends from 607 to 596. This position corresponds very closely, if it be not identical, with Piazzi Smyth's rain band,[1] and also with the band seen in 330 feet of high-pressure steam by Janssen.[2]

Fig. 1 represents this spectrum. It will be seen that the absorption at the red end extends up to the line C, and the end of the shadow is so sharp that it is probable there is a band at this point also, but masked by the general absorption. To convince ourselves that this band belonged to water and not to any accidental impurity, we experimented with different samples of water, using ordinary tap-water, ordinary distilled water, also water which had been made with much care absolutely pure; in all these samples this same band was visible, and as long as the water was clear, as far as we could judge, it was of the same degree of intensity. A column of water eight feet long shows the band clearer than one only six feet; still greater lengths we have not yet tried. We next tried the effect of increase of temperature on the water. For this purpose the glass tube containing the water was fitted into an air-bath, and the temperature was raised from 20° to 60° without removing the tube from before the spectroscope; no change in the band, either in position or intensity, as far as we could see, occurred. Further, it seemed to us that it would be interesting to try whether, on dissolving different colourless substances in water, the band would be affected. We consequently examined saturated solutions of the following substances in a tube 8 feet long:—Ammonium chloride, ammonium nitrate, ammonium carbonate, potassium nitrate, lead nitrate, sodium chloride, and sugar. In all these cases the band was as visible as in pure water, and no additional band was seen. With a mixture of 1 volume of sulphuric acid and 5 of water the band was unaffected, but if pure commercial hydrochloric acid was examined in a 6-feet tube the band was invisible, but with 8 feet a faint indication of it was seen.

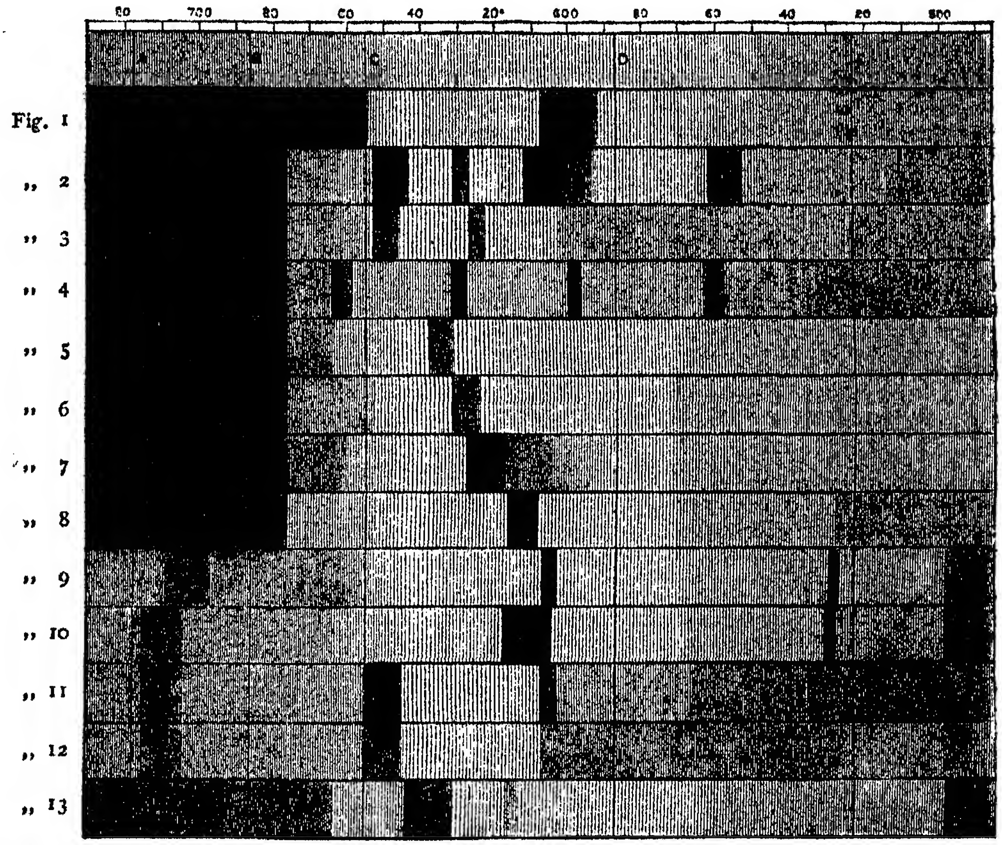
This absorption with water being so marked, we naturally went on to try whether other so-called colourless liquids gave, when depths of 6 or 8 feet of them were examined, absorption bands, and at first really our difficulty was to find any liquid which did not show clearly one or more bands.

The ordinary solution of ammonia gave a very clear and marked spectrum (Fig. 2). It consists of four bands, the centres of which are at 650, 630, 610, and 556. The band at 650 is much the darkest, and the band at 630 is remarkably sharp. Then with regard to the 610 band, it is characterised by sharpness only on the least refrangible side, but shades off gradually on the other side, the shade extending as far as 596; this shade is probably due to the water band; and lastly, the band at 556 is by far the

[1] Piazzi Smyth, "Edinburgh Astronomical Observations," vol. xiv.

[2] In this and the following experiments a Desaga's spectroscope with a single heavy glass prism was used, and the source of light was an Argand gas-burner. The measurements are expressed in the millionths of a metre.

faintest, and is only visible in a column of 8 feet. With the exception of the 556 band, the other bands are so distinct that in a nearly saturated solution $4\frac{1}{2}$ feet in depth, they are clearly seen. This spectrum was so marked and intense that at first we were sceptical with regard to its belonging really to ammonia, thinking that possibly some coal-tar product might be still clinging to the commercial ammonia solution which in the first instance we used. To satisfy ourselves that this was not the case, first we added lime, and distilled the ammonia gas into pure water; this acted in exactly the same way as the former solution; then we obtained from Messrs. Hopkins and Williams what they guaranteed to be volcanic ammonia. A solution of this gave exactly the same spectrum as the former solutions. And lastly we prepared pure ammonia by Stas' method, by the action of caustic potash and zinc—free from carbon—on potassic nitrite; this also gave precisely the same bands as the other ammonia solutions; there could therefore be no doubt that this spectrum belonged to the ammonia solution. Thirty-six feet of ammonia gas did not give us any indication of bands. Obviously this is only a mere trace of gas as compared with the amount held in the solutions before examined. To have as gas the same amount as there was of solution in our 6-feet tube, we should require a tube nearly a mile long. If absolute alcohol instead of water be saturated with ammonia, a spectrum (Fig. 3) still sharper than that with water is obtained, but similar to it, excepting that the band at 610 is wanting and the two bands at 650 and 630 now are of equal intensity, instead of the 650 band being decidedly and constantly the darker of the two. Ammonia giving so definite a spectrum it was evidently



1, Water; 2, Ammonia; 3, Ammonia in Alcohol; 4, Ethylamine; 5, Amyl Alcohol; 6, Ethyl Alcohol; 7, Aldehyd; 8, Acetic Acid; 9, Benzene; 10, Toluene; 11, Aniline; 12, Toluidine; 13, Turpentine.

of much interest to ascertain what spectra would be given by bodies of allied chemical constitution. Ethylamine was the next substance we tried. Using a 33 per cent. solution, this gave a spectrum (Fig. 4) similar in character to that of ammonia, but the dominant band, as far as we could ascertain, has clearly moved towards the red. It was now at 665 to 656. The next band is also somewhat nearer the red than the corresponding ammonia band. The position of the third band is very nearly identical with that of the water-band, but instead of being a wide band shading off on both sides, is now narrow and perfectly sharp. It will be noticed that in the alcoholic ammonia solution it is this band and the next more refrangible one that are absent.

For lack of material we have not yet examined the spectra of other organic ammonias, but intend doing so.

A solution of peroxide of hydrogen was also examined, using the commercial 20-volume solution. The liquid was not absolutely free from colour, and consequently there was a very appreciable amount of absorption over the whole spectrum. The water band was not visible, and in fact no sharp band could be seen; there was however a decidedly marked absorption commencing about 674, then the absorption is both dark and sharp; it extends, diminishing gradually, to 638; very probably this absorption may prove to be a band, but the experiment was not altogether satisfactory.

We naturally returned to alcohol and other typical organic liquids. Alcohol gives in the six-feet tube a very visible and fairly-defined band, more sharply defined than the water band and nearer the red. It extends from 632 to 624. The spectrum is given in Fig. 6. It will be

seen that a faint absorption extends as far as 650, and very likely the termination of this shade is a band. Fig. 6 represents the spectrum of a sample of pure absolute alcohol. Ordinary methylated spirit gives a very similar spectrum, differing only in the presence of some general absorption, and with a mixture of equal parts of methylated spirit and water the alcohol band was still clearly visible, and only a faint indication of the water band.

On referring now to the alcoholic solution of ammonia (Fig. 3), it will be seen that the probable explanation of the darkening of the 630 band is owing to the coincidence of the alcohol band with that of the ammonia, so that really the marked difference of the two ammonia spectra is in the absence of the 610 band, and this, we have seen, may be accounted for by one being an aqueous and the other an alcoholic solution.

Ethylic alcohol giving this definite band, it was a matter of much interest to examine other alcohols belonging to the same series. We found that amylic alcohol ($C_5H_{11}HO$) gave a single visible band (Fig. 5), which in character is like the one given by ethylic alcohol, but differs in position; it extends from 638 to 630, the centre being 634, so that it is decidedly nearer to the red end of the spectrum.

A sample of amylene (C_5H_{10}) gave also a band in the same position as that of the alcohol, but it differs apparently in being broader and less defined at the edges.

The sample of methylic alcohol was not quite pure nor free from colour, but it gave a band quite similar to that of the other two alcohols. Its position is certainly very nearly the same as that of the ethylic alcohol, but as far as our measurements went it was a little nearer the blue, but with our method of measuring hardly discernible.

It seems—pending further investigations—highly probable that this band—and of course there may be others not visible—is common to all the alcohols of the ethylic series, and that its position is a function of the density of the particular alcohol. Apparently however the significance of this line does not stop here, for in ordinary ether there is a band coincident with this alcohol-band—in fact practically the visible spectrum produced by alcohol and ether are identical; but in all cases that we have seen the ether spectrum is clearer and sharper than the alcohol one. We thought it of importance to examine a sample of ether which should be as far as possible rendered pure by ordinary means, especially that it should be free from all traces of moisture: this sample gave a band precisely similar to the band in the ordinary commercial ether. Another sample of ether was saturated with water: in this case the ether band was as marked as ever, but the water-band was not visible.

We have also examined two other bodies which belong to the ethylic series, namely, aldehyde and acetic acid. Both give bands, but they are not so clear or definite as the alcohol or ether bands. Figs. 8 and 9 show these bands. The aldehyde band commences sharply at 628, but on the other side it shades gradually off and ceases at 620. The band in acetic acid is very faint, in fact at first, when using the 6-feet tube, we were led to think there was no visible band.

We also tried a few of the saline ethers, and, as far as our investigations have gone, the ethyl compounds give a band coincident with the alcohol- and ether-band. And the band of the amyl compounds is coincident with that of amylic alcohol. There appears, however, to be this general difference between the bands in the alcohols and those in the corresponding saline ethers, namely, that in the latter the bands are always broader and less distinct; the saline ethers we have examined are ethyl oxalate, amyl acetate, amyl iodide, and amyl nitrate.

Passing now to the aromatic series, we find that they give very marked absorption bands. Fig. 9 represents the bands given by benzene; the spectrum is remarkably sharp and clear, quite as clear as the ether spectrum; the figure is drawn from the spectrum produced by 8 feet of the liquid. The absorption extends as far as 656; the first band is from 707 to 698, the second from 609 to 605; both are very dark and distinct. The third band extends from 531 to 528, and is very much fainter.

Toluene, the next higher member of this series, gave also a similar spectrum, and it is equally sharp (Fig. 10). As in the case of the alcohols, with increase of density the bands have moved nearer the red. It will be seen that the band in the red differs in position from the corresponding benzene band more than either of the other two bands do.

Cresol, unfortunately at present, we have not been able to examine for want of a sufficient quantity of the pure substance.

Phenol gives a spectrum very similar to the benzene spectrum; possibly the band about 610 is somewhat nearer the blue, but beyond this we could see no difference. In the first instance we tried melting the phenol, but afterwards found it far preferable to keep it liquid by the presence of a mere trace of water.

We looked with much interest to the two following experiments, with bodies of this series, namely, aniline and toluidene, to see how far their constitution might be indicated by their spectrum. Figs. 11 and 12 give respectively the spectra of these bodies. There is a band in the red in the same position as the toluene band, and in the case of aniline a band agreeing in part with the 606 benzene band. With toluidene, however, this band was not visible, but probably this arose from its being hidden by general absorption, the liquid used being slightly coloured. However, besides these two bands, both of these amido compounds gave a very clear band from 656 to 645, and it is certainly not without interest that this is coincident with one of the bands given by ammonia; whether any other band coincidences occur between these bodies we cannot say, as in both cases there was sufficient general absorption to hide them even if present.

Among other liquids we have tried turpentine, which appears to give a definite spectrum. This is shown at Fig. 13. With a thickness of 8 feet of carbon disulphide and a similar thickness of carbon tetrachloride, we could see no bands. However, with the former liquid it may prove that there is a band in the green, but as far as we could tell this is doubtful. One other experiment, which has some interest, is that the benzene spectrum is unaltered when the liquid is saturated with sulphur.

Such are the principal observations which we have made up to the present time. As stated at first, we look upon these results as preliminary, and as having to be repeated with more accurate means. Of course we have only dealt with the bands visible under ordinary conditions; still, the above results, as far as they go, have been made with much care, and we think show that most interesting relations exist between the chemical composition and constitution of a body and its absorption spectrum. Obviously a far more extended series of observations must be made before any general conclusions of value can be deduced.

St. Bartholomew's Hospital

CELLULOID

THE product of the action of strong nitric acid upon cellulose has of late years met with many applications in the arts.

When cotton wool, linen, paper, or other substance largely consisting of cellulose, is immersed in strong nitric acid, a mixture of two or more nitro-celluloses is produced; a solution of this mixture in alcohol and ether has been long known as collodion.

About three or four years ago it was shown that this

product may be dissolved under pressure and at moderately high temperatures in camphor, and that on cooling a hard, compact mass closely resembling ivory, is produced. This observation furnished the starting-point in the manufacture of "Celluloid," a substance which has already been put to many and varied uses, and promises to be of much importance in the future.

In the process of Tribouillet and Besaucèle—patented in January, 1879—the raw material, consisting of paper, linen, cotton wool, hemp, or white wood, is dried at 100°, and is then nitrated in vessels of glass, clay, or glazed sheet-iron, furnished with a double bottom, between the parts of which water is constantly flowing. The nitrating acid consists of a mixture of 3 parts concentrated sulphuric acid (sp. gr. = 1·834) and 2 parts concentrated nitric acid, containing nitrous acid. The dry and finely-divided material is first treated with acid which has been already once used for nitrating; the materials are mixed for ten or fifteen minutes by the help of a kind of trowel; the mass is pressed in a glazed iron cylinder with perforated sides and bottom, through which the acid runs out. The material is again treated with a fresh mixture of acids in the proportions already mentioned; it is then washed with water in a series of wooden vessels with perforated bottoms placed one beneath the other on an inclined plane. The last particles of acid are removed by washing with very dilute soda or ammonia, and again with water. The material is then dissolved in appropriate solvents, from which it is again recovered in a paste-like form, by distilling off the solvent.

For making artificial ivory and similar opaque substances, about 100 parts of the prepared nitro-cellulose are intimately mixed with from 42 to 50 parts of very finely-divided camphor, and the mixture pressed in a warm press, into which steam is conducted, and which is connected with a moist chamber wherein the fumes from the press are condensed. After being for some time in a warmer press, the material is dried in a chamber containing calcium chloride or sulphuric acid, and connected with an air-pump.

Other manufacturers appear to mix ivory-dust, nitrocellulose, and camphor, and to press the mixture when moist, heat it with ethyl nitrite in a closed vessel until perfectly homogeneous, and distil off the nitrite.

Celluloid is a hard, perfectly homogeneous substance, which is not attacked by ordinary reagents (it dissolves slowly in cold concentrated sulphuric acid), cannot be easily broken, and becomes plastic at about 125°. It may be obtained in thin layers 0·5 millims. in thickness, which may be encrusted on wood, marble, &c. At about 140° celluloid suddenly decomposes, emitting a reddish vapour; this liability to complete decomposition may be prevented by washing the celluloid with sodium silicate solution and then immersing it in a solution of sodium or ammonium phosphate; thus treated, the material is non-inflammable.

If colouring materials be mixed with the celluloid during the manufacture, artificial coral, amber, malachite, and *lapis lazuli* may be prepared.

Celluloid is an admirable material for forming the backs of brushes, handles of knives or umbrellas, combs, playthings for children, &c.; it is also employed in America as a substitute for linen in the manufacture of collars, scarves for the neck, &c. Articles made of it may be washed with soap and a brush, and are practically indestructible.

M. M. P. M.

L. F. DE POURTALES

[OUR readers will be glad to have the following further notice of the late Count Pourtales from his intimate friend and colleague, Prof. A. Agassiz.—ED.]

Louis François de Pourtales died at Beverly Farms, Massachusetts, in the fifty-seventh year of his age, on July 17, 1880. Spite of a magnificent constitution and a manly vigour of body and mind which seemed to defy disease and to promise years of activity, he sank, after a severe illness, under an internal malady.

Educated as an engineer, he showed from boyhood a predilection for natural history. He was a favourite student of Prof. Agassiz, and when his friend and teacher came to America in 1847, he accompanied him, and remained for some time with the little band of naturalists who, first at East Boston, and subsequently at Cambridge, shared his labours.

In 1848 Pourtales entered the U.S. Coast Survey, where his ability and indefatigable industry were at once recognised, and he remained attached to that branch of our public service for many years. He then became deeply interested in everything relating to the study of the bed of the ocean. Thanks to the enlightened support of the then Superintendent of the Coast Survey, Prof. Bache, and of his successors, Prof. Peirce and Capt. Patterson, he was enabled to devote his talents and industry to the comparatively new field of "thalassography" and the biological investigations related to it. The large collections of specimens from the sea-bottom accumulated by the different hydrographic expeditions of the U.S. Coast Survey were carefully examined by him, and the results were published, in advance of their appearance in the Coast Survey Reports, in *Petermann's Mittheilungen*, accompanied by a chart of the sea-bottom on the east coast of the United States.

So interesting and valuable were the results obtained, not only as an aid to navigation, but in their wider bearing on the history of the Gulf Stream and on the distribution of animal life at great depths, that in 1866 he was sent out by Prof. Peirce, then superintendent of the Coast Survey, to continue these investigations on a larger scale. During 1866, 1867, and 1868 he was in charge of the extensive dredging operations carried on by the U.S. Coast Survey Steamer *Bibb*, acting-master Platt, along the whole line of the Florida reefs and across the Straits of Florida to Cuba, Salt Key, and the Bahama Banks. The results of these expeditions, published in the *Bulletin* of the Museum of Comparative Zoology, excited great interest among zoologists and geologists. M. Pourtales was indeed the pioneer of deep-sea dredging in America, and he lived long enough to see that these expeditions had paved the way not only for similar English, French, and Scandinavian researches, but had led in this country to the *Hassler*, and finally to the *Blake* expeditions, under the auspices of the Hon. Carlile P. Patterson, the present Superintendent of our Coast Survey. On the *Hassler* expedition from Massachusetts through the Straits of Magellan to California, he had entire charge of the dredging operations; owing to circumstances beyond his control, the deep-sea explorations of that expedition were not as successful as he anticipated.

At the death of his father M. Pourtales was left in an independent position, which allowed him to devote himself more completely than ever to his zoological studies. He resigned his official connection with the Coast Survey and returned to Cambridge, where he became thenceforth identified with the progress of the Museum of Comparative Zoology. To Prof. Agassiz his presence there was invaluable. In youth one of his favourite pupils, throughout life his friend and colleague, he now became the support of his failing strength.

The materials of the different deep-sea dredging expeditions above-mentioned had been chiefly deposited at the Museum in Cambridge, and were thence distributed to specialists in this country and in Europe. A large part of the special reports upon them have already appeared. M. Pourtales reserved to himself the Corals, Halcyonarians, Holothurians, and Crinoids. A number of his papers on the deep-sea corals of Florida, of the

Caribbean Sea, and of the Gulf of Mexico have appeared in the Museum publications. He had begun to work at the magnificent collection of Halcyonarians made by the *Blake* in the Caribbean Sea, and had already made good progress with his final report on the Holothurians. The Crinoid memoirs published by him relate to a few new species of Comatula and to the interesting genera Rhizocrinus and Holopus.

The titles of his memoirs indicate the range of his learning and his untiring industry. His devotion to science was boundless. A model worker, so quiet that his enthusiasm was known only to those who watched his steadfast labour, he toiled on year after year without a thought of self, wholly engrossed in his search after truth. He never entered into a single scientific controversy, nor ever asserted or defended his claims to discoveries of his own which had escaped attention. But while modest to a fault and absolutely careless of his own position, he could rebuke in a peculiarly effective, though always courteous, manner ignorant pretensions or an assumption of infallibility.

Appointed keeper of the Museum of Comparative Zoology after the death of Prof. Agassiz, he devoted a large part of his time to the administration of the museum affairs. Always at his post, he passed from his original investigations to practical details, carrying out plans which he had himself helped to initiate for the growth of the institution. As he had been the devoted friend of Prof. Agassiz' father, he became to his son a wise and affectionate counsellor, without whose help in the last ten years the Museum could not have taken the place it now occupies.

If he did not live to see the realisation of his scientific hopes, he lived at least long enough to feel that their fulfilment is only a matter of time. He has followed Wyman and Agassiz, and like them has left his fairest monument in the work he has accomplished and the example he leaves to his successors.

Cambridge, Mass., August 2 ALEXANDER AGASSIZ

NOTES

THE honour of a Knight-Commandership of the Bath has been conferred upon Mr. E. J. Reed, C.B., F.R.S., late Chief Constructor of the Navy.

WE give this week, by the continued kindness of General Myer, the International Monthly Chart for October, 1878, showing mean pressure, temperature, force and prevailing direction of wind at 7.35 a.m. Washington mean time, for that month. The lessons which it teaches may be learned by comparison with the chart for the previous month; any remarks we may have to make upon it we reserve for the issue of the next chart.

WE are happy to state that the Worshipful Company of Drapers have intimated their intention of continuing, at all events for the present, their annual subscription of one hundred guineas to the Research Fund of the Chemical Society.

THE eighth session of the French Association for the Advancement of Science was opened on August 11 at Rheims, under the presidency of M. Krantz, senator and ex-director of the Universal Exhibition of 1878. In his opening speech M. Krantz paid a tribute to the memory of Paul Broca, and spoke of the late Universal Exhibition as well as the construction of the Trocadéro Palace. The General Secretary, M. Mercadier, according to the routine of the French Association, reviewed the work done last year at Montpellier. Addresses were also delivered by M. Diancourt, Mayor of Rheims, and M. Paulane, ex-Mayor, President of the Local Committee. The report read by M. Georges Masson, the treasurer, shows that the French Association is very prosperous, numbering 3,000 members, with a capital of 300,000 francs. The income is 60,000 francs. The attendance is considered to be very good, the local attractions being really unexceptionable in a city whose wines are famous in the whole world, and which is the centre of interesting excursions. On the 12th M. Perrier delivered, in the General Session, an address on the law of selection.

THE Cambridge meeting of the British Medical Association last week is considered to have been one of the most successful which the Association has held. The presidential address by Prof. Humphry traced the history of medical science in the English universities, and showed the causes of the gradual divorce between university and medical studies up to the last few years. He reiterated his advocacy of university residence for medical students, and of continual advance and expansion of good teaching and examining. He claimed that in no other branch of knowledge were true science and sound practice so perfectly conjoined; in no other was there so much that was calculated to give strength and balance to the thinking and the observing faculties; nor was there any in which mental and bodily effort were more required or more telling. What problems were harder of solution than those relating to the aberrations of the human organism? The very difficulty of the problems caused them to be overlooked. Clearer knowledge of physiology and pathology, of heredity, of the effects of social laws and climatic variations, would have a vast influence on the whole framework of civilisation; and thus he was led to conclude with Descartes that all great movements in the world of thought, of philosophy, or of morals, and of government, were to come out of medicine. Cambridge ought not to fail in doing its share in the great work, and renewed life would come to all its best interests from a wise encouragement of medicine. The British Medical Association brings together in one aim an enormous power, and ought to aid in wearing away false dogmas and false notions of conflicting interests. Dr. Humphry further urged on the vast mass of members of the Association a hearty participation in the collection of facts bearing on the effects of temperature, climate, soil, &c., on disease, under the guidance of a medical investigation committee. The latter proposal awakened a cordial response, and the Council were requested to see it carried out. The honorary degree of LL.D. was conferred on Doctors Brown-Séquard, Donders of Utrecht, Gross of Philadelphia, Sir W. Jenner, Sir W. Gull, Sir George Burrows, Prof. Haughton of Dublin, Mr. Wm. Bowman, Mr. Joseph Lister, Dr. Denis O'Connor of Cork (the retiring president of the British Medical Association), Mr. John Simon, C.B., and Dr. Andrew Wood. Dr. Chauveau of Lyons was unavoidably absent from the meeting, and consequently could not receive in person the degree which would otherwise have been conferred upon him; and Prof. Broca's lamented death caused another variation from the list as originally settled.

THE International Congress of Hygiene will meet at Turin on September 6 under the presidency of King Humbert, who will give the inaugural address. The general meeting will take place in the Carignan Palace. The Congress will end by an excursion to Milan, where a cremation will take place.

IN a brief report of the recent French scientific cruise in the *Travailleur*, in the Bay of Biscay, M. Alph. Milne-Edwards says the weather was very good, allowing them in the last fortnight of July to dredge twenty-four times, sometimes using two dredges at once. The bottom has a thick layer of greenish-grey ooze, which was apt to fill the dredges, so recourse was had largely to weighted rods with hemp or twig bundles, swabs, &c., attached, to sweep the bottom. Sir William Thomson's wire apparatus proved very serviceable in sounding. The greatest depth reached was 2,700 m., and the least exceeded 300 m. An important collection of marine

organisms was obtained, including, besides most of the species described by English and Scandinavian naturalists, many new animals not previously known. Some large Gorgonians of the genus Isis, once brought up from 600 m., about midnight presented a curious sight: the whole of the sarcosoma between the zooids emitted a green phosphorescent light so strong that on agitating these animals they seemed to produce a shower of fire, and with the light emitted one could read the smallest type. The collections are distributed thus: M. Vaillant examines the fishes, nemertians, and sponges; M. Fischer, the molluscs; M. Marion, the annelids, echinoderms, and other zoophytes; M. de Folin, the foraminifera; M. A. Milne-Edwards, the crustacea; while M. Perier has made thermometric observations, and will analyse the samples of sea-bottom.

AMONG our letters this week are some referring to the recent remarkable displays of auroræ. Another correspondent writes that similar displays were seen from Caithness-shire on the evenings of Wednesday the 11th, and Thursday the 12th inst. The finer of the two displays was on the Thursday, lasting from about 10 p.m. to midnight. The outburst of streamers at 10.15 p.m. was very fine, the streamers appearing like wavy swaying curtains from the zenith to near the horizon, with a development of tints of the loveliest green near the zenith. The aurora of the 11th was to the north-west of Wick, but that of the 12th chiefly to the north-east. From Kirkwall also fine displays were seen on the 13th till past midnight. Reports in the daily papers also show that the phenomena have been seen from many parts of England as well as Scotland. Fine displays of this beautiful meteor may very confidently be looked for during the next three months, and if our spectroscopists bestir themselves a large extension of our knowledge of the aurora is close at hand.

PROF. SILVESTRI writes to the *Daily News* Naples correspondent that in a short time the Observatory on Etna will be an accomplished fact. The Italian Government contributes half of the expenses, the Province of Catania a fourth, and the Commune of Catania the remaining fourth. The object of the observatory is the study of vulcanology, and therefore it has been built at the base of the central cone, exactly on the former site of the well-known refuge called the "Casa degli Inglesi.' It will be in connection with several small sismic stations posted on the slopes of the mountain, and the whole will communicate telegraphically with another vulcanic station which he proposes to establish in Catania. In the central observatory, so favourably situated about 3,000 metres above the level of the sea on the isolated mountain, where the extent of view is unlimited, and the sky peculiarly transparent, meteorological observations most interesting to science will be carried on, and Prof. Tacchini, the astronomer, proposes to make there experiments in physical astronomy, particularly relating to the spectroscopical study of the fixed stars. The Observatory will therefore be divided into three scientific branches—vulcanology, astronomy, and meteorology, connected with the University of Catania, and dependent on the Minister of Public Instruction. It was intended that the inauguration should take place during the Congress of the Alpine Club at Catania, but unforeseen delays in the execution of the works will defer it to next year.

THE United States Government has taken prompt and vigorous action on the basis of the recent conclusions come to by scientific investigators as to the prevalence of colour-blindness. Both in the army and the navy, and in the case of pilots, systems of examination have been devised and are enforced to secure the detection of colour-blindness in all cases in which such a defect would be likely to lead to inefficient discharge of duty. As we formerly intimated, also, the State of Connecticut insists that all railway *employés* within its borders be tested for the same purpose, and doubtless in time a similar law will be passed in all the other States. The following are the rules for conducting the examinations in the State of Connecticut:—Rule 1.—For the qualitative estimation of colour-blindness the following tests are to be employed: Holmgren's worsteds, the tables of Stilling, Donders' colour-test patterns, Pflüger's letters with tissue papers. Däae tests and Woinow's revolving cards may also be used. For the quantitative test for colour-blindness, Donders' reflected spots, Donders' method with transmitted light, Holmgren's shadow-tests shall be employed. Rule 2.—The following are the requirements for a certificate in the first class: 1. Healthy eyes and eyelids without habitual congestion or inflammation. 2. Unobstructed visual field. 3. Normal visual acuteness. 4. Freedom from colour-blindness. 5. Entire absence of cataract or other progresssive disease of the eyes. The second class shall have:—1. Healthy eyes and eyelids without habitual congestion or inflammation. 2. Unobstructed visual field. 3. Visual acuteness at least equal to three-fifths without glasses and normal with glasses in one eye, and at least one-half in the other eye with glasses. 4. Freedom from colour-blindness in one eye, colour-perception at least equal to three-fourths in the other eye. Rule 3.—In the case of *employés* who have held their positions five years or more, the standards required in each class shall be determined under special instructions from the Board of Health.

THE third instalment of Dr. Elliott Coues's "Ornithological Bibliography" is, we learn from the New York *Nation*, still in the press, having been delayed by its unexpected extent. Meantime, extracted from the *Proceedings* of the United States National Museum, we have the fourth instalment, being a "List of Faunal Publications relating to British Birds." Such a list, of course, could not possibly be made complete out of England, and the compiler himself points out its inadequacy. Nevertheless, it embraces something like a thousand titles, only in a comparatively few cases taken at second-hand, and is so accurate and punctilious as far as it goes that to call it a "published proof-sheet" is almost an excess of modesty. The titles are given in full, and even, as in the first two (different editions of the same book), with the typographic errors and inconsistencies of the originals. Further, they are arranged chronologically, and copiously annotated, not seldom with the aid of Prof. Alfred Newton, of Magdalene College, Cambridge.

"PALÆONTOLOGISTS and naturalists generally," the *Nation* states, "will learn with satisfaction of the appearance in connected form of the results of a portion of Prof. Marsh's wonderful palæontological discoveries in the Western Territories. The series of explorations so successfully carried on by this distinguished naturalist in the Rocky Mountain region since 1868, undertaken at no inconsiderable personal risk and no less considerable outlay of private capital, has resulted in the acquisition by Yale College of the most extensive collection of fossil vertebrate remains in the world. Huxley's visit to this country in 1876 was largely, if not mainly, brought about by his desire to examine personally this collection. Some notion of its extent may be gleaned from the fact that of Pterodactyls (flying reptiles) alone it embraces fragments belonging to at least 600 individuals, and of Mesozoic birds—a class of remains which, as far as number is concerned, has thus far yielded the most barren results in extra-American countries—fragments representing more than 100 individuals. The work before us, which is intended to form vol. vii. of the geological reports of the Fortieth Parallel Survey, deals with the *Odontornithes*, or extinct toothed birds of North America. These, belonging to the middle-cretaceous period, are the oldest ornithic remains as yet discovered on this continent, and, with the exception of the three specimens of the *Archæopteryx* unearthed from the Jurassic lithographic limestone of Solenhofen, Bavaria, represent the oldest known form of

birds altogether, for the footprints in the Triassic sandstone of the Connecticut valley are now generally referred to Dinosaurian reptiles. Despite their strongly reptilian characters—among others, the presence of teeth in the beaks—which point to a position low down in the avian branch of the Sauropsida, Prof. Marsh argues, from the structural differences existing between such forms as *Hesperornis* and *Ichthyornis*, and between these and *Archæopteryx*, which appear greater than those presented by any two living birds, that they represent comparatively highly specialised types, and that we must look for the earliest appearance of birds in strata possibly as old as the Permian (Palæozoic). The magnificent engravings which accompany the work render it a *livre de luxe*, and place it in the category of recent American scientific works next to Leidy's 'Rhizopods,' to which we lately had occasion to call attention. We are informed that another important work on the extinct vertebrata of the West is shortly to appear, from the pen of Prof. Cope."

Mr. Thomas Bolton of Birmingham has sent us No. 3 of his "Portfolio of Drawings and Descriptions of Living Organisms (Animal and Vegetable) Illustrative of Freshwater and Marine Life," which have been sent out by him with the living specimens.

An interesting paper by Mr. G. M. Dawson on the distribution of some of the more important trees of British Columbia is reprinted from the *Canadian Naturalist*. In connection with this subject we learn from the *Gardener's Chronicle* that three of the most distinguished botanists of America—Dr. C. C. Parry, Dr. George Engelmann, and Prof. C. S. Sargent—are now on their way to Vancouver's Island; thence they propose to return and ascend the Columbia River as far as it is necessary to settle vexed tree questions in the extensive forest region along its shores; they will thence journey southward *viâ* Portland through the centre of Oregon to the great Fir forests of Shasta. We may hope that much "clearing-up" in the nomenclature of certain Conifers will accrue from the visit.

We have received the five Annual Reports of the Little Miami Natural History Society, which was founded in 1875 at Antioch College, Yellow Springs, Ohio. The objects of this Society are:—(1) To develop among the students a habit of accurate observation and patient investigation rather than mere acquisition in studying the natural sciences, and thus to accustom them to the methods and rules of scientific study; and (2) to work out the natural history of the district in which the college is situated, especially the valley of the Little Miami and its tributary streams. The membership of the Society is open to all students of the College who wish to join for the purpose of doing actual work in furtherance of this purpose. Each of the Reports covers only one side of a sheet of paper, but from the catalogue of papers and reports contributed to the Society, it is evidently doing good work in the natural history of its district.

Dr. R. F. Hutchinson of Mussoorie, N.W.P., India, writes with reference to Nature, vol. xxii. p. 119, that he has frequently seen Mercury with the naked eye out there, especially in the cold weather when the atmosphere is clear and dry. He has also twice seen two of Jupiter's satellites under the same circumstances.

Several important changes have been made in the method of conducting the technological examinations in connection with the City and Guilds of London Institute; those interested should apply for a programme of the changes to the Secretary, Gresham College, E.C.

Telephone experiments with a new apparatus by Dr. Herz have been made with the French Atlantic cable between Brest and Penzance, and are said to have yielded satisfactory results.

On Sunday, August 8, a young man named Brest ascended at Marseilles in a balloon he had constructed himself. He was lost to view in the direction of the sea, and his aërial craft was found by fishermen close to Bastia, in Corsica. It is feared that the unfortunate aëronaut was drowned.

The lady who took so high a place in the London University B.Sc. examination, referred to last week, was not Miss, but Mrs. Bryant, the well-known teacher at the North London Collegiate School for Girls.

The additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus erythræus*) from India, presented by Mr. J. E. Kincaid; a Black-handed Spider Monkey (*Ateles geoffroyi*) from South America, presented by Capt. Woolward; a Common Squirrel (*Sciurus vulgaris*), British, presented by Capt. Tholandir; a Spotted Ichneumon (*Herpestes auropunctatus*) from India, presented by the Hon. L. S. Jackson; four Richardson's Skuas (*Lestris crepidatus*), Shetland Isles, presented by Mr. Robt. T. C. Scott; three Abyssinian Guinea Fowls (*Numida ptilorhyncha*) from Abyssinia, presented by Mr. Gerald Waller; two Common Nightjars (*Caprimulgus europæus*), British, presented by Mr. E. Ockenden; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Mr. Percy Howard; an Areolated Tortoise (*Homopus areolatus*), a Geometric Tortoise (*Testudo geometrica*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; three Richardson's Skuas (*Lestris crepidatus*), Shetland Isles, four Glass Snakes (*Pseudopus pallasi*) from Dalmatia, deposited; a Yellow-collared Parrakeet (*Platycercus semitorquatus*) from West Australia, received in exchange.

OUR ASTRONOMICAL COLUMN

The August Meteors.—The meteors annually encountered by the earth on arriving at the descending node of the third comet of 1862, in the orbit of which they are found to travel, are reported to have been less numerous this month than in most recent years. The earth arrived in the longitude of the node about midnight on the 9th inst., and in this position is only 430,000 miles, or less than twice the moon's distance from the comet's track. Even if less frequent than in several past years, a considerable number was observed on August 9, 10, and 11, and on the latter night a conspicuous Aurora Borealis, which phenomenon has so often accompanied meteoric displays, was witnessed in the north of England. Early on the evening of August 12 the meteors were sufficiently frequent and bright to attract the attention of persons in the suburbs of London who were not looking for them, but there were very few later in the evening.

It has been frequently remarked that the August meteors, or, to call them by their astronomical designation, the *Perseids*, must be much more widely distributed along the cometary orbit than are those of the November period—the *Leonids*—moving in the track of the first comet of 1866. The comet which appears to generate the August meteors, or at any rate to be followed by them, has now receded beyond the orbit of Neptune, and will continue to recede until about the year 1923. It was last in aphelion, according to Prof. Oppolzer's investigation, about 1801 or 1802, and, notwithstanding the great distance of the comet, there was a remarkable meteoric display. Herrick reports a letter from Dr. Joseph Priestley describing the phenomenon as he witnessed it on August 8, 1801, amongst the meteors being "a prodigious number of fire-balls." He compared the whole to a brilliant display of fire-works.

It is rather singular that in the history of comets we should not have been able to recognise any previous appearance of the body connected with the *Perseids*, notwithstanding its close approach to the earth's orbit when the perihelion passage takes place in the summer. Perhaps for many past centuries the perihelion may have fallen in the winter, when the comet would have greater chance of escaping notice.

Cape Observations of Comet 1880 (I).—Mr. Gill sends us the fully reduced observations of the great comet of the present year made at the Royal Observatory, Cape of Good

Hope. A ring-micrometer was used, the aperture of the telescope and the unsatisfactory illuminating arrangements not permitting the use of the parallel-wire micrometer. The stars of comparison have been observed in the early morning with the meridian circle; also the $7\frac{1}{2}$ mag. star used by Mr. Ellery on February 14. Mr. Gill expresses himself as by no means proud of his observations, the comet's nucleus being an object which could not be satisfactorily observed, but he did his best with the available means. He also writes disparagingly of the ring-micrometer, a tool which we incline to agree with him has been very much over-landed. As Mr. Gill will no doubt communicate the details of his observations and reductions to the Royal Astronomical Society or the *Astronomische Nachrichten*, we shall confine ourselves to appending his final results:—

	Cape M.T. h. m. s.	App. R.A. h. m. s.	App. N.P.D. ° ′ ″
Feb. 10	8 50 2	0 3 58·59	
—	8 52 49	—	123 43 15·53
11	8 33 4	0 20 22·16	—
—	8 45 42	0 20 31·53	123 31 30·78
12	8 42 18	0 36 28·06	123 11 33·93
—	8 42 18	0 36 28·29	— 23·44
13	8 30 57	0 51 39·32	122 44 20·93
14	8 23 5	1 6 7·89	122 11 17·23
—	8 42 51	1 6 19·25	122 10 52·86
—	8 42 51	1 6 19·79	— 57·19
15	8 24 31	1 19 54·92	121 32 52·17

On February 12 two, and on February 14 three, comparison stars were employed. The observations are not yet corrected for parallax.

PHYSICAL NOTES

PROF. O. N. ROOD claims to have produced a *new* improvement into the Sprengel pump, by which he says he can easily exhaust to $\frac{1}{5000000}$ or $\frac{1}{10000000}$. The alleged improvement is in two parts; the first being an arrangement whereby "the mercury, instead of being at once introduced into the pump, passes beforehand through an exhausted bulb"; the second being a "theoretically perfect fluid valve," formed by bending the fall-tube into a crenellated form at one point. It is hardly necessary to point out that neither of these improvements is new. The first has been adopted in the Sprengel pumps sold by instrument makers in London for the last ten years, and the second, in a form superior even to that of Prof. Rood (since the fall-tube was furnished with more than one fluid valve of a form identical with that devised by Prof. Rood), was to be seen in one of the improved Sprengel pumps exhibited in the Loan Collection at South Kensington in 1876.

M. TROUVÉ has suggested a new improvement in the old and simple longitudinal armature employed by Siemens in his earlier magneto-electric machines, and lately revived by M. Marcel Deprez in his little motors. M. Trouvé's improvement consists in constructing the armature, not with parallel sides, but with sides forming part of a skew-cylinder. Thus one part of the armature is ready to leave the poles of the field magnets when the other is approaching it, and the currents produced are therefore much more nearly continuous than with the parallel form. This will probably be a considerable advantage in the case where the armature is employed in a small motor, which will be driven much more steadily than has hitherto been possible. With three cells of Reynier's new battery this little motor will drive a sewing-machine.

M. J. PLATEAU proposes a method of estimating approximately the apparent distance at which the moon seems to different people to be in the sky. This means consists in looking at the moon steadily until the retina is sufficiently fatigued to produce an "accidental" image or ghost. The observer must then turn his gaze to a blank wall, on which he will see the accidental image projected as a tinted patch of the same shape as the moon. He is then to retreat from, or advance to, the wall until this image appears to him to be of the same size as the moon itself did. The distance measured off between the observer and the wall will be the same as that at which he unconsciously takes the moon to be. One of the sons of the author having made this experiment, found the distance to be in his case about fifty metres. This seems a small distance, but it was the result of a single experiment under circumstances which were not very favourable. M. Plateau concludes the brief memoir on the subject, presented by him to the Belgian Académie, by cautioning all persons who may be interested in the subject to take care in repeating the experiment lest the great brilliance of the luminary should damage their sight.

M. REYNIER recommends as a powerful and constant battery for electric light work a modified Daniells' cell, in which the zinc is immersed in a solution of caustic soda placed in a rectangular porous cell of parchment paper. The electromotive force of this combination varies from 1·47 to 1·35 volts, and the resistance may be less a Thomson's tray battery. The actual energy which a cell of this battery would furnish is calculated to be twice that of the ordinary round Bunsen cell.

A FEW months ago Prof. Boltzmann of Vienna published a calculation of the velocity of the electric current in a conductor based upon the discovery of Mr. E. H. Hall that a magnet acts upon a current in a conductor, tending to alter its path in the substance of the conductor. In the July number of the *American Journal of Science* Mr. Hall combats Boltzmann's calculation, and shows that by parallel reasoning a current should tend to urge forward with considerable force the conductor through which it flows; which mechanical effect is certainly non-existent. Mr. Hall now gives us the very interesting additional piece of information that the displacing force exercised by the magnet upon the current in the conductor is in an opposite direction in gold to what it is in iron—which is also quite irreconcilable with Boltzmann's theory.

AN improved centrifugal machine for schools is described in the *Nachrichten* of the Göttingen Society of Sciences (No. 9), by Herr W. Holtz. The driving-wheel runs in a vertical plane, and the quick axis may (with one and the same length of cord) be set either in a horizontal or a vertical plane, and higher or lower, also at varied distance from the frame of the machine; further, it can be so rotated that an object to be rotated with it can be suspended from it. On the same axis and of equal size with the large driving-wheel, but independent of it, runs another grooved wheel. The endless cord passes under these and round two smaller wheels higher up, one of which is on the axis to be quickly rotated (which is set in a movable support). The machine has been patented in Germany.

IN a communication to the Göttingen Society of Sciences (*Nachr.*, No. 13), Herr Wöhler states that with aluminium *alone* and with very few elements, a galvanic battery may be formed of strength sufficient to deflect a magnetic needle strongly, decompose water, and raise a thin platinum wire to glow. In a cylindrical glass vessel holding very dilute muriatic acid or dilute soda lye, is placed a roll of sheet aluminium, and within this a porous cell containing concentrated nitric acid and a smaller roll of aluminium. A projecting piece of the metal from each roll is inserted in a circular cover of ebonite.

DURING a recent thunderstorm at Hamburg the British Consul, Mr. Pogson, observed the phenomenon of St. Elmo's fire playing above the tip of the spire of a church three-quarters of a mile away. Twenty times within one hour a pale bluish ball of light resembling in tint the flame of burning potassium was seen. It appeared to be spherical in form, and from three to six feet in diameter. It seemed to hover above the spire without touching it, and lasting about forty seconds at each time of appearance.

Apropos of the approaching meeting of the British Association at Swansea, we may note that on the occasion of the last meeting at Swansea of the Association, in 1848, a paper was read by Mr. F. Wishaw "On the Telekouphon, or Speaking Telegraph." This antedates Philip Reis's "Telephon" by several years.

ANOTHER improved bichromate battery is announced, this time by the Silvertown Company. In no essential respect does this battery differ from the form known as "Fuller's battery," save in the addition of certain "exciting powders" to the liquids, a "grey compound" being dissolved in the inner cell in which the amalgamated zinc is placed, and a "red compound" in the outer cell with the carbon-rod. The use of dilute sulphuric acid is avoided by employing the "grey compound;" the avowed aim of this change is the increase of internal conductivity. The result is certainly an increase of cost.

SPEAKING of bichromate batteries, it appears to us that the true function of the porous cell now usually employed with them is entirely misunderstood. The bichromate solution, as reduced by the zinc in the cell on standing, is a colloidal substance. The

porous cell prevents this from mixing with the fresher strong solution outside, and thus enables the operator to remove the exhausted portion.

An adaptation of the telephone to the needs of deaf persons has been brought out by one H. G. Fiske of Springfield (Massachusetts). To the centre of the disk of the receiving telephone is attached a short rod of wood, ebonite, or other elastic hard material which can be held between the teeth. The sonorous vibrations imparted to the disk by the magnet are thus transmitted mechanically to the auditory nerves through the teeth and the bones of the skull. The advantages are probably limited, since, as experiments with the audiphone have shown, only a small percentage of truly deaf persons retain the power of hearing through the teeth. In the greater majority of cases it is the auditory nerve itself, not the mechanical adjustments and auditory apparatus of the ear, that is the cause of deafness.

GEOGRAPHICAL NOTES

Some modifications have been made in the composition of the fifth International Expedition to Central Africa. Lieut. Harou, who was to have formed part of the expedition, will only join his companions at a later period on the Upper Congo. He is charged, meantime, with a secret mission to Africa, for the accomplishment of which about ten months are necessary. After the termination of this mission he will join the expedition. M. Harou will embark about the 23rd for his new destination. We learn that Dr. Dutrieux, who had to return from Africa to Belgium to recruit his health, is about to return to Africa to take part in the service for the abolition of slavery, at the head of which is Col. Sala. He had begun when in Africa a dictionary of the Suaheli language, so common all over Central Africa. Although incomplete, the Executive Committee of the Association have decided to print the dictionary as it is, and put it in the hands of travellers for correction and completion.

The *Berег* states that next autumn Baron Nordenskjöld will visit St. Petersburg to make preparations for his proposed expedition to the New Siberian Islands in 1882, the expenses of which will be borne by the Russian merchant, M. Sibiriakoff. Nordenskjöld will go to the mouth of the Lena overland, and thence embark for his destination.

The Congress of French Societies of Geography was held this year at Nancy during the first week of August. M. Levasseur, honorary president, gave an address, in which he reviewed the progress realised by the creation of so many geographical societies. In the evening the members were invited to the Town Hall, where they were entertained by M. Volland, the mayor. A number of toasts were delivered by his Worship, as well as by M. Levasseur and others.

A letter from Dr. Matteucci, written in May last, intimates the arrival of the expedition under Prince Borghese at El Fasher, the capital of Darfur, and the approaching departure for Wadai. Dr. Matteucci remarks on the almost absolute want of water in Darfur, and the consequent recent cultivation of water-melons by the natives as far as the arid soil will permit. They also utilise the Baobab tree in a curious manner. Hollowing out the huge trunk of the older trees by fire, they by some prehistoric primitive method get the hollow trunk filled with water during the rainy season, the water keeping sweet for eight months. The people of Darfur, Dr. Matteucci says, are still in a primitive uncorrupted condition, a contrast to the Egyptianised natives of Kordofan.

M. Bischoffsheim pays the expenses of M. G. Capu, a young geologist and botanist, who will accompany M. de Ujfalvy on his new mission to Central Asia, referred to last week; M. Gabriel Bovalt, as topographer and naturalist, will also accompany the mission.

THE ALGÆ OF THE SIBERIAN POLAR SEA[1]

Before the voyage of the *Vega* our knowledge of the algæ of the Siberian Polar Sea outside the Kara Sea was limited to the fact of their existence in Tschaun Bay and along the coast between that bay and the mouth of the Kolyma. This information was obtained by Baron Maydell, the leader of a scientific expedition sent out in 1869, under the auspices of the Russian Geographical Society, to explore the Tchuktchi Peninsula. A statement previously made by Matiuschin, one of Wrangel's companions during his Siberian journey, that algæ exist at Tschaun Bay, was thereby confirmed. Maydell brought home with him only three incomplete specimens of algæ, which he obtained from a native living at Cape Schelagskoj. From the description given by him they appear to belong to the genera Alaria and Laminaria.

From observations made during the voyage of the *Vega* it appears that algæ exist at several places along the whole coast of the Siberian Polar Sea. They occur almost exclusively within the sublittoral region. In the elittoral area, which was the best and most completely examined during the expedition, Dr. Kjellman found only at two places, viz., between Port Dickson and Tajmur Island, an exceedingly scanty flora consisting of three species, two Florideæ—*Lithothamnion polymorphum* and *Phyllophora interrupta*—and a Phæozoosporacea—*Lithoderma fatiscens*. The littoral region along the north coast of Siberia is, like that of the coasts of Novaya Zemlya and clearly for the same reasons, nearly everywhere devoid of algæ. Only at two places did Dr. Kjellman find traces of a strand vegetation. They consisted of two small green algæ, *Enteromorpha compressa* and *Urospora penicilliformis*, both known from the same region in other parts of the North Polar Sea. Fucaceæ occur nowhere within the littoral region, not a single individual of this group having been found at any of the places visited between Port Dickson and Koljuschin Fjord near Behring's Straits. To the east of this fjord there was found in the sublittoral region in limited quantity *Fucus evanescens*, which is extensively distributed in the North Polar Sea. In the sublittoral belt of the bottom, too, the vegetation in the Siberian Polar Sea is very scanty. Dr. Kjellman had not an opportunity of examining any region where the flora was not considerably poorer in individuals than in those places on the coasts of Spitzbergen and Novaya Zemlya where algæ are pretty abundant. The eastern portion of the sea appears to be somewhat less poor in algæ than the western. The places where they most abounded were Cape Irkajpij—Cook's North Cape (N. L. 68° 55′ W. L. 179° 25′), and the mouth of Koljuschin Fjord. From the natives settled between this fjord and Cape Serdze, situated about fifty miles to the east of it, Dr. Kjellman repeatedly obtained during the first half of 1879 very large masses of algæ, which appears to show that a pretty abundant vegetation of algæ is to be found at certain places along this part of the coast. There are not wanting, however, in the western part of the Siberian Sea some comparatively very good places for algæ. One such at least was found, viz., the region round Tajmur Island, between Port Dickson and Cape Chelyuskin.

The species that occurred most frequently were *Polysiphonia arctica*, *Rhodomela tenuissima*, a variety of *Rhodomela subfusca*, *Sarcophyllis arctica*, *Phyllophora interrupta*, species belonging to the family Laminarieæ, *Sphacelaria arctica*, and *Phloeospora tortilis*. The Laminarieæ give in general their stamp to the vegetation; at one place however *Phyllophora interrupta*, at another the above-mentioned variety of *Rhodomela subfusca* occurred in quantity surpassing that of the Laminarieæ.

Of this family six species were found, viz., four species of Laminaria: *L. Agardhii*, *L. cuneifolia*, *L. solidungula*, and one belonging to the digitata group, in which Dr. Kjellman believed that he recognised the *L. atro-fulva* of J. G. Agardh, and two species of Alaria, one standing near to *A. esculenta*, the other corresponding in much to *A. musæfolia*, but probably belonging each to species allied to these, and yet incompletely known, which occur in the north part of the Pacific. The distribution of the Laminaria along the north Siberian coast is different. *Laminaria solidungula* occurs both east and west of Cape Chelyuskin. *Laminaria Agardhii* was found only at that promontory and at a couple of places west, but nowhere east of it. Eastward it is replaced by *L. cuneifolia*, found first at Irkajpij and afterwards east of it in comparatively large quantities. Both the two species of Alaria and *Laminaria atro-fulva* appear also to be confined to the eastern portion of the Siberian Polar Sea. None of them were seen west of Irkajpij. Some of the species already mentioned as occurring most frequently enter into the composition of the vegetation in different proportions east and west of Cape Chelyuskin. *Polysiphonia arctica* and *Phyllophora interrupta* were more common west; *Rhodomela tenuissima* again more numerous east of the northernmost point of Asia. *Phloeospora tortilis* was nowhere seen east of Tajmur Island, nor *Sarcophyllis arctica* and the variety of *Rhodomela subfusca* west

[1] Abstract of preliminary communication by Dr. F. R. Kjellman in "Öfvers. af Kongl. Vet. Akad. Förhandl.," 1879.

of Irkajpij. Hence it follows that the algal flora differs in its composition in a noteworthy degree in the eastern and western portions of the Siberian Polar Sea.

It has been stated that an abundance of large-sized luxuriant plants is a characteristic of the Arctic algæ. In this respect the vegetation of the Siberian Sea is considerably behind that in other parts of the North Polar Sea. The largest alga seen by Dr. Kjellman was a *Laminaria Agardhii*, whose length was 210 and greatest breadth 37 centimetres. Among the many specimens of *L. cuneifolia* examined there was none more than half so large as this. *L. solidungula* is about as large as middle-sized specimens of this plant from the coasts of Spitzbergen and Novaya Zemlya, about 90 centimetres long and 15 to 20 broad. The two species of Alaria, when they are largest, are about a metre in length. Other algæ almost without exception are stunted in comparison with plants of the same species from other portions of the North Polar Sea.

The collections of algæ made by Dr. Kjellman, according to the examination to which it has been possible to subject them, consist only of thirty-five species, of which there belong to the

Florideæ	12
Fucoideæ	16
Chlorophyllophyceæ	6
Phycochromophyceæ	1

These are not more than half as many as are known from the Murman and Spitzbergen Seas. With the exception of two, or possibly three, species, all also occur in other parts of the North Polar Sea.

The western part of the Siberian Polar Sea, at least to Cape Chelyuskin, must doubtless be considered to belong to the territory of the Spitzbergen marine flora, though poorer in individuals and species and more stunted than it. The algæ in the eastern part of the same sea also in a considerable degree correspond with those on the coasts of Spitzbergen and Novaya Zemlya, but in the composition of its Laminaria vegetation it has a trait foreign to the latter, and indicating a connection with the algæ in the north part of the Pacific.

ON THE COMPRESSIBILITY OF GLASS[1]

THE following experiments were undertaken with a view to determine by actual observation the effect produced on solids by hydraulic pressure. The instrument was constructed according to my directions by Mr. Milne, of Milton House, about two years ago, but it is only now that I have been able to devote myself to its application to the purposes for which it was designed. It consists of a hydraulic pump, which communicates with a steel receiver capable of holding instruments of considerable size, and also with a second receiver of peculiar form. This receiver consists essentially of a steel tube terminated at each end by thick glass tubes fitted tightly. It is tapped at the centre with two holes, the one to establish connection with the pump, and the other to admit a pressure-gauge or manometer. The steel tube may be of any length, being limited only by the extent of laboratory accommodation at disposal. The tube which I am using at present has a length of a little over six feet, and an internal diameter of about three-tenths of an inch. The solid to be experimented on must be in the form of rod or wire, and must, at the ends at least, be sufficiently small to be able to enter the terminal glass tubes, which have a bore of 0·08 inch, and an external diameter of 0·42 inch. The length of the solid is such that when it rests in the steel tube its ends are visible in the glass terminations.

When the joints have all been made tight the experiment is conducted as follows:—

A microscope with micrometer eyepiece is brought to bear on each end of the rod or wire. These microscopes stand on substantial platforms altogether independent of the hydraulic apparatus. The pressure is now raised to the desired height, as indicated by the manometer, and the ends of the rod are observed and their position with reference to the micrometer noted. The pressure is then carefully relieved and a displacement of both ends is seen to take place, and its amplitude noted. The sum of the displacements of the ends, regard being had to their signs, gives the absolute expansion in the direction of its length, of the glass rod, when the pressure at its surface is reduced by the observed amount, and consequently also by the compression when the process is reversed. As in the case of non-crystalline bodies, like glass, there is no reason why a given pressure should produce a greater effect in one direction more than in another, we may, without sensible error, put the cubical compression at three times the linear contraction for the same pressure.

As yet I have only experimented on glass, and only on one sort, namely, that made by Messrs. Ford and Co. of Edinburgh. It contains lead, and is very suitable for glass-blowing purposes. I have not yet analysed it. I have observed its compressibility up to a pressure of 240 atmospheres, and before proceeding to higher pressures I intend to determine the compressibilities of other solids, especially metals at pressures up to 240 atmospheres. The reason for taking this course is that having got two glass tubes to stand this pressure I am anxious to utilise them as far as possible before risking them at higher pressures.

The pressure in these experiments was measured by a manometer, which consists simply of a mercurial thermometer with a stout bulb, which is immersed in the water under pressure, whilst its stem projects outside.

The values of the readings of this instrument were determined by comparing it with a piezometer containing distilled water. This piezometer had been compared with others which had been subjected to the pressure of very considerable and measured columns of water on the sounding-line.

The mean apparent compressibility of water in glass was thus found[1] to be 0·00004868, or, multiplying by 1,000, to reduce the number of figures 0·04868 per atmosphere at temperatures from 1° to 4° C.

The manometer (No. 2) was compared with this piezometer. The temperature of the manometer was 12°·5 C., while the piezometer was enveloped in ice in the receiver. The ice was thus melting under the same pressure as the instrument was undergoing, consequently the piezometer was not exposed really to precisely the same temperature at each succeeding experiment.

For our present purpose the effect of the possible variation in volume due to this thermic cause is negligable, and we assume that the indications of our piezometer are comparable with those obtained in deep ocean waters. In a future communication I hope to return to this point.

In Table I. we have in the first column the number of observations meaned for each pressure from which the average values of the manometer-reading under A, and of the piezometer-indication under H are computed.

Manometer No. 2, when treated simply as a thermometer, showed at atmospheric pressure a rise of one division for a rise of 0·233° C. in temperature. Piezometer K, No. 4, was filled with distilled water, and contained 7·74 cubic centimetres at 0° and atmospheric pressure. It is made of Ford's glass, though not drawn at the same date as the experimental rod.

TABLE I.—*Comparison of Manometer No. 2 at 12·5° C. with Piezometer K, No. 4, in ice melting under pressure*

Piezometer K, No. 4, contains at 0° and atmospheric pressure 7·74 cub. cent. of water.	Number of observations meaned.	Pressure in divisions of manometer No. 2.	Apparent contraction of water per thousand. K, No. 4.
		A.	H.
Temperature of manometer 12·5° C.	4	26·08	4·0228
Piezometer immersed in ice	4	30·28	4·6534
Melting under pressure A	1	36·20	5·5972
Probable temperature between − 1° and 0° C.	5	40·08	6·1045
	3	50·08	7·6043
	3	60·20	9·1057
	3	70·08	10·5163
Total number of observations ...	23		
Mean reading of manometer ...	... ...	43·61	
Mean apparent contraction of water in piezometer	... ...	... ...	6·6495

Dividing the mean apparent contraction of the water in the piezometer by the apparent compressibility of water in glass (0·04868), we have for the pressure corresponding to a rise of 43·61 divisions on manometer No. 2 at 12·5° C.

$$P = \frac{H}{0·04868} = \frac{6·6495}{0·04868} = 136·6 \text{ atmospheres.}$$

[1] Substance of a paper read before the Royal Society of Edinburgh, June 21, by J. Y. Buchanan.

[1] *Proc.* Royal Society of London, 1876, p. 162.

But this pressure produces a rise of 43·61 divisions on manometer No. 2. We have then for the value of one division on the manometer—

$$a = \frac{136·6}{43·61} = 3·132.$$

Hence to convert readings of manometer No. 2 into atmospheres we have to multiply by 3·132 the difference between the manometer reading under pressure and that at atmospheric pressure.

In another series of experiments piezometer K, No. 4, was compared with manometer No. 2, both being at a temperature of 12·5° C., and the following results were obtained as the mean of nineteen observations:—

Mean rise of manometer No. 2 ...	(A)	41·35 divisions.
Mean apparent contraction per thousand of water in piezometer K, No. 4	(H)	5·8782

But from the results in Table I. we have for the pressure in atmospheres—

$$P = 3·132 \times A = 3·132 \times 41·35 = 129·5 \text{ atmospheres.}$$

And the apparent compressibility of water in glass at this temperature (12·5° C.) in volumes per thousand per atmosphere is—

$$M = \frac{H}{P} = \frac{5·8782}{129·5} = 0·04539.$$

We see then that at pressures up to 240 atmospheres the property peculiar to water of diminishing in compressibility with rise of temperature is preserved unimpaired, and the amount of change corresponds closely with that found at low pressures in the experiments of Regnault and Grassi.

In Table II. the results obtained are summarised. In the first column we have the number of the series, and in the second the number of observations which constitute the series. Under T we have the temperature of the receiver and therefore of the rod in it. The experiments were made at the temperature of the room, which varied very slightly. The arithmetical mean of the values of T is 12°·77 C. Under A we have the pressure in terms of the scale of the manometer; that is the difference between the readings of the manometer when the pressure was up and when it was equal to that of the atmosphere. Under P (3·132 × A) we have the pressure in atmospheres which is obtained by multiplying A by 3·132 (see Table I.) Under D we have the sum of the expansions observed at each end in terms of the micrometer, divisions which had identical values. Under F we have the values of D reduced to parts of an inch by multiplying them by 0·000417. Under Q we have the greatest deviations from the mean amongst the individual observations forming this particular series. R represents this deviation as a percentage of the total expansion (F). Under H we have the linear compression (in inches) of a rod one million inches long under a pressure of P atmospheres. K is the corresponding value for one atmosphere, and N = 3K is the cubical compression of the glass per million per atmosphere.

The total expansion on D was determined by observing the expansion at each end and adding them together. These partial expansions were not always, nor indeed often, of exactly the same extent; the excess was sometimes on the one side and sometimes on the other. The effect of the rise of pressure is to extend the containing tube and to compress the contained rod. On the relief of pressure the tube shortens again and the rod recovers its length, and there is necessarily a sliding of the one or the other, and it depends entirely on minute local circumstances whether the rod finds it easier to return to its original relative position or to another. In some experiments made previously to those quoted in Table II. the rod had greater freedom of motion longitudinally, and it happened several times that it crept bodily to the one end, necessitating the opening of the apparatus to replace it in a position suited to observation. Afterwards stops were placed in the tube, which, while setting limits to the crawling motion, did not in any way interfere with the expansion and contraction. The results of these previous experiments are not included in the table, because they were merely tentative with a view to learning the details of the kind of experimentation; and further, because in the microscope at the east end the power used was very low, and the micrometer insufficiently delicate.

The micrometers used were: at the east end a photographic copy of Hartnack's eyepiece micrometer, and at the west end one of Morz's. They were both compared, and the values of their divisions as used determined by comparison with a stage micrometer of Smith and Beck, obligingly lent me by my friend Dr. William Robertson, who had very carefully verified its graduations. It is remarkable as a coincidence that the values of the divisions turned out to be identical, namely, 0·000417".

In the observations recorded I made no attempts to subdivide the micrometer divisions further than to estimate a half. As the micrometer readings are not affected directly by the pressure,

TABLE II.—*Summary of Experiments on the Compression produced on a Glass Rod by Pressures up to 240 Atmospheres*

Series No.	Number of observations meaned.	Temperature. Cents.	Pressure. Manometer No. 2.	Pressure. Atmospheres.	Compression of rod. Micrometer divisions.	Compression of rod. Inch.	Greatest deviation from mean. Inch.	Greatest deviation from mean. Per cent.	Linear compression per million.	Linear compression per million per atmosphere.	Cubical compression per million per atmosphere.
		T.	A.	P. (3·132 × A).	D.	F. (0·000417 × D)	Q.	R. 100.	H. $\left(\frac{10^6}{75·05}F\right)$	K. $\left(\frac{H}{P}\right)$	N. (3 K).
1	5	13·5	20·40	64	11·13	0·0047	0·00047	10·0	62·6	0·98	3·0
6	11	12·2	34·81	109	18·05	0·0075	0·00044	5·8	100	0·92	2·8

3	13	12·8	50·49	158	26·84	0·0112	0·00056	5·0	149	0·95	2·9
4	8	12·5	56·88	177	32·00	0·0133	0·00042	3·2	178	1·00	3·0
8	7	12·5	62·21	195	33·71	0·0140	0·00033	2·3	187	0·96	2·9
5	10	12·5	62·97	197	35·39	0·0148	0·00046	3·1	197	1·00	3·0
9	10	12·8	68·94	216	37·10	0·0155	0·00058	3·7	206	0·96	2·9
10	6	12·9	76·53	240	40·08	0·0167	0·00059	3·5	223	0·93	2·8
										0·960	2·92

The micrometers used were eye-piece scale micrometers. The values of their divisions as used were identical. One division in the eye-piece corresponded to 0·000417 inch on the stage. Length of glass rod experimented on 75·05 inches. Diameter of ditto, 0·28 inches. Weight of rod 209·5 grammes. Date of experiments June 3, 4, and 7, 1880.

the deviation per cent. should be, as it is, the less the higher the pressure; and there is no doubt that the higher the pressure is the greater is the accuracy of the observation. The only way in which the pressure affects the reading of the micrometer is that when it is sufficiently high it produces a microscopic distortion of the tube which throws the point very slightly out of focus. This is remedied by a slight touch of the fine-adjustment screw of the microscope.

The general result of these experiments is that the linear compressibility of the glass experimented on is 0·96 and its cubical compressibility 2·92 per million.

Grassi[1] gives as the means of his observations at pressures up to ten atmospheres:

Glass ... 2·25 ... Crystal ... 2·804 and 2·8584

So that our results agree closely with those found by him for crystal.

[1] *Ann. Chim. Phys.*, (1851) [3], 31, p. 477.

We have then the apparent compressibility of water in glass at 2·5° C.	0·04868	
Add compressibility of glass	0·00292	
True compressibility of water at 2·5° C. ...		0·05160
And the apparent compressibility of water at 12·5° C. is	0·04539	
Add compressibility of glass	0·00292	
True compressibility of water at 12·5° C. ...		0·04831

Grassi gives the following values for the true compressibility of water at various temperatures:—

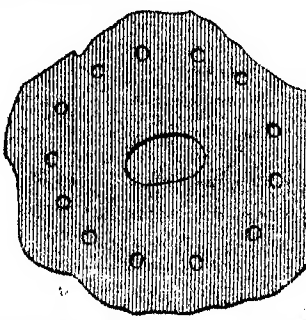
At 1·5° C.	0·0515	
At 4·1° C.	0·0499	
Mean		0·0507
At 10·8° C.	0·0480	
At 13·4° C.	0·0477	
Mean		0·0478

My results agree very closely with these.

Before concluding I would call attention to a very curious phenomenon which I have never seen noticed, namely, the peculiar *noise* which accompanies the relief of pressure in a mixture of ice and water.

In comparing the Piezometer K No. 4, in melting ice with the manometer at 12·5° C., I proceeded gradually from lower to higher pressures. When the pressure which was relieved was 100 or 120 atmospheres, I thought I noticed a slight noise. On raising the pressure higher the noise became more and more distinct, until when the pressure relieved was over 200 atmospheres, it was distinctly audible at a distance of 5 feet or 6 feet. It resembles the noise produced by bending a piece of tin backwards and forwards, and is markedly intensified by accelerating the relief, just as the noise made by blowing off steam is intensified by enlarging the outlet. When the relief valve is opened very carefully it whispers gently but very distinctly, till the pressure is all down. If opened comparatively briskly, but still with great care, the noise is comparatively loud but more rapidly used up. I forbear making any reflections until I have been able to study this phenomenon more closely.

Pieces of clear ice which had been subjected to high pressure in the receiver were finely laminated in parallel planes. In each plane there was a central patch surrounded near the sides of the block by a ring of spherules.



The annexed figure gives an idea of the arrangement in a plane of lamination; the size of the spherules is greatly exaggerated.

The lamination of ice by pressure in one direction is well known. I am not aware that its production by pressure in all directions has been noticed. I hope to pursue my observations on this subject.

J. Y. Buchanan

THE CONGRESS OF BOHEMIAN PHYSICIANS AND NATURALISTS

The first Congress of Bohemian Naturalists and Physicians met at Prague on May 14 last. More than 400 members met under the presidency of M. Krejcí, M. Eiselt, M. Koristka, and M. Studnicka. The first general meeting was opened by M. Krejcí, Professor of Geology, who delivered an inaugural address "On the share of the Bohemian Nation in the Development of Natural Science." He showed that not only Bohemian workers in science were in the field up to the seventeenth century, but that when the Bohemian nation, after two centuries of political and national slavery, awoke to life again, it very soon took its part in the progress of natural science. The names of Purkyne, Rokytanský, Skoda, Bohdálek, Pitha, Blazina, Safarík, Celakovský, Fric, Krejcí, Helmhacker, and of many others, are known even beyond the boundaries of Bohemia. Many obstacles were placed in the way of these promoters of science; they were not assisted by Government, and even the ancient university of Prague was, and indeed is, almost exclusively German. But in spite of all difficulties scientific progress went on steadily, and at present the number of workers in science is very fair. Knowing the cosmopolitan character of science, the Bohemian nation values equally the progress made in England, France, Germany, Italy, and Russia; it wishes only that its own share—if proportionately small—may be recognised by others. The great languages of the world are like the sea, which carries the ships and steamers of all nations; but the languages and literature, of small nationalities—of the Danes, Swedes, Dutch, and Bohemians—resemble so many rivers irrigating and fertilising the continents by which the sea is surrounded.

On May 15 and 17 sectional meetings took place. On the 16th the members visited the village Chuchel, where Prof. Krejcí explained to them the very interesting distortions of the silurian strata on the left bank of the river Vltava (Moldau). In the evening of the same day the members assembled at a banquet, where especially the healths proposed by Prof. Safarík were heartily responded to. He spoke first of the progress of science in Bohemia and its relation to scientific investigation in England and France; he then proposed the health of the distinguished Russian naturalists, referring chiefly to Mendeleeff, Butleroff, Menshutkin, Chebysheff, Shecheneff, Mechnikoff, and Kowalewski; finally he drank to the Nestor of palæontological research, to Joaquin Barrande, who at Prague has carried out the chief part of his scientific work.

In the first section (medicine) papers were read on purely professional subjects.

The second section was devoted to mathematics. Besides several mathematical papers Prof. Augustin spoke on cyclones and anticyclones; M. Doubrava read a paper on electricity; M. Domalip explained the action of a magnet on a current of electricity traversing a rarified medium; Prof. Charles Zengef gave an account of his method of constructing achromatic lenses by means of a combination of crown-glass and certain liquids. Excellent microscopic photographs made by the aid of these lenses were shown. For astronomical purposes lenses with an opening of 2 inches and a focal distance of only 9 inches have been constructed according to this method with complete success.

In the third section (Natural Science) the following papers were read:—Prof. Borický, on the structure of the Bohemian porphyries. He showed that they frequently contain the mineral "cordierite," which hitherto had not been found in Bohemia. According to Prof. Borický a great part of the Bohemian porphyries must be classed as *siliceous porphyrites*. Prof. Fric demonstrated a new genus of the ganoids found at Kounová, near Rakovník. This fish resembles the genus Palæoniscus, but its scales are very different. He gave to the new genus the name of *Trissolepis kounoviensis*.

M. Bayer gave a report on the characters of the skulls of some batrachia. Comparing the skull of the genus Pelobates with that of other genera, he found that the skull of Pelobates differs essentially from all others, and that this genus does *not* form the connecting link between the Ranidæ and the Bufonidæ. M. Hellich read a report on the genital apparatus of the genus Cypris. He supplemented the data given by Zenker, and corroborated in a certain sense the new observations of Weissmann. A series of plates belonging to a new work on Bohemian cretaceous Echinodermata was shown by Dr. Ottomar Novák, and their peculiarities were explained. M. Ladislav Duda gave a preliminary account of the anatomy of the Bohemian hemiptera, especially of the section Scutata. He has discovered on the fore feet of these insects a comb-like apparatus, by means of which the insect cleans its tentacles. In Bohemia as yet 401 species of hemiptera have been found. Prof. Borický showed to the members many interesting novelties in mineralogy, as, *e.g.*, the Rösslerit, a mineral of which as yet only three specimens are known. Dr. Vejdovský exhibited the second part of his work on the comparative morphology of the annelida, containing a new system of the Oligochæta and their anatomical details, together with their affinities to the Turbellaria and vertebrata. Dr. Vejdovský proposes the following arrangement of the new families of the Oligochæta:—(1) Aneduliata (Aeolosoma), (2) Chætogastrida, (3)

Discodrilida (Branchiobdella), (4) Naidea, (5) Echytraeida, (6) Tubificida, (7) Lumbriculida, (8) Phreorzetida, (9) Criodrilida, (10) Lumbricida. M. V. Fric showed to the members a specimen of the body of a chimpanzee, four years old, which was prepared by the injection of Wickersheim's conserving fluid. He explained all methods hitherto known and used to preserve the bodies of animals, and he declared the method of Wickersheim to be the best of them.

In chemistry some interesting papers were read and an animated discussion took place on educational and scientific questions.

On the 17th the second general meeting took place, Prof. Albert, of the Innsbruck University, delivering an address "On Theory and Practice in University Education."

During the session of the Congress a journal was published containing the abstracts of the papers read before the Congress. The addresses of M. Krejci and Dr. Albert, however, were printed *in extenso*, and of the former afterwards also a German translation appeared in print.

Fornioni and Prof. Schiaparelli.—On univocal plane transformations and particularly on involutory, by Prof. Bertini.—Notes on the fishes, and in particular on the male eels, observed at the Berlin Exhibition, by Prof. Pavesi.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, August 9.—M. Wurtz in the chair.—The following papers were read:—Summary report of a zoological exploration in the Bay of Biscay in the Government ship *Le Travailleur*, by M. A. Milne-Edwards.—Experiments tending to prove that fowls vaccinated for cholera are refractory for *charbon*, by M. Pasteur.—Results of observations of solar spots and faculæ during the first two quarters of 1880, by P. Tacchini. The numbers indicate rapid increase of solar activity. The days without spots form five groups separated by a mean interval of twenty-nine days, showing that in one hemisphere (which is that visible in the end of last December) the spots were formed with difficulty.—On a class of linear differential equations of the second order, by M. Brioschi.—Experiments on the discharge in rarefied gases, by M. Righi. *Inter alia*, the glass seems to become luminous at the point where it acts as positive electrode. During discharge the negative electrode is probably much more heated than the positive. The cause of mechanical action of the negative electrode is the same as in the radiometer.—On some properties of flames, by M. Meyreneuf. The gas which feeds a flame is subject to two opposing influences, one creating a draught outwards, the other (expansion through combustion) tending to drive the gas back. By diminishing the rate of outflow without modifying the combustion, one may regulate these movements so as to get vibrations of the nature of sound. Better sonorous effects are had by making a flame impinge on a round rod or on another flame.—Indices of refraction of aqueous solutions of acetic acid and of hyposulphite of soda, by M. Damien.—On an improvement of the Bunsen battery by M. Azapis, by M. Ducretet. For acidulated water is substituted a 15 per cent. solution of cyanide of potassium, caustic potash, marine salt, or ordinary sal ammoniac. The zincs need not be amalgamated. They are less consumed than in the Bunsen; the intensity of the current is no less, and its constancy is remarkable.—On the spectra of ytterbium and erbium, by M. Thalén.—On thulium, by M. Clève.—Researches on the heats of combustion of some substances of the fat-series, by M. Louguinine.—Secondary reaction between sulphuretted hydrogen and hyposulphite of soda, by M. Bel'amy.—On the acid obtained by M. Boutroux in the fermentation of glucose, by M. Maumené.—On a new process for producing malleable nickel of different degrees of hardness, by M. Garnier. This consists in incorporating phosphorus with the nickel (to take up oxygen); *e.g.*, adding to the bath of nickel a phosphide of nickel containing about 6 per cent. phosphorus. Very thin sheets of the material can be produced.—On propylnervine, by Mr. Morley.—Influence of light on transpiration of plants, by M. Comes. Plants transpire more in light than in darkness, and more the intenser the light. The more intense the colour of the organ, the greater the transpiration. The luminous rays absorbed alone favour the transpiration.—On the source of muscular work and on supposed respiratory combustions, by M. Sanson. The liberation of energy is due greatly, if not wholly, to phenomena of dissociation similar to those in fermentations; in presence of anatomical elements (blood-corpuscles specially) the immediate principles of the plasma are dissociated, give carbonic acid and doubtless other compounds which borrow oxygen from the hæmoglobin for their formation, and yield their energy to the muscular elements, which then manifest it by doing work in contracting, or to the blood for maintenance of animal heat.—On the use of nitrite of ethyl for rendering contaminated places healthy, by M. Peyrusson. It acts like ozone, but more powerfully.—Complement of the biological evolution of pucerons of galls of poplar (*Pemphigus bursarius*, Lin.), by M. Lichtenstein.—On the affinities of the genus *Polygordius* with annelides of the family of *Opheliidæ*, by M. Giard.—Discovery of new mammalia in the phosphate of lime deposits of Quercy (Upper Eocene), by M. Filhol.—On the structure and functions of the embryonal suspensor in some leguminous plants, by M. Guignard.—On deforming pilosism in some plants, by M. Heckel.—On a new instrument for pointing guns, by M. Arnoux.

DR. BASTIAN ON THE BRAIN

The Brain as an Organ of Mind. By H. Charlton Bastian, M.A., M.D., F.R.S. International Scientific Series. (London: Kegan Paul and Co., 1880.)

WITHOUT preface or other proposition than that suggested by the title of his book, Dr. Bastian commences to deal with his subject by an inquiry into the Uses and Origin and the Structure of a Nervous System. His motive, as expressed farther on, in giving such a wide scope to himself in his method of exposition was to ascertain whether the general similarity in structure of the nervous system in the lower animals as compared with that of man, "carried with it a general similarity in mode of action." To all those who, like Dr. Bastian, look upon mental phenomena from the evolutionary aspect—aiming as they do at reducing psychology to a more or less transcendental branch of physiology—this, if not a necessary, seems at least to be a favourite plan. Such readers as require to be initiated into the earliest mysteries of zoology and physiology must find this method a useful one, inasmuch as by submitting themselves to the guidance of an accomplished and trustworthy guide such as Dr. Bastian, they are led with ease and interest through a field of attractive information to the consideration of the main problem which the author keeps continually in view. To the author himself, however, the method is one which is not free from disadvantages. It leads him, for instance, at the very beginning of his task into the most hypothetical region of evolutionism, namely, that which has to do with the commencement of divergences from the homogeneous to the heterogeneous in structure and function; and so affords to sceptics and even to others who may have a stronger predisposition to accept his views, an opportunity of assigning to his argument a weakness which is inherent not in the argument itself but in the present state of a rapidly-progressing branch of science, of which he has submitted a sketch for the guidance of his readers. When Dr. Bastian, for instance, discusses the method in which muscular tissue may be produced by recurring contractions, his language is necessarily so hypothetical that his readers may incline to think that a work which commences in such a nebulous form can scarcely end in the satisfactory exposition of a new philosophy. It is a pity that false conclusions should be suggested by sentences which have no direct or essential connection with the author's argument.

When, however, Dr. Bastian has disposed of the preliminary parts of his work he enters with emphasis into the statement of his views regarding the Scope of Mind. He considers it a "legitimate inference" that the term "'Mind' no more corresponds to a definite self-existing principle than the word 'Magnetism.'" He repeats the demonstration of the fallacy which pervades every region of introspective metaphysics (H) that, namely, of regarding all mental phenomena as being limited or bounded by the sphere of consciousness; and, with admirable clearness, expands into a definition the title of his work.

"In treating of 'The Brain as an Organ of Mind,'" he says "it will be understood that we use the word 'organ' merely in the sense that it is a part whose molecular changes and activities constitute the essential *correlatives* (the italics are ours) of those phases of Consciousness known as Sensations, Emotions, Thoughts, and Volitions, as well as of a considerable part of the sum total of those other related nerve actions which are unattended by Consciousness, and whose results form, in accordance with the views above stated, so large a proportion of the phenomena comprehended under the general abstract word 'Mind.'"

This sentence expresses admirably the position which has been arrived at by all who have studied psychology from the biological point of view, and it is difficult to understand how such a moderate statement of the relationship of Mind to Brain should require in Dr. Bastian's and other recent books to be supported by an imposing presentation of facts relating to the comparative anatomy and physiology of the nervous system.

Dr. Bastian's volume is a valuable and opportune addition to the International Scientific Series. It will supply a want which has been much felt by specialists as well as by general readers who have been desirous of obtaining a knowledge of the opinions held by exponents of this line of thought—a class of writers whose style is apt to be obscure, and whose writings are too frequently contained in scattered and unattainable periodicals. The writer of this work deserves to be complimented on the success with which he has propounded his own special views regarding brain functions without assigning to them such an undue predominance as to rob his work of the credit of being a fair and comprehensive statement of what has been discovered and believed by other workers in the same field. Dr. Bastian writes in all departments of his subject with that ease and clearness which are indicative of perfect knowledge. If in anything this statement does not hold good the exception could be made only with regard to an apparent tendency to do some little injustice to the views of Hughlings-Jackson by attaching a meaning to some of his terms which is too bald and mechanical. Dr. Bastian himself excludes the processes taking place in the Motor Centres of the Cerebrum from "the cerebral substrata of Mind," and he cannot consequently be expected to lavish much sympathy on doctrines of an opposite tendency.

"The Cerebral substrata of Mind," he says, "in no way include, as the writer believes, the processes taking place in the Motor Centres of the Cerebrum wheresoever they may be situated. Mental operations, in other words, can no longer be legitimately postulated as being in part immediately due to the activity of Motor Centres. Nor can 'ideal' words be rightly described as 'motor processes.' This is a point so fundamental that in regard to it there should be no misunderstandings or ambiguities other than those which may be inherent in the subject itself."

Similarly the author speaks of "Mind as comprising the results of all nerve actions, other than those of outgoing currents." To us this exclusion of the motor element from the constitution of mind and the range of mental phenomena appears somewhat arbitrary, and, from an evolutionary point of view, unnatural; but the opponents of Dr. Bastian's views will prefer to fight their own battle, and the question is one which as yet has not been sufficiently discussed to justify a critical judgment.

Some of the last chapters of this excellent work are specially rich in information and suggestiveness. That on "Will and Voluntary Movements" deals lucidly with a difficult subject; and the chapters on "Speaking, Reading, and Writing," and on "The Cerebral Relations of Speech and Thought" contain much valuable information regarding the physiology and pathology of intellectual expression and the light which they throw upon the nature of mind as a function of the brain—a phrase which must be read subject to the explanation which Dr. Bastian gives of the title of his work. There may be some reason to doubt whether transcendental metaphysicians will be prepared to admit that their belief in mind as an entity has been so completely destroyed, as Dr. Bastian thinks, by the demonstration of the doctrine of unconscious cerebration and the consequent vitiation of all deductions drawn exclusively from within the range of consciousness; but there is no room for doubt that metaphysicians of all shades must make themselves familiar with such researches as those embodied in Dr. Bastian's work. Should they fail to do so they must be prepared to find their carefully-nurtured speculations exposed to many severe rebuffs, and open at all times to that kind of merciless danger which theories experience when they run against conflicting facts.

This work is the best book of its kind. It is full, and at the same time concise; comprehensive, but confined to a readable limit; and though it deals with many subtle subjects it expounds them in a style which is admirable for its clearness and simplicity.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Eozoic and Palæozoic

PERMIT an old worker in fossils to protest mildly against the slapdash manner in which writers sometimes hit off great palæontological questions. In your review of Roemer's valuable "Lethæa Palæozoica" it is stated that in regard to *Eozoon canadense*, he "accepts the verdict of Möbius against its organic origin, and rejects it from the list of palæozoic fossils." Now as to the acceptance of the "verdict" in question, I have nothing to say, except that the naturalist to whom are assigned the functions of judge and jury in the case very obviously lacks some of the qualifications for that high office, and has not been recognised by those best qualified to understand the case of *Eozoon*. But why Roemer or your reviewer should "reject *Eozoon* from the list of palæozoic fossils" I am at a loss to understand. As a writer on palæozoic fossils, Roemer has nothing to do with *Eozoon*. It belongs to that great series of eozoic or archæan formations which precedes the palæozoic, and which probably represents quite as long a period. Little comparatively is known of the fossils of these oldest rocks; but what we do know of their *Eozoon*, *Archæospherinæ*, *Spiral arenicolites*, and *Aspidella*, and of their immense deposits of graphitised plants, is sufficient to assure us that the life of the eozoic period was very different from that of the palæozoic; *Eozoon*, whatever its nature, is one of the most characteristic of these eozoic fossils. It has been recognised through a great vertical thickness of beds, and over so wide areas, that it is now equally characteristic of eozoic rocks in Canada and Brazil, in Bavaria and in Scandinavia. Further, it has obviously been connected with the accumulation of some of the greatest limestones of the eozoic time.

One can excuse a palæontologist familiar only with mesozoic or kainozoic fossils, when he doubts as to the organic nature of such obscure markings as *Oldhamia*, or even as to those wrinklings and scratchings on Cambrian slates which are recognised as trilobites and sponges; but we never think of asking him to accept or reject them as mesozoic fossils. In like manner those who are working out the dim traces of life remaining in the eozoic rocks will be content if geologists who scarcely condescend to recognise these great formations in their arrangements will abstain in the mean time from pronouncing judgment on eozoic remains supposed to be organic.

To us in Canada who have long regarded the eozoic formations as being quite as important in a physical point of view as the palæozoic, it is a matter of congratulation that they are now attracting so much of the attention of British geologists. Their palæontology, it is true, is still meagre, but our knowledge of it is gradually increasing, and those who have lived to see the Cambrian fauna grow from nothing to its present satisfactory condition need not despair of the Laurentian or Huronian.

Montreal, August 5 J. W. DAWSON

Algæ

I NOTICE in NATURE, vol. xxii. p. 319, that amongst other subjects you answer inquiries about minute "algæ."

I venture to send you herewith specimens of one of the Oscillatoriaceæ, which I believe is rare. In form it is nearest to what is described in the "Micrographical Dictionary" as "*Spirulina oscillaroides*" (Turp. ?), but it is very much larger. When two join and intertwine they form a cable. Under an ⅛th objective it is a most striking object; it has the characteristic deep blue-green colour, and also its movements.

I shall be glad to know if it has been described by any one.

G. F. CHANTRELL

St. James's Mount, Liverpool, August 6

[The alga is *Spirulina jenneri*, Kutz, and the *Spirillum jenneri*, Hassall. It is described in the "Fresh Water Algæ" of the latter author, and the description occurs also in Rabenhorst's "Algæ aquæ-dulcis."

During this year, in a paper read by the Rev. J. E. Vize at the Montgomery Society, and printed in their *Proceedings*, it is called *Spirulina oscillarioides*, but it is larger, and more distinctly articulated than that species. The figure given by Mr. Vize is accurate. It is not very common, but we have heard of it in two or three localities during the past twelve months.—ED.]

Lightning Conductors

I SHALL feel exceedingly obliged if you will have the kindness to reply to the following question:—The painter of my villa (Villa Calpe) having taken the liberty to paint the chain of the lightning conductor attached to my house, I should like to know whether it will interfere with the efficiency of the apparatus.

CATHERINE MCPHERSON DE BREMON

Biarritz, August 5

[A coat of paint on a lightning conductor will not at all affect its efficiency. It will protect it from rust, which of course is an advantage. But if the note is to be read literally and *a chain* is used as a conductor, it is the worst possible form, and it ought to be changed for a continuous conductor. The links of a chain only touch each other at *points*, so that even a link made of half an inch in diameter of metal is reduced to the size of less than $\frac{1}{16}$ of an inch of metal. We would rather trust to a copper wire of $\frac{1}{16}$ than to *a link* of much larger size. A point of great importance is to have a good discharge in the earth, either wet soil or a large quantity of metal joined to the conductor.—ED.]

Strange Method of Crossing a Torrent

REFERRING to the inquiry of your correspondent as to the existence in modern times of the practice of carrying a stone to steady oneself whilst crossing a torrent, I may state that it is well known to the inhabitants of mountainous districts, and though practically it may not often have to be resorted to in Switzerland, where the streams are mostly well bridged, I have myself been glad to adopt it in Dauphiné. As, however, a weight on the head or shoulders would, by raising the centre of gravity, rather diminish than add to the steadiness of the bearer, it is more usual to fill the lower side pockets of the coat, and per-

haps take a large stone in each hand, and I have certainly found this useful in traversing rapid glacier streams when mid-thigh deep.

Frenchay, near Bristol, August 18 F. F. TUCKETT

Fascination

Is it a fact that snakes can fascinate birds? With reference to the fascination of man, the ingenious explanation offered in NATURE, vol. xxii. p. 338, seems to me unsatisfactory, in that it supposes the individual fascinated to be self-conscious in a degree necessary for the consideration which of two courses to adopt to escape danger. This supposition implies an amount of self-consciousness which surely is absent in such cases as narrated? I have frequently experienced this fascination when standing on the railway platform as the engine was steaming in, and with myself at those times it was to be accounted for by the *absorption of attention by the external object, little being left for self.* That cries for assistance showed consciousness of danger, as in cases mentioned by Mr. Curran in NATURE, vol. xxii. p. 318, might be explained by the fact that these would follow on a much less attention to self than would be required for movement to carry the body out of danger. Indeed they would be the outcome of *feeling* rather than of *thought.* This view seems to be borne out by the very description of those fascinated, *e.g.*, "have had their senses so engaged by a shell in its descent," "whose every gyration in the air he could count" (NATURE, vol. xxii. p. 318), and it is expressed definitely by Mr. Spencer ("Principles of Psychology," vol. ii. p. 438):—

"When the external object or act is an astounding one, the observer partially loses consciousness of himself. He is, as we say, *lost* in wonder, or has *forgotten* himself; and we describe him as afterwards *returning* to himself, *recollecting* himself. In this state, the related impressions received from the external object, joined with representations of the objective changes about to follow, monopolise consciousness, and keep out all those feelings and ideas which constitute self-consciousness. Hence what is called 'fascination;' and hence the stupefaction on witnessing a tremendous catastrophe. Persons so 'possessed' are sometimes killed from the inability to recover self-consciousness in time to avoid danger." RICHARD HODGSON

Cambridge, August 17

"Hyper-Space"

IF some one learned in many dimensions would throw some light on *rudimentary contour lines in hyper-space*, it would doubtless interest many readers of NATURE, and inconceivably yours, $\sqrt{-1}$

August 9

THE BRITISH ASSOCIATION

THE fiftieth Annual Meeting of the British Association was opened yesterday evening at Swansea, when Prof. Allman resigned the presidential chair to Prof. Ramsay, who gave his inaugural address.

At midday on Monday the reception rooms at the Agricultural Hall, St. Helen's Road, were formally opened for the transaction of the business of the Association, under the direction of Mr. Gordon, the permanent under-secretary of the general staff, and the local honorary secretaries, Dr. Wm. Morgan and Mr. James Strick, and their efficient local staff. The hall, our Swansea correspondent informs us, is admirably situated on the border-line that separates the business part of the town from the west end residential suburbs, and the conveniences of the place are augmented by a good line of tramway and a temporary cab-stand in front, and telegraph, telephone, and post-office within the building. The arrangements had been brought to a very creditable state of completion by Monday, and the visitors have been pouring into the town steadily since Saturday. The suburban watering-place of Oystermouth, or The Mumbles, and many others of the favourite summer resorts of Gower are full to overflowing, but in the more immediate outskirts of the town, on the gently-sloping hill-sides that offer such excellent fresh air and such extended prospects of landscape and sea-view, there is ample accommodation for all comers, thanks to the really warm local hospitality and to the careful arrangements of the Local Committee.

A fair number of papers are down for reading in the various sections, the usually popular section of geography, however, exhibiting a sad dearth of contributions; we trust things may look brighter here before the end of the meeting.

INAUGURAL ADDRESS OF ANDREW CROMBIE RAMSAY, LL.D., F.R.S., V.P.G.S., DIRECTOR-GENERAL OF THE GEOLOGICAL SURVEY OF THE UNITED KINGDOM, AND OF THE MUSEUM OF PRACTICAL GEOLOGY, PRESIDENT

On the Recurrence of Certain Phenomena in Geological Time

IN this address I propose to consider the recurrence of the same kind of incidents throughout all geological time, as exhibited in the various formations and groups of formations that now form the known parts of the external crust of the earth. This kind of investigation has for many years forced itself on my attention, and the method I adopt has not heretofore been attempted in all its branches. In older times, Hutton and Playfair, in a broad and general manner, clearly pointed the way to the doctrine of uniformity of action and results, throughout all known geological epochs down to the present day; but after a time, like the prophets of old, they obtained but slight attention, and were almost forgotten, and the wilder cosmical theories of Werner more generally ruled the opinions of the geologists of the time. Later still, Lyell followed in the steps of Playfair, with all the advantages that the discoveries of William Smith afforded, and aided by the labours of that band of distinguished geologists, Sedgwick, Buckland, Mantell, De la Beche, Murchison, and others, all of whom some of us knew. Notwithstanding this new light, even now there still lingers the relics of the belief (which some of these geologists also maintained), that the physical phenomena which produced the older strata were not only different in kind, but also in degree from those which now rule the external world. Oceans, the waters of which attained a high temperature, attended the formation of the *primitive* crystalline rocks. Volcanic eruptions, with which those of modern times are comparatively insignificant, the sudden upheaval of great mountain chains, the far more rapid decomposition and degradation of rocks, and, as a consequence, the more rapid deposition of strata formed from their waste—all these were assumed as certainties, and still linger in some parts of the world among living geologists of deservedly high reputation. The chief object of this address is, therefore, to attempt to show, that whatever may have been the state of the world long before geological history began, as now written in the rocks, all known formations are comparatively so recent in geological time, that there is no reason to believe that they were produced under physical circumstances differing either in kind or degree from those with which we are now more or less familiar.

It is unnecessary for my present purpose to enter into details connected with the recurrence of marine formations, since all geologists know that the greater part of the stratified rocks were deposited in the sea, as proved by the molluscs and other fossils which they contain, and the order of their deposition and the occasional stratigraphical breaks in succession are also familiar subjects. What I have partly to deal with now, are exceptions to true marine stratified formations, and after some other important questions have been considered, I shall proceed to discuss the origin of various non-marine deposits from nearly the earliest known time down to what by comparison may almost be termed the present day.

Metamorphism.—All, or nearly all, stratified formations have been in a sense metamorphosed, since, excepting certain limestones, the fact of loose incoherent sediments having been by pressure and other agencies turned into solid rocks constitutes a kind of metamorphism. This, however, is only a first step toward the kind of metamorphism the frequent recurrence of which in geological time I have now to insist upon, and which implies that consolidated strata have undergone subsequent changes of a kind much more remarkable.

Common stratified rocks chiefly consist of marls, shales, slates, sandstones, conglomerates, and limestones, generally distinct and definite; but not infrequently a stratum, or strata, may partake of the characters in varied proportions of two or more of the above-named species. It is from such strata that meta-

morphic rocks have been produced, exclusive of the metamorphism of igneous rocks, on which I will not enter. These may be looked for in every manual of geology, and usually they may be found in them.

As a general rule, metamorphic rocks are apt to be much contorted, not only on a large scale, but also that the individual layers of mica quartz and felspar in gneiss are bent and folded in a great number of minute convolutions, so small that they may be counted by the hundred in a foot or two of rock. Such metamorphic rocks are often associated with masses of granite both in bosses and in interstratified beds or layers, and where the metamorphism becomes extreme it is often impossible to draw a boundary line between the gneiss and the granite; while, on the other hand, it is often impossible to draw any true boundary between gneiss (or other metamorphic rocks) and the ordinary strata that have undergone metamorphism. Under these circumstances it is not surprising that when chemically analysed there is often little difference in the constituents of the unmetamorphosed and the metamorphosed rock. This is a point of some importance in relation to the origin and non-primitive character of gneiss and other varieties of foliated strata, and also of some quartzites and crystalline limestones.

I am aware that in North America formations consisting of metamorphic rocks have been stated to exist of older date than the Laurentian gneiss, and under any circumstances it is obvious that vast tracts of pre-Laurentian land must have existed in all regions, by the degradation of which, sediments were derived wherewith to provide materials for the deposition of the originally unaltered Laurentian strata. In England, Wales, and Scotland attempts have also been made to prove the presence of more ancient formations, but I do not consider the data provided sufficient to warrant any such conclusion. In the Highlands of Scotland, and in some of the Western Isles, there are gneissic rocks of pre-Cambrian age, which, since they were first described by Sir Roderick Murchison in the North-west Highlands, have been, I think justly, considered to belong to the Laurentian series, unconformably underlying Cambrian and Lower Silurian rocks, and as yet there are no sufficient grounds for dissenting from his conclusion that they form the oldest known rocks in the British Islands.

It is unnecessary here to discuss the theory of the causes that produced the metamorphism of stratified rocks, and it may be sufficient to say, that under the influence of deep underground heat, aided by moisture, sandstones have been converted into quartzites, limestones have become crystalline, and in shaly, slaty, and schistose rocks, under like circumstances, there is little or no development of new material, but rather, in the main, a re-arrangement of constituents according to their chemical affinities in rudely crystalline layers, which have very often been more or less developed in pre-existing planes of bedding. The materials of the whole are approximately the same as those of the unaltered rock, but have been re-arranged in layers, for example, of quartz, felspar, and mica, or of hornblende, &c., while other minerals, such as schorl and garnets, are of not infrequent occurrence.

It has for years been an established fact that nearly the whole of the mountain masses of the Highlands of Scotland (exclusive of the Laurentian, Cambrian, and Old Red Sandstone formations) mostly consist of gneissic rocks of many varieties, and of quartzites and a few bands of crystalline limestone, which, from the north shore to the edge of the Old Red Sandstone, are repeated again and again in stratigraphical convolutions great and small. Many large bosses, veins, and dykes of granite are associated with these rocks, and, as already stated, it sometimes happens that it is hard to draw a geological line between granite and gneiss and *vice versâ*. These rocks, once called Primary or Primitive, were first proved by Sir Roderick Murchison to be of Lower Silurian age, thus revolutionising the geology of nearly one-half of Scotland. To the same age belongs by far the greater part of the broad hilly region of the south of Scotland that lies between St. Abb's Head on the east and the coast of Ayrshire and Wigtonshire on the west. In the south-west part of this district, several great masses of granite rise amid the Lower Silurian rocks, which in their neighbourhood pass into mica-schist, and even into fine-grained gneiss.

In Cornwall the occurrence of Silurian rocks is now well known. They are of metamorphic character, and partly associated with granite; and at Start Point, in South Devonshire, the Silurian strata have been metamorphosed into quartzites.

In parts of the Cambrian areas, Silurian rocks in contact with granite have been changed into crystalline hornblendic gneiss, and in Anglesey there are large tracts of presumed Cambrian strata, great part of which have been metamorphosed into chlorite and mica-schist and gneiss, and the same is partly the case with the Lower Silurian rocks of the centre of the island, where it is almost impossible to disentangle them from the associated granite.

In Ireland similar metamorphic rocks are common, and, on the authority of Prof. Hull, who knows them well, the following statements are founded:—"Metamorphism in Ireland has been geographical and not stratigraphical, and seems to have ceased before the Upper Silurian period.

"The epoch of greatest metamorphism appears to have been that which intervened between the close of the Lower Silurian period and the commencement of the Upper Silurian, taking the formations in ascending order.

"It is as yet undecided whether Laurentian rocks occur in Ireland. There are rocks in north-west Mayo very like those in Sutherlandshire, but if they are of Laurentian age they come directly under the metamorphosed Lower Silurian rocks, and it may be very difficult to separate them.

"Cambrian purple and green grits are not metamorphosed in the counties of Wicklow and Dublin, but the same beds at the southern extremity of county Wexford, near Carnsore Point, have been metamorphosed into mica-schist and gneiss.

"In the east of Ireland the Lower Silurian grits and slates have not been metamorphosed, except where in proximity to granite, into which they insensibly pass in the counties of Wicklow, Dublin, Westmeath, Cavan, Longford, and Down; but in the west and north-west of Ireland they have been metamorphosed into several varieties of schists, hornblende-rock, *and gneiss, or foliated granite*."

It would be easy to multiply cases of the metamorphism of Silurian rocks on the continent of Europe, as, for example, in Scandinavia and in the Ural Mountains, where, according to Murchison, "by following its masses upon their strike, we are assured that the same zone which in one tract has a mechanical aspect and is fossiliferous, graduates in another parallel of latitude into a metamorphic crystalline condition, whereby not only the organic remains, but even the original impress of sedimentary origin are to a great degree obliterated." The same kind of phenomena are common in Canada and the United States; and Medlicott and Blanford, in "The Geology of India," have described the thorough metamorphism of Lower Silurian strata into gneiss and syenitic and hornblende schists.

In Britain none of the Upper Silurian rocks have undergone any serious change beyond that of ordinary consolidation, but in the Eastern Alps at Gratz, Sir Roderick Murchison has described both Upper Silurian and Devonian strata interstratified with separate courses of metamorphic chloritic schist.

Enough has now been said to prove the frequent occurrence of metamorphic action among Cambrian and Lower and Upper Silurian strata.

If we now turn to the Devonian and Old Red Sandstone strata of England and Scotland, we find that metamorphic action has also been at work, but in a much smaller degree. In Cornwall and Devon five great bosses of granite stand out amid the stratified Silurian, Devonian, and Carboniferous formations. Adjoining or near these bosses the late Sir Henry De la Beche remarks, that "in numerous localities we find the coarser slates converted into rocks resembling mica-slate and gneiss, a fact particularly well exhibited in the neighbourhood of Meavy, on the south-east of Tavistock," and "near Camelford we observed a fine arenaceous and micaceous grauwacke turned into a rock resembling mica-slate near the granite." Other cases are given by the same author of slaty strata turned into mica-schist and gneiss in rocks now generally considered to be of Devonian age.

The Devonian rocks and Old Red Sandstone are of the same geological age, though they were deposited under different conditions, the first being of marine, and the latter of fresh-water origin. The Old Red Sandstone of Wales, England, and Scotland has not, as far as I know, suffered any metamorphism, excepting in one case in the north-east of Ayrshire, near the sources of the Avon Water, where a large boss of granite rises through the sandstone, which all round has been rendered crystalline with well-developed crystals of felspar.

On the continent of Europe a broad area of Devonian strata lies on both banks of the Rhine and the Moselle. Forty years ago Sedgwick and Murchison described the crystalline quartzites, chlorite, and micaceous slates of the Hundsrück and the Taunus,

and from personal observation I know that the rocks in the country on either side of the Moselle are, in places, of a foliated or semi-foliated metamorphic character. In the Alps also, as already noticed, metamorphic Devonian strata occur interstratified with beds of metamorphic schists, and, Sir Roderick adds, "we have ample data to affirm that large portions of the Eastern Alps . . . are occupied by rocks of true palæozoic age, which in many parts have passed into a crystalline state."

I know of no case in Britain where the Carboniferous strata have been thoroughly metamorphosed, excepting that in South Wales beds of coal, in the West of Caermarthenshire and in South Pembrokeshire, gradually pass from so-called bituminous coal into anthracite. The same is the case in the United States, in both instances the Carboniferous strata being exceedingly disturbed and contorted. In the Alps, however, Sir Roderick Murchison seems to have believed that Carboniferous rocks may have been metamorphosed: a circumstance since undoubtedly proved by the occurrence of a coal-measure calamite, well preserved, but otherwise partaking of the thoroughly crystalline character of the gneiss in which it is imbedded, and which was shown to me by the late Prof. Gastaldi, at Turin.

I am well acquainted with all the Permian strata of the British Islands and of various parts of Continental Europe, and nowhere, that I have seen, have they suffered from metamorphic action, and strata of this age are, I believe, as yet unknown in the Alps. This closes the list of metamorphism of Palæozoic strata.

I will not attempt (they are so numerous) to mention all the regions of the world in which Mesozoic or Secondary formations have undergone metamorphic action. In Britain and the non-mountainous parts of France they are generally quite unaltered, but in the Alps it is different. There, as every one knows who is familiar with that region, the crystalline rocks in the middle of the chain have the same general strike as the various flanking stratified formations. As expressed by Murchison, "as we follow the chain from north-east to south-west we pass from the clearest types of sedimentary rocks, and, at length, in the Savoy Alps, are immersed in the highly-altered mountains of Secondary limestone," while "the metamorphism of the rocks is greatest as we approach the centre of the chain," and indeed any one familiar with the Alps of Switzerland and Savoy knows that a process of metamorphism has been undergone *by all the Jurassic rocks* (Lias and Oolites) of the great mountain chain. Whether or not any strata of Neocomian and Cretaceous age have been well metamorphosed in this region I am unable to say; but it seems to be certain that the Eocene or Lower Tertiary Alpine formation, known as the Flysch, contains beds of black schists which pass into Lydian stone, and also that in the Grisons it has been converted into gneiss and mica-schist, a fact mentioned by Studer and Murchison. I also have seen in the country north of the Oldenhorn nummulitic rocks so far foliated that they formed an imperfect gneiss.

In Tierra del Fuego, as described by Darwin, clay slates of early cretaceous date pass into gneiss and mica-slate with garnets, and in Chonos Islands, and all along the great Cordillera of the Andes of Chili, rocks of Cretaceous or Cretaceo-oolitic age have been metamorphosed into foliated mica-slate and gneiss, accompanied by the presence of granite, syenite, and greenstone.

This ends my list, for I have never seen or heard of metamorphic rocks of later date than those that belong to the Eocene series. Enough however has been said to prove that from the Laurentian epoch onward the phenomenon of extreme metamorphism of strata has been of frequent recurrence all through Palæozoic and Mesozoic times, and extends even to a part of the Eocene series equivalent to the soft unaltered strata of the formations of the London and Paris basins, which, excepting for their fossil contents, and sometimes highly-inclined positions, look as if they had only been recently deposited.

Volcanoes.—The oldest volcanic products of which I have personal knowledge are of Lower Silurian age. These in Wales consist of two distinct series, the oldest of which, chiefly formed of felspathic lavas and volcanic ashes, lie in and near the base of the Llandeilo beds, and the second, after a long interval of repose, were ejected and intermingled with the strata forming the middle part of the Bala beds. The Lower Silurian rocks of Montgomeryshire, Shropshire, Radnorshire, Pembrokeshire, Cumberland, and Westmoreland are to a great extent also the result of volcanic eruptions, and the same kind of volcanic rocks occur in the Lower Silurian strata of Ireland. I know of no true volcanic rocks in the Upper Silurian series.

In the Old Red Sandstone of Scotland lavas and volcanic ashes are of frequent occurrence, interstratified with the ordinary lacustrine sedimentary strata. Volcanic rocks are also intercalated among the Devonian strata of Devonshire. I know of none in America or on the continent of Europe.

In Scotland volcanic products are common throughout nearly the whole of the Carboniferous sub-formations, and they are found also associated with Permian strata.

I now come to the Mesozoic or Secondary epochs. Of Jurassic age (Lias and Oolites), it is stated by Lyell with some doubt, that true volcanic products occur in the Morea and also in the Apennines, and it seems probable, as stated by Medlicott and Blanford, that the Rajmahal traps may also be of Jurassic age.

In the Cordillera of South America, Darwin has described a great series of volcanic rocks intercalated among the Cretaceo-oolitic strata that forms so much of the chain; and the same author, in his "Geological Observations in South America," states that the Cordillera has been, probably with some quiescent periods, a source of volcanic matter from an epoch anterior to our Cretaceo-oolitic formation to the present day. In the Deccan volcanic traps rest on Cretaceous beds, and are overlaid by Nummulitic strata, and, according to Medlicott and Blanford, these were poured out in the interval between Middle Cretaceous and Lower Eocene times.

In Europe the only instance I know of a volcano of Eocene age is that of Monte Bolca near Verona, where the volcanic products are associated with the fissile limestone of that area.

The well-preserved relics of Miocene volcanoes are prevalent over many parts of Europe, such as Auvergne and The Velay, where the volcanic action began in Lower Miocene times, and was continued into the Pliocene epoch. The volcanoes of the Eifel are also of the same general age, together with the ancient Miocene volcanoes of Hungary.

The volcanic rocks of the Azores, Canaries, and Madeira are of Miocene age, while in Tuscany there are extinct volcanoes that began in late Miocene, and lasted into times contemporaneous with the English Coralline Crag. In the north of Spain, also, at Olot in Catalonia, there are perfect craters and cones remaining of volcanoes that began to act in newer Pliocene times and continued in action to a later geological date. To these I must add the great *coulées* of Miocene lava, so well known in the Inner Hebrides, on the mainland near Oban, &c., in Antrim in the north of Ireland, in the Faroe Islands, Greenland, and Franz-Joseph Land. It is needless, and would be tiresome, further to multiply instances, for enough has been said to show that in nearly all geological ages volcanoes have played an important part, now in one region, now in another, from very early Palæozoic times down to the present day; and, as far as my knowledge extends, at no period of geological history is there any sign of their having played a more important part than they do in the epoch in which we live.

Mountain Chains.—The mountain-chains of the world are of different geological ages, some of them of great antiquity, and some of them comparatively modern.

It is well known that in North America the Lower Silurian rocks lie unconformably on the Laurentian strata, and also that the latter had undergone a thorough metamorphism and been thrown into great anticlinal and synclinal folds, accompanied by intense minor convolutions, before the deposition of the oldest Silurian formation, that of the Potsdam Sandstone. Disturbances of the nature alluded to imply beyond a doubt that the Laurentian rocks formed a high mountain-chain of pre-Silurian date, which has since constantly been worn away and degraded by sub-aërial denudation.

In Shropshire, and in parts of North Wales, and in Cumberland and Westmoreland, the Lower Silurian rocks by upheaval formed hilly land before the beginning of the Upper Silurian epoch; and it is probable that the Lower Silurian gneiss of Scotland formed mountains at the same time, probably very much higher than now. However that may be, it is certain that these mountains formed high land before and during the deposition of the Old Red Sandstone, and the upheaval of the great Scandinavian chain (of which the Highlands may be said to form an outlying portion) also preceded the deposition of the Old Red Strata. In both of these mountain regions the rocks have since undergone considerable movements, which in the main seem to have been movements of elevation, accompanied undoubtedly by that constant atmospheric degradation to which all high land is especially subject.

The next great European chain in point of age is that of the Ural, which according to Murchison is of pre-Permian age, a fact proved by the Permian conglomerates which were formed from the waste of the older strata. On these they lie quite unconformably and nearly undisturbed on the western flank of the mountains.

In North America the great chain of the Alleghany Mountains underwent several disturbances, the last (a great one) having taken place after the deposition of the Carboniferous rocks, and before that of the New Red Sandstone. The vast mountainous region included under the name of the Rocky Mountains, after several successive disturbances of upheaval, did not attain its present development till after the Miocene or Middle Tertiary epoch.

In South America, notwithstanding many oscillations of level recorded by Darwin, the main great disturbance of the strata that form the chain of the Andes took place apparently *in post-cretaceous times*.

The Alps, the rudiments of which began in more ancient times, received their greatest disturbance and upheaval in post-Eocene days, and were again raised at least 5,000 feet (I believe much more) at the close of the Miocene epoch. The Apennines, the Pyrenees, the Carpathians, and the great mountain region on the east of the Adriatic and southward into Greece, are of the same general age, and this is also the case in regard to the Atlas in North Africa, and the Caucasus on the borders of Europe and Asia. In the north of India the history of the Great Himalayan range closely coincides with that of the Alps, for while the most powerful known disturbance and elevation of the range took place after the close of the Eocene epoch, a subsequent elevation occurred in post-Miocene times closely resembling and at least equal to that sustained by the Alps at the same period.

It would probably not be difficult by help of extra research to add other cases to this notice of recurrences of the upheaval and origin of special mountain chains, some of which I have spoken of from personal knowledge; but enough has been given to show the bearing of this question on the argument I have in view, namely, that of repetition of the same kind of events throughout all known geological time.

Salt and Salt Lakes.—I now come to the discussion of the circumstances that produced numerous recurrences of the development of beds of various salts (chiefly common rock-salt) in many formations, which it will be seen are to a great extent connected with continental or inland conditions. In comparatively rainless countries salts are often deposited on the surface of the ground by the effect of solar evaporation of moisture from the soil. Water dissolves certain salts in combination with the ingredients of the underlying rocks and soils, and brings it to the surface, and when solar evaporation ensues the salt or salts are deposited on the ground. This is well known to be the case in and near the region of the Great Salt Lake in North America, and in South America in some of the nearly rainless districts of the Cordillera, extensive surface-deposits of salts of various kinds are common. The surface of the ground around the Dead Sea is also in extra dry seasons covered with salt, the result of evaporation, and in the upper provinces of India (mentioned by Medlicott and Blanford) "many tracts of land in the Indo-Gangetic alluvial plain are rendered worthless for cultivation by an efflorescence of salt known in the North-West Provinces as *Reh*," while every geographer knows that in Central Asia, from the western shore of the Caspian Sea to the Kinshan Mountains of Mongolia, with rare exceptions nearly every lake is salt in an area at least 3,500 miles in length. This circumstance is due to the fact that all so-called fresh-water springs, and therefore all rivers, contain small quantities of salts in solution only appreciable to the chemist, and by the constant evaporation of pure water from the lakes, in the course of time, it necessarily happens that these salts get concentrated in the water by the effect of solar heat, and, if not already begun, precipitation of solid salts must ensue.

The earliest deposits of rock-salt that I know about have been described by Mr. A. B. Wynne of the Geological Survey of India, in his memoir "On the Geology of the Salt Range in the Punjab."[1] The beds of salt are of great thickness, and along with gypsum and dolomitic layers occur in marl of a *red colour* like our Keuper Marl. This colour I have for many years considered to be, in certain cases, apt to indicate deposition of sediments in inland lakes, salt or fresh, as the case may be, and with respect to these strata in the Punjab Salt Range, authors seem to be in doubt whether they were formed in inland lakes or in lagoons near the seaboard, which at intervals were liable to be flooded by the sea, and in which in the hot seasons salts were deposited by evaporation caused by solar heat. For my argument, it matters but little which of these was the true physical condition of the land of the time, though I incline to think the inland lake theory most probable. The age of the strata associated with this salt is not yet certainly ascertained. In "The Geology of India" Medlicott and Blanford incline to consider them of Lower Silurian age, and Mr. Wynne, in his "Geology of the Salt Range," places the salt and gypsum beds doubtfully on the same geological horizon.

The next salt-bearing formation that I shall notice is the Salina or Onondaga Salt Group of North America, which forms part of the Upper Silurian rocks, and lies immediately above the Niagara Limestone. It is rich in gypsum and in salt-brine, often of a very concentrated character, "which can only be derived from original depositions of salt," and it is also supposed by Dr. T. Sterry Hunt to contain solid rock-salt 115 feet in thickness at the depth of 2,085 feet, near Saginaw Bay in Michigan.

In the Lower Devonian strata of Russia near Lake Ilmen, Sir R. Murchison describes salt springs at Starai Russa. Sinkings, "made in the hope of penetrating to the source of these salt springs," reached a depth of 600 feet without the discovery of rock salt, "and we are left in doubt whether the real source of the salt is in the lowest beds of the Devonian rocks or even in the Silurian system."

In the United States brine springs also occur in Ohio, Pennsylvania, and Virginia, in Devonian rocks.

In Michigan salts are found from the Carboniferous down to the Devonian series; and in other parts of the United States, Western Pennsylvania, Virginia, Ohio, Illinois, and Kentucky, from the lower Coal-measures salts are derived which must have been deposited in inland areas, since even in the depths of inland seas that communicate with the great ocean, such as the Mediterranean and the Red Sea, no great beds of salt can be deposited. Before such strata of salt can be formed, supersaturation must have taken place.

In the North of England, at and near Middlesborough, two deep bore-holes were made some years ago in the hope of reaching the Coal-measures of the Durham coal-field. One of them at Salthome was sunk to a depth of 1,355 feet. First they passed through 74 feet of superficial clay and gravel, next through about 1,175 feet of red sandstones and marls, with beds of rock-salt and gypsum. The whole of these strata (excepting the clay and gravel) evidently belong to the Keuper marls and sandstones of the upper part of our New Red series. Beneath these they passed through 67 feet of dolomitic limestone, which in this neighbourhood forms the upper part of the Permian series, and beneath the limestone the strata consist of 27 feet of gypsum and rock-salt and marls, one of the beds of rock-salt having a thickness of 14 feet. This bed of Permian salt is of some importance, since I have been convinced for long that the British Permian strata were deposited, not in the sea, but in salt lakes comparable in some respects to the great salt lake of Utah, and in its restricted fauna to the far greater salt lake of the Caspian Sea. The gypsum, the dolomite or magnesian limestone, the red marls covered with rain-pittings, the sun-cracks, and the impressions of footprints of reptiles made in the soft sandy marls when the water was temporarily lowered by the solar evaporation of successive summers, all point to the fact that our Permian strata were not deposited in the sea, but in a salt lake or lakes once for a time connected with the sea. The same may be said of other Permian areas in the central parts of the Continent of Europe, such as Stassfurt and Anhalt, Halle and Altern in Thuringia, and Sperenberg, near Berlin, and also in India.[1]

Neither do I think that the Permian strata of Russia, as described by Sir Roderick Murchison, were necessarily, as he implies, deposited in a wide ocean. According to his view all marine life universally declined to a minimum after the close of the Carboniferous period, that decline beginning with the Permian and ending with the Triassic epoch. Those who believe in the doctrine of evolution will find it hard to accept the idea which this implies, namely, that all the prolific forms of the Jurassic series sprang from the scanty faunas of the Permian

[1] Many earlier notices and descriptions of the Salt Range might be quoted, but Mr. Wynne's is enough for my purpose.

[1] See "Physical Geology and Geography of Great Britain," 5th edition, where the question is treated in more detail.

and Triassic epochs. On the contrary, it seems to me more rational to attribute the poverty of the faunas of these epochs to accidental abnormal conditions in certain areas, that for a time partially disappeared during the deposition of the continental Muschelkalk which is absent in the British Triassic series.

In the whole of the Russian Permian strata only fifty-three species were known at the time of the publication of "Russia and the Ural Mountains," and I have not heard that this scanty list has been subsequently increased. I am therefore inclined to believe that the red marls, grits, sandstones, conglomerates, and great masses of gypsum and rock-salt were all formed in a flat inland area which was occasionally liable to be invaded by the sea during intermittent intervals of minor depression, sometimes in one area, sometimes in another, and the fauna small in size and poor in numbers is one of the results, while the deposition of beds of salt and gypsum is another. If so, then in the area now called Russia, in sheets of inland Permian water, deposits were formed strictly analogous to those of Central Europe and of Britain, but on a larger scale.

Other deposits of salt deep beneath overlying younger strata are stated to occur at Bromberg in Prussia, and many more might be named as lying in the same formation in Northern Germany.

If we now turn to the Triassic series it is known that it consists of only two chief members in Britain, the Bunter Sandstones and the Keuper or New Red Marls, the Muschelkalk of the Continent being absent in our islands. No salt is found in the Bunter Sandstones of England, but it occurs in these strata at Schöningen in Brunswick, and also near Hanover. In the lower part of the Keuper series deposits of rock-salt are common in England and Ireland. At Almersleben, near Calbe, rock-salt is found in the Muschelkalk, and also at Erfurt and Slottenheim in Thuringia and at Wilhelmsglück in Würtemburg. In other Triassic areas it is known at Hönigsen, Hanover, in middle Keuper beds. In the red shales at Sperenberg and Lieth on the Lower Elbe, salt was found at the depth of 3,000 feet, and at Stassfurth the salt is said to be "several hundred yards thick."

In Central Spain rock-salt is known, and at Tarragona, Taen, and also at Santander in the north of Spain, all in Triassic strata. Other localities may be named in the Upper Trias, such as the Salzkammergut, Aussee, Hallstatt, Ischl, Hallein in Salzburg, Halle in the Tyrol, and Berchesgaden in Bavaria.

In the Salt Range of mountains in Northern India saliferous strata are referred with some doubt by Medlicott and Blanford to the Triassic strata.

In the Jurassic series (Lias and Oolites) salt and gypsum are not uncommon. One well-known instance occurs at Berg in the valley of the Rhone in Switzerland, where salt is derived from the Lias. Salt and gypsum are also found in Jurassic rocks at Burgos in Spain. At Gap in France there is gypsum, and salt is found in the Austrian Alps in Oolitic limestone.

In the Cretaceous rocks salt occurs, according to Lartet, at Jebel Usdom by the Dead Sea, and other authorities state that it occurs in the Pyrenees and at Biskra in Africa, where "mountains of salt" are mentioned as of Cretaceous age. The two last-named localities are possibly uncertain; but whether or not this is the case, it is not the less certain that salt has been deposited in Cretaceous rocks, and, judging by analogy, probably in inland areas of that epoch.

In the Eocene or Older Tertiary formations, rock-salt is found at Cardona in Spain, and at Kohat in the Punjab it occurs at the base of Nummulitic beds. It is also known at Mandi in India in strata supposed to be of Nummulitic Eocene age.

The record does not end here, for a zone of rock-salt lies in Sicily at the top of the Salina clays in Lower Miocene beds, and in Miocene strata gypsum is found at several places in Spain, while salt also occurs in beds that are doubtfully of Miocene age (but may be later) at Wielitzka in Poland, Kalusz in Galicia, Bukowina, and also in Transylvania.

In Pliocene or Later Tertiary formations, thick beds of gypsum are known in Zante, and strata of salt occur in Roumania and Galicia, while in Pliocene rocks, according to Dana, or in Post-Tertiary beds, according to others, a thick bed of pure salt was penetrated to a depth of 38 feet at Petit Anse in Louisiana. This ends my list, though I have no doubt that, by further research, many more localities might be given. Enough, however, has been done to show that rock-salt (and other salts) are of frequent recurrence throughout all geological time, and as in my opinion it is impossible that common salt can be deposited in the open ocean, it follows that this and other salts must have been precipitated from solutions, which, by the effect of solar evaporation, became at length supersaturated, like those of the Dead Sea, the great salt lake of Utah, and in other places which it is superfluous to name.

Fresh-water. Lakes and Estuaries.—I now come to the subject of recurrences of fresh-water conditions both in lakes and estuaries. In the introduction to the "Geology of India," by Messrs. Medlicott and Blanford, mention is made of the Blaini and Krol rocks as probably occupying "hollows formed by denudation in the old gneissic rocks," and the inference is drawn that "if this be a correct view, it is probable that the cis-Himalayan Palæozoic rocks are in great part of fresh-water origin, and that the present crystalline axis of the Western Himalayas approximately coincides with the shore of the ancient Palæozoic continent, of which the Indian peninsula formed a portion." The Krol rocks are classed broadly with "Permian and Carboniferous" deposits, but the Blaini beds are doubtfully considered to belong to Upper Silurian strata. If this point be by and by established, this is the earliest known occurrence of fresh-water strata in any of the more ancient Palæozoic formations.

It is a fact worthy of notice that the colour of the strata formed in old lakes (whether fresh or salt) of Palæozoic and Mesozoic age is apt to be red: a circumstance due to the fact that each little grain of sand or mud is usually coated with a very thin pellicle of peroxide of iron. Whether or not the red and purple Cambrian rocks[1] may not be *partly* of fresh-water origin, is a question that I think no one but myself has raised.[2]

There is however, in my opinion, no doubt with regard to the fresh-water origin of the Old Red Sandstone, as distinct from the contemporaneous marine deposits of the Devonian strata. This idea was first started by that distinguished geologist, Dr. Fleming, of Edinburgh, followed by Mr. Godwin-Austen, who, from the absence of marine shells and the nature of the fossil fishes in these strata, inferred that they were deposited, not in the sea, as had always been asserted, but in a great fresh-water lake or in a series of lakes. In this opinion I have for many years agreed, for the nearest analogies of the fish are, according to Huxley, the Polypterus of African rivers, the Ceratodus of Australia, and in less degree the Lepidosteus of North America. The truth of the supposition that the Old Red Sandstone was deposited in fresh water, is further borne out by the occurrence of a fresh-water shell, *Anodonta jukesii*, and of ferns in the Upper Old Red Sandstone in Ireland; and the same shell is found at Dura Den in Scotland, while in Caithness, along with numerous fishes, there occurs the small bivalve crustacean *Estheria murchisoniæ*.

I think it more than probable that the red series of rocks that form the Catskill Mountains of North America (and with which I am personally acquainted) were formed in the same manner as the Old Red Sandstones of Britain; for, excepting in one or two minor interstratifications, they contain no relics of marine life, while "the fossil fishes of the Catskill beds, according to Dr. Newberry, appear to represent closely those of the British Old Red Sandstone" (Dana).

The Devonian rocks of Russia, according to the late Sir Roderick Murchison, consist of two distinct types, viz., Devonian strata identical in general character with those in Devonshire and in various parts of the continent of Europe. These are exclusively of a marine character, while the remainder corresponds to the Old Red Sandstone of Wales, England, and Scotland.

At Tchudora, about 105 miles south-east of St. Petersburg, the lowest members of the series consist of flag-like, compact limestones accumulated in a tranquil sea, and containing fucoids and encrinites, together with shells of Devonian age, such as Spirifers, Terebratulæ, Orthis, Leptænas, Avicula, Modiola, Natica, Bellerophon, &c., while the upper division graduates into the Carboniferous series as it often does in Britain, and, like the Old Red Sandstone of Scotland, contains only fish-remains, and in both countries they are of the same species. "Proceeding from the Valdai Hills on the north," the geologist "quits *a Devonian Zone with a true 'Old Red' type* dipping under the

[1] By Cambrian, I mean only the *red and purple* rocks of Wales, England, Scotland, and Ireland, older than the Menevian beds, or any later division of the Silurian strata that may chance to rest upon them.

[2] "On the Red Rocks of England of older date than the Trias." *Jour. Geol. Soc.*, 1871, vol. xxviii.

Carboniferous rocks of Moscow, and having passed through the latter he finds himself suddenly in a yellow-coloured region, entirely dissimilar in structure to what he had seen in any of the northern governments, which, of a different type as regards fossils, is the true stratigraphical *equivalent of the Old Red system*." This seems to me, as regards the Russian strata, to mean that just as the Devonian strata of Devonshire are the true equivalents of the Old Red Sandstone of Wales and Scotland, they were deposited under very different conditions, the first in the sea and the others in inland fresh-water lakes. At the time Sir Roderick Murchison's work was completed, the almost universal opinion was that the Old Red Sandstone was a marine formation. In the year 1830 the Rev. Dr. Fleming of Edinburgh read a paper before the Wernerian Society in which he boldly stated that the "*Old Red Sandstone* is a *fresh-water formation*" of older date than the Carboniferous Limestone. This statement, however, seems to have made no impression on geologists till it was revived by Godwin-Austen in a memoir "On the Extension of the Coal-measures," &c., in the *Journal* of the Geological Society, 1856. Even this made no converts to what was then considered a heretical opinion. I have long held Dr. Fleming's view, and unfortunately published it in the third edition of "The Physical Geology and Geography of Great Britain," without at the time being aware that I had been forestalled by Dr. Fleming and Mr. Godwin-Austen.

To give anything like a detailed account of all the fresh-water formations deposited in estuaries and lakes from the close of the Old Red Sandstone times down to late Tertiary epochs is only fitted for a manual of geology, and would too much expand this address; and I will therefore give little more than a catalogue of these deposits in ascending order.

In the Coal-measure parts of the Carboniferous series a great proportion of the shales and sandstones are of fresh-water origin. This is proved all over the British Islands by the shells they contain, while here and there marine interstratifications occur, generally of no great thickness. There is no doubt among geologists that these Coal-measure strata were chiefly deposited under estuarine conditions, and sometimes in lagoons or in lakes, while numerous beds of coal formed by the life and death of land plants, each underlaid by the soil on which the plants grew, evince the constant recurrence of terrestrial conditions. The same kind of phenomena are characteristic of the Coal-measures all through North America, and in every country on the continent of Europe, from France and Spain on the west to Russia in the east, and the same is the case in China and in other areas.

In Scotland, according to Prof. Judd, fresh-water conditions occur more or less all through the Jurassic series, from the Lias to the Upper Oolites. In England fresh-water strata, with thin beds of coal, are found in the Inferior Oolite of Yorkshire, and in the middle of England and elsewhere in the Great Oolite. The Purbeck and Wealden strata, which in a sense fill the interval between the Jurassic and Cretaceous series, are almost entirely formed of fresh-water strata, with occasional thin marine interstratifications. By some the Wealden beds are considered to have been formed in and near the estuary of a great river, while others, with as good a show of reason, believe them to have been deposited in a large lake subject to the occasional influx of the sea.

In the eastern part of South Russia the Lias consists chiefly of fresh-water strata, as stated by Neumayr.

The Godwana rocks of Central India range from Upper Palæozoic times well into the Jurassic strata, and there all these formations are of fresh-water origin. Fresh-water beds with shells are also interstratified with the Deccan traps of Cretaceous and Tertiary (Eocene) age, while 2,000 feet of fresh-water sands overlie them.

In South-Western Sweden, as stated by Mr. Bauerman, "the three coal-fields of Hoganas, Stabbarp, and Rodingé lie in the uppermost Triassic or Rhætic series." In Africa the Karoo beds, which it is surmised may be of the age of the New Red Sandstone, contain beds of coal. In North America certain fresh-water strata, with beds of lignite, apparently belong to the Cretaceous and Eocene epochs, and in the north of Spain and south of France there are fresh-water lacustrine formations in the highest Cretaceous strata.

In England the Lower and Upper Eocene strata are chiefly of fresh-water origin, and the same is the case in France and other parts of the Continent. Certain fresh-water formations in Central Spain extend from the Eocene to the Upper Miocene strata.

There is only one small patch of Miocene beds in England, at Bovey Tracey, near Dartmoor, formed of fresh-water deposits with interstratified beds of lignite or Miocene coal. On the continent of Europe Miocene strata occupy immense independent areas, extending from France and Spain to the Black Sea. In places too numerous to name they contain beds of "brown coal," as lignite is sometimes called. These coal-beds are often of great thickness and solidity. In one of the pits which I descended near Teplitz, in Bohemia, the coal, which lies in a true basin, is 40 feet thick, and underneath it there is a bed of clay, with rootlets, quite comparable to the underclay which is found beneath almost every bed of coal in the British and other coal-fields of the Carboniferous epoch. The Miocene rocks of Switzerland are familiar to all geologists who have traversed the country between the Jura and the Alps. Sometimes they are soft and incoherent, sometimes formed of sandstones, and sometimes of conglomerates, as on the Righi. They chiefly consist of fresh-water lacustrine strata, with some minor marine interstratifications which mark the influx of the sea during occasional partial submergences of portions of the area. These fresh-water strata, of great extent and thickness, contain beds of lignite, and are remarkable for the relics of numerous trees and other plants which have been described by Prof. Heer of Zurich with his accustomed skill. The Miocene fresh-water strata of the Sewalik Hills in India are well known to most students of geology, and I have already stated that they bear the same relation to the more ancient Himalayan Mountains that the Miocene strata of Switzerland and the North of Italy do to the pre-existing range of the Alps. In fact it may be safely inferred that something far more than the rudiments of our present continents existed long before Miocene times, and this accounts for the large areas on those continents which are frequently occupied by Miocene fresh-water strata. With the marine formations of Miocene age this address is in no way concerned, nor is it essential to my argument to deal with those later Tertiary phenomena, which in their upper stages so easily merge into the existing state of the world.

Glacial Phenomena.—I now come to the last special subject for discussion in this address, viz., the Recurrence of Glacial Epochs, a subject still considered by many to be heretical, and which was generally looked upon as an absurd crotchet when, in 1855, I first described to the Geological Society boulder-beds containing ice-scratched stones and erratic blocks in the Permian strata of England. The same idea I afterwards applied to some of the Old Red Sandstone conglomerates, and of late years it has become so familiar, that the effects of glaciers have at length been noted by geologists from older Palæozoic epochs down to the present day.

In the middle of last July I received a letter from Prof. Geikie, in which he informed me that he had discovered mammilated *moutonnée* surfaces of Laurentian rocks, passing underneath the Cambrian sandstones of the north-west of Scotland at intervals, all the way from Cape Wrath to Loch Torridon, for a distance of about 90 miles. The mammilated rocks are, says Prof. Geikie, "*as well rounded off as any recent roche moutonnée*," and "in one place these bosses are covered by a huge angular breccia of this old gneiss (Laurentian) with blocks sometimes 5 or 6 feet long." This breccia, where it occurs, forms the base of the Cambrian strata of Sutherland, Ross, and Cromarty, and while the higher strata are always well stratified, where they approach the underlying Laurentian gneiss "they become pebbly, passing into coarse unstratified agglomerates or boulder-beds." In the Gairloch district "it is utterly unstratified, the angular fragments standing on end and at all angles," just as they do in many modern moraine mounds wherever large glaciers are found. The general subject of Palæozoic glaciers has long been familiar to me, and this account of more ancient glaciers of Cambrian age is peculiarly acceptable.

The next sign of ice in Britain is found in the Lower Silurian rocks of Wigtonshire and Ayrshire. In the year 1865 Mr. John Carrick Moore took me to see the Lower Silurian graptolitic rocks at Corswall Point in Wigtonshire, in which great blocks of gneiss, granite, &c., are imbedded, and in the same year many similar erratic blocks were pointed out to me by Mr. James Geikie in the Silurian strata of Carrick in Ayrshire. One of the blocks at Corswall, as measured by myself, is nine feet in length, and the rest are of all sizes, from an inch or two up to several feet in diameter. There is no gneiss or granite in this region nearer than those of Kirkcudbrightshire and Arran, *and these are of later geological date than the strata amid which the*

erratic blocks are imbedded. It is therefore not improbable that they may have been derived from some high land formed of Laurentian rocks of which the outer Hebrides and parts of the mainland of Scotland form surviving portions. If so, then I can conceive of no agent capable of transporting large boulders and dropping them into the Lower Silurian mud of the seas of the time save that of icebergs or other floating ice, and the same view with regard to the neighbouring boulder-beds of Ayrshire is held by Mr. James Geikie. If however any one will point out any other natural cause still in action by which such results are at present brought about, I should be very glad to hear of it.

I must now turn to India for further evidence of the action of Palæozoic ice. In the Himalayas of Pangi, south-east of Kashmir, according to Medlicott and Blanford, "old slates, supposed to be Silurian, contain boulders in great numbers," which they believe to be of glacial origin. Another case is mentioned as occurring in "transition beds of unknown relations," but in another passage they are stated to be "very ancient, but no idea can be formed of their geological position." The *underlying rocks are marked by distinct glacial striations.*

The next case of glacial boulder-beds with which I am acquainted is found in Scotland, and in some places in the north of England, where they contain what seem to be indistinctly ice-scratched stones. I first observed these rocks on the Lammermuir Hills, south of Dunbar, lying unconformably on Lower Silurian strata, and soon inferred them to be of glacial origin, a circumstance that was subsequently confirmed by my colleagues Prof. and Mr. James Geikie, and is now familiar to other officers of the Geological Survey of Scotland.

I know of no boulder formations in the Carboniferous series, but they are well known as occurring on a large scale in the Permian brecciated conglomerates, where they consist "of pebbles and large blocks of *stone, generally angular,* imbedded in a marly paste . . . the fragments have mostly travelled from a distance, apparently from the borders of Wales, and some of them are three feet in diameter." Some of the stones are as well scratched as those found in modern moraines or in the ordinary boulder-clay of what is commonly called the Glacial epoch. In 1855 the old idea was still not unprevalent that during the Permian epoch, and for long after, the globe had not yet cooled sufficiently to allow of the climates of the external world being universally affected by the constant radiation of heat from its interior. For a long time, however, this idea has almost entirely vanished, and now, in Britain at all events, it is little if at all attended to, and other glacial episodes in the history of the world have continued to be brought forward and are no longer looked upon as mere ill-judged conjectures.

The same kind of brecciated boulder-beds that are found in our Permian strata occur in the Rotheliegende of Germany, which I have visited in several places, and I believe them to have had a like glacial origin.

Mr. G. W. Stow, of the Orange Free State, has of late years given most elaborate accounts of similar Permian boulder-beds in South Africa. There great masses of moraine matter not only contain ice-scratched stones, but on the banks of rivers where the Permian rock has been removed by aqueous denudation the underlying rocks, well rounded and mammillated, *are covered by deeply incised glacier grooves* pointing in a direction which at length leads the observer to the Pre-Permian mountains from whence the stones were derived that formed these ancient moraines.[1]

Messrs. Blanford and Medlicott have also given in "The Geology of India" an account of boulder-beds in what they believe to be Permian strata, and which they compare with those described by me in England many years before. There the Godwana group of the Talchir strata contains numerous boulders, many of them six feet in diameter, and in one instance *some of the blocks were found to be polished and striated, and the underlying Vindhyan rocks were similarly marked.*" The authors also correlate these glacial phenomena with those found in similar deposits in South Africa, discovered and described by Mr. Stow.

In the Olive group of the Salt range, described by the same authors, there is a curious resemblance between a certain conglomerate "and that of the Talchir group of the Godwana system." This "Olive conglomerate" belongs to the Cretaceous series, and contains ice-transported erratic boulders derived from unknown rocks, one of which of red granite "is polished and striated on three faces in so characteristic a manner that very little doubt can exist of its having been transported by ice." One block of red granite at the Mayo Salt Mines of Khewra "is 7 feet high and 19 feet in circumference." In the "Transition beds" of the same authors, which are supposed to be of Upper Cretaceous age, there also are boulder beds with erratic blocks of great size.

I know of no evidence of glacial phenomena in Eocene strata excepting the occurrence of huge masses of included gneiss in the strata known as Flysch in Switzerland. On this question, however, Swiss geologists are by no means agreed, and I attach little or no importance to it as affording evidence of glacier ice.

Neither do I know of any Miocene glacier-deposits excepting those in the north of Italy, near Turin, described by the late eminent geologist, Gastoldi, and which I saw under his guidance. These contain many large erratic boulders derived from the distant Alps, which, in my opinion, were then at least as lofty or even higher than they are now, especially if we consider the immense amount of denudation which they underwent during Miocene, later Tertiary, and post-Tertiary times.

At a still later date there took place in the north of Europe and America what is usually misnamed "*The* Glacial Epoch," when a vast glacial mass covered all Scandinavia and distributed its boulders across the north of Germany, as far south as the country around Leipzig, when Ireland also was shrouded in glacier ice, and when a great glacier covered the larger part of Britain and stretched southward, perhaps nearly as far as the Thames on the one side, and certainly covered the whole of Anglesey, and probably the whole, or nearly the whole, of South Wales. This was after the advent of man.

Lastly, there is still a minor Glacial epoch in progress on the large and almost unknown Antarctic continent, from the high land of which in latitudes which partly lie as far north as 60° and 62°, a vast sheet of glacier-ice of great thickness extends far out to sea and sends fleets of icebergs to the north, there to melt in warmer latitudes. If in accordance with the theory of Mr. Croll, founded on astronomical data, a similar climate were transferred to the northern hemisphere, the whole of Scandinavia and the Baltic would apparently be covered with glacier-ice, and the same would probably be the case with the Faroe Islands and great part of Siberia, while even the mountain tracts of Britain might again maintain their minor systems of glaciers.

Conclusions.—In opening this address I began with the subject of the oldest metamorphic rocks that I have seen—the Laurentian strata. It is evident to every person who thinks on the subject that their deposition took place *far from the beginning of recognised geological time.* For there must have been older rocks by the degradation of which they were formed. And if, as some American geologists affirm, there are on that continent metamorphic rocks of more ancient dates than the Laurentian strata, there must have been rocks more ancient still to afford materials for the deposition of these pre-Laurentian strata.

Starting with the Laurentian rocks, I have shown that the phenomena of *metamorphism* of strata have been continued from that date all through the later formations, or groups of formations, down to and including part of the Eocene strata in some parts of the world.

In like manner I have shown that ordinary volcanic rocks have been ejected in Silurian, Devonian, Carboniferous, Jurassic, Cretaceo-Oolitic, Cretaceous, Eocene, Miocene, and Pliocene times, and from all that I have seen or read of these ancient volcanoes I have no reason to believe that volcanic forces played a more important part in any period of geological time than they do in this our modern epoch.

So also mountain chains existed before the deposition of the Silurian rocks, others of later date before the Old Red Sandstone strata were formed, and the chain of the Ural before the deposition of the Permian beds. The last great upheaval of the Alleghany Mountains took place between the close of the formation of the Carboniferous strata of that region and the deposition of the New Red Sandstone.

According to Darwin, after various oscillations of level, the Cordillera underwent its chief upheaval after the Cretaceous epoch, and all geologists know that the Alps, the Pyrenees, the Carpathians, the Himalayas, and other mountain-chains (which I have named) underwent what seems to have been their chief great upheaval after the deposition of the Eocene strata, while

[1] Mr. Stow's last memoir on this subject is still in manuscript. It is so exceedingly long, and the sections that accompany it are of such unusual size, that the Geological Society could not afford their publication. It was thought that the Government of the Orange Free State might undertake this duty, but the late troubles in South Africa have probably hindered this work —it is to be hoped only for a time.

some of them were again lifted up several thousands of feet after the close of the Miocene epoch.

The deposition of salts from aqueous solutions in inland lakes and lagoons appears to have taken place through all time—through Silurian, Devonian, Carboniferous, Permian, Triassic, Jurassic, Cretaceous, Eocene, Miocene, and Pliocene epochs—and it is going on now.

In like manner fresh-water and estuarine conditions are found now in one region, now in another, throughout all the formations or groups of formations, possibly from Silurian times onward; and glacial phenomena, so far from being confined to what was and is generally still termed *the* Glacial epoch, are now boldly declared, by independent witnesses of known high reputation, to begin with the Cambrian epoch, and to have occurred somewhere, at intervals, in various formations, from almost the earliest Palæozoic times down to our last post-Pliocene "Glacial epoch."

If the nebular hypothesis of astronomers be true (and I know of no reason why it should be doubted), the earth was at one time in a purely gaseous state, and afterwards in a fluid condition, attended by intense heat. By and by consolidation, due to partial cooling, took place on the surface, and as radiation of heat went on, the outer shell thickened. Radiation still going on, the interior fluid matter decreased in bulk, and, by force of gravitation, the outer shell being drawn towards the interior, gave way, and, in parts, got crinkled up, and this, according to cosmogonists, was the origin of the earliest mountain-chains. I make no objection to the hypothesis, which, to say the least, seems to be the best that can be offered, and looks highly probable. But, assuming that it is true, these hypothetical events took place so long before authentic geological history began, as written in the rocks, that the earliest of the physical events to which I have drawn your attention in this address was, to all human apprehension of time, so enormously removed from these early assumed cosmical phenomena, *that they appear to me to have been of comparatively quite modern occurrence, and to indicate that, from the Laurentian epoch down to the present day, all the physical events in the history of the earth have varied neither in kind nor in intensity from those of which we now have experience.* Perhaps many of our British geologists hold similar opinions, but, if it be so, it may not be altogether useless to have considered the various subjects separately on which I depend to prove the point I had in view.

SECTION C

GEOLOGY

Opening Address by H. C. Sorby, LL.D., F.R.S., &c., President of the Section

In selecting a subject for an address to be given in accordance with the custom of my predecessors, I was anxious that it should be in some way or other connected with the locality in which we have met. If I had been adequately acquainted with the district, I should have thought it incumbent on me to give such an outline of the general geology of the surrounding country as would have been useful to those attending this meeting. I am, however, practically a stranger to South Wales, and must therefore leave that task to others. On reflecting on the various subjects to which I might have called your attention, it appears to me that I could select one which would be eminently appropriate in a town and district where iron and copper are smelted on so large a scale, and, as I think, also equally appropriate from a geological point of view. This subject is the comparative structure of artificial slags and erupted rocks. In making this choice I was also influenced by the fact that in my two anniversary addresses as President of the Geological Society, I have recently treated on the structure and origin of modern and ancient stratified rocks, and I felt that, if in the present address I were to treat on certain peculiarities in the structure of igneous rocks, I should have described the leading conclusions to which I have been led by studying the microscopical structure of nearly all classes of rocks. It would, however, be impossible in the time now at disposal to treat on all the various branches of the subject. Much might be said on both the purely chemical and purely mineralogical aspects of the question; but though these must not be ignored, I propose to draw your attention mainly to another special and remarkable class of facts, which, so far as I am aware, have attracted little or no attention, and yet, as I think, would be very instructive if we could fully understand their meaning. Here, however, as in so many cases, the observed facts are clear enough, but their full significance is somewhat obscure, owing to the want of adequate experimental data, or of sufficient knowledge of general physical laws.

A considerable amount of attention has already been paid to the mineral constitution of slags, and to such peculiarities of structure as can be learned independently of thin microscopical sections. A very complete and instructive work, specially devoted to the subject, was published by von Leonhard about twenty-two years ago, just at the time when the microscope was first efficiently applied to the study of rocks. Since then, Vogelsang and others have described the microscopical structure of some slags in connection with their study of obsidian and other allied volcanic rocks. At the date of the publication of von Leonhard's work the questions in discussion differed materially from those which should now claim attention. There was still more or less dispute respecting the nature and origin of certain rocks which have now been proved to be truly volcanic by most unequivocal evidence. I am not at all surprised at this, since, as I shall show, there is such a very great difference in their characteristic structure and that of the artificial products of igneous fusion, that but for the small portions of glass inclosed in the constituent crystals, described by me many years ago under the name of "glass-cavities," there would often be no positive proof of their igneous origin. There was also considerable doubt as to the manner in which certain minerals in volcanic rocks had been generated. The observed facts were sufficient to prove conclusively that some had been formed by sublimation, others by igneous fusion, and others deposited from more or less highly-heated water, but it was difficult or impossible to decide whether in particular cases certain minerals had been formed exclusively by one or other process, or sometimes by one and sometimes by the other, or by the combined action of water and a very high temperature. I must confess that, even now that so much may be learned by studying with high magnifying powers the internal structure of crystals, I should hesitate very much in deciding what were the exact conditions under which certain minerals have been formed. This hesitation is probably as much due to inadequate examination, and to the want of a complete study of typical specimens, both in the field and by means of the microscope, as to the unavoidable difficulties of the subject. Such doubt, however, applies more to the origin of minerals occurring in cavities than to those constituting a part of true rock masses, to which latter I shall almost exclusively refer on the present occasion. In the formation of these it appears to me that sublimation has occurred to a very limited extent. In many cases true igneous fusion has played such a leading part that the rocks may be fairly called *igneous*, but, in other cases water in some form or other has, I think, had so much influence, that we should hesitate to call them *igneous*, and the term *erupted* would be open to far less objection, since it would adequately express the manner of their occurrence, and not commit us to anything open to serious doubt.

In studying erupted rocks of different characters we see that at one extreme they are as truly igneous as any furnace-product, and at the other extremity hardly, if at all, distinguishable from certain deposits met with in mineral veins, which furnish abundant evidence of the preponderating, if not exclusive influence of water, and have very little or nothing in common with products certainly known to have been formed by the action of heat, and of heat alone. Between these extremes there is every connecting link, and in certain cases it is almost, if not quite, impossible to say whether the characteristic structure is due more to the action of heat than of water. The great question is whether the presence of a small quantity of water in the liquid or gaseous state is the true cause of very well-marked differences in structure, or whether greater pressure and the necessarily slower rate of cooling were not the more active causes, and the presence of water in one state or another was merely the result of the same cause. This is a question which ought to be solved by experiment, but I fear it would be almost impossible to perform the necessary operations in a satisfactory manner.

What I now propose to do is to describe a particular class of facts which have lately attracted my attention, and to show that the crystalline minerals in products known to have been formed by the action of heat alone have a certain very well-marked and characteristic structure, which is gradually modified as we pass

through modern and more ancient volcanic to plutonic rocks, in such a manner as to show at once that they are intimately related and yet differ in such characteristic particulars that I think other agencies than mere heat must have had great influence in producing the final results.

In dealing with this subject I propose in the first place to describe the characteristic structure of products formed artificially under perfectly well-known conditions, and then to pass gradually to that of rocks whose origin must be inferred, and cannot be said to have been completely proved.

Crystalline Blowpipe Beads.—Some years ago I devoted a considerable amount of time to the preparation and study of crystalline blowpipe beads, my aim being to discover simple and satisfactory means for identifying small quantities of different earths and metallic oxides, when mixed with others, and I never supposed that such small objects would throw any light on the structure and origin of vast masses of natural rock. The manner in which I prepared them was as follows.—A small bead of borax was so saturated with the substance under examination at a high temperature that it became opaque either on cooling or when slowly re-heated. It was again fused so as to be quite transparent, and then very slowly cooled over the flame. If properly managed, the excess of material held in solution at a high temperature slowly crystallised out, the form and character of the crystals depending on the nature of the substance and on the presence of other substances added to the bead as test reagents. By this means I proved that in a few exceptional cases small simple solid crystals are formed. More frequently they are compound, or occur as minute needles, but the most characteristic peculiarity is the development of complex skeleton crystals of extreme beauty, built up of minute attached prisms, so as to give rise to what would be a well-developed crystal with definite external planes, if the interspaces were all filled up.

In many cases the fibres of these skeletons are parallel to three different axes perpendicular to one another, and it might be supposed that the entire skeleton was due to the growth of small needle-shaped crystals, all uniformly elongated in the line of one crystalline axis, so that the resulting mass would be optically and crystographically complex; but in some cases the different systems of fibres or needles are inclined obliquely, and then the optical characters enable us to prove that the separate prisms are not similar to one another, but developed along different crystalline planes, so as to build up one definite crystal, mechanically complex, but optically and crystographically simple, or merely twinned. In a few special cases there is a well-pronounced departure from this rule, and truly compound groups of prisms are formed. In the centre there is a definite simple prism, but instead of this growing continuously in the same manner, so as to produce a larger prism, its ends, as it were, break up into several smaller prisms slightly inclined to the axis of the first, and these secondary prisms in like manner break up into still smaller, so as ultimately to give rise to a curious complex, brush-like growth, showing in all positions a sort of fan-shaped structure, mechanically, optically, and crystographically complex.

I have done my best to describe these various kinds of crystals seen in blowpipe beads as clearly as can be done without occupying too much time, but feel that it is impossible to make the subject as simple as it really is without numerous illustrations. However, for the purpose now in view, it will I trust suffice to have established the fact that we may divide the crystals in blowpipe beads into the following groups, which, on the whole, are sufficiently distinct, though they necessarily pass one into the other:—

1. Simple crystals.
2. Minute detached needles.
3. Fan-shaped compound groups.
4. Feathery skeleton crystals.

It must not be supposed that crystals of one or other of these groups occur promiscuously and without some definite relation to the special conditions of the case. Very much depends upon their chemical composition. Some substances yield almost exclusively those of one group, and other substances those of another, whilst in some cases a difference in the rate of cooling and other circumstances give rise to variations within certain limits; and, if it were possible to still further vary some of the conditions, these limits would probably be increased. Thus, for example, the earliest deposition of crystalline matter from the glassy solvent is sometimes in the form of simple solid prisms or needles, but later on in the process it is in the form of compound feathery tufts; and, if it were possible to cool the beads much more slowly whilst they are very hot, I am inclined to believe that some substances might be found that in the early stage of the process would yield larger and more solid crystals than those commonly met with. This supposition at all events agrees with what takes place when such salts as potassium chloride are crystallised from solution in water. Some of my blowpipe beads prove most conclusively that several perfectly distinct crystalline substances may be contemporaneously deposited from a highly-heated vitreous solvent, which is an important fact in connection with the structure of igneous rocks, since some authors have asserted that more than one mineral species cannot be formed by the slow cooling of a truly melted rock. The great advantage of studying artificial blowpipe beads is that we can so easily obtain a variety of results under conditions which are perfectly well known and more or less completely under control.

Artificial Slags.—I now proceed to consider the structure of slags, and feel tempted to enter into the consideration of the various minerals found in them, which are more or less perfectly identical with those characteristic of erupted rocks, but some of the most interesting, like the felspars, occur in a well-marked form only in special cases, where iron ores are smelted with fluxes, seldom if ever employed in our own country, so that my acquaintance with them is extremely small. My attention has been mainly directed to the more common products of our blast furnaces. On examining these, after having become perfectly familiar with the structure of blowpipe beads, I could see at once that they are very analogous, if not identical, in their structure. In both we have a glassy solvent, from which crystals have been deposited; only in one case this solvent was red hot melted borax, and in the other glassy, melted stone. Thus, for example, some compounds, like what I believe is Humboldtilite, crystallise out in well-marked solid crystals, like those seen occasionally in blowpipe beads, whereas others crystallise out in complex feathery skeletons, just like those so common in, and characteristic of, the beads. In both we also often see small detached needles scattered about in the glassy base. These skeleton crystals and minute needles have been described by various writers under the names *crystallites*, *belonites*, and *trichites*. Though we have not the great variety of different forms met with in the beads, and cannot so readily vary the conditions under which they are produced, yet we can at all events see clearly that their structural character depends both on their chemical constitution and on the physical conditions under which they have crystallised. None of my microspical preparations of English slags appear to contain any species of felspar, but several contain what I believe is some variety of augite, both in the form of more or less solid prisms, and of feathery skeletons of great beauty and of much interest in connection with the next class of products to which I shall call your attention, viz., rocks artificially melted and slowly cooled.

Rocks Artificially Melted.—I have had the opportunity of preparing excellent thin microscopical sections of some of the results of the classic experiments of Sir James Hall. I have also carefully studied the product obtained by fusing and slowly cooling much larger masses of the basalt of Rowley, and have compared its structure with that of the original rocks. Both are entirely crystalline, and, as far as I can ascertain, both are mainly composed of the same minerals. Those to which I would especially call attention are a triclinic felspar and the augite. The general character of the crystals is, however, strikingly different. In the artificial product a considerable part of the augite occurs as flat, feathery plates, like those in furnace slags, which are quite absent from the natural rock, and only part occurs as simple solid crystals, analogous to those in the rock, but much smaller and less developed. The felspar is chiefly in the form of elongated, flat, twinned prisms, which, like the prisms in some blowpipe beads, commence in a more simple form and end in complex fan-shaped brushes, whereas in the natural rock they are all larger than in the artificial, and exclusively of simple characters. On the whole then, though the artificially melted and slowly cooled basalt is entirely crystalline, and has a mineral composition closely like that of the natural rock, its mechanical structure is very different, being identical with that of blowpipe beads and slags.

Volcanic Rocks.—Passing now to true natural igneous rocks, we find some, like obsidian, which closely correspond with blowpipe beads, slags, and artificially melted rocks, in having a glassy base through which small crystalline needles are scattered;

but the more completely crystalline volcanic rocks have, on the whole, a structure very characteristically unlike that of the artificial products. I have most carefully examined all my sections of modern and ancient volcanic rocks, but cannot find any in which the augite or magnetite is crystallised in feathery skeletons. In the case of only one single natural rock from a dyke near Beaumaris have I found the triclinic felspar arranged in just the same fan-shaped, brush-like groups, as those in similar rocks artificially melted and slowly cooled. The large solid crystals in specimens from other localities sometimes show that towards the end of their growth small flat prisms have developed on their surface, analogous to those first deposited in the case of the artificial products. In slags composed almost exclusively of what I believe is Humboldtilite, the crystals are indeed uniformly as simple and solid as those in natural rocks, but the examination of different blowpipe beads shows that no fair comparison can be made between altogether different substances. We must compare together the minerals common to the natural and the artificial products, and we then see that, on the whole, the two classes are only just distinctly connected by certain exceptional crystals and by structural characters which, as it were, overlap enough to show that there is a passage from one type to the other. In the artificial products are a few small solid crystals of both augite and a triclinic felspar, which closely correspond to the exceptionally small crystals in the natural rocks, but the development of the great mass of the crystals is in a different direction in the two cases. In the artificial products it is in the direction of complex skeletons, which are not seen in the natural rock, but in the natural rock it is in the direction of large simple solid crystals, which are not met with in the artificial products. There is a far closer analogy in the case of partially vitreous rocks, which, independent of the true glassy base common to them and the artificial products, often contain analogous crystalline needles. Even then, however, we see that in the artificial products the crystals tend to develop into complex skeletons, but in the natural rocks into simple solid crystals.

It must not be supposed that these facts in any way lead me to think that thoroughly crystalline modern and ancient volcanic rocks were never truly fused. The simple, large, and characteristic crystals of such minerals as augite, felspar, leucite, and olivine often contain so many thoroughly well-marked glass inclosures as to prove most conclusively that when the crystals were formed they were surrounded by, and deposited from, a melted glassy base, which was caught up by them whilst it was still melted. This included glass has often remained unchanged, even when the main mass became completely crystalline, or has been greatly altered by the subsequent action of water. I contend that these glass inclosures prove that many of our British erupted rocks were of as truly igneous origin as any lava flowing from a modern volcano. The difference between the structure of such natural rocks and that of artificial slags must not in my opinion be attributed to the absence of true igneous fusion, but to some difference in the surrounding conditions, which was sufficient to greatly modify the final result when the fused mass became crystalline on cooling. The observed facts are clear enough, and several plausible explanations might easily be suggested, but I do not feel at all convinced that any single one would be correct. That which first suggests itself is a much slower cooling of the natural rocks than is possible in the case of the artificial products, and I must confess that this explanation seems so plausible that I should not hesitate to adopt it if certain facts could be accounted for in a satisfactory manner. Nothing could be more simple than to suppose that skeleton crystals are formed when deposition takes place in a hurried manner, and they so overgrow the supply that they develop themselves along certain lines of growth before there has been time to solidly build up what has beeen roughly sketched in outline. I cannot but think that this must be a true, and to some extent active, cause, even if it be inadequate to explain all the facts. What makes me hesitate to adopt it by itself is the structure of some doleritic rocks when in close contact with the strata amongst which they have been erupted. In all my specimens the effects of much more rapid cooling are perfectly well marked. The base of the rock when in close contact is sometimes so extremely fine-grained that it is scarcely crystallised, and is certainly far less crystalline and finer-grained than the artificial products to which I have called attention, and yet there is no passage towards those structures which are most characteristic of slags, or at least no such passage as I should have expected if these structures depended exclusively on more rapid cooling. We might well ascribe something to the effect of mass, but one of my specimens of basalt melted and slowly cooled in a small crucible is quite as crystalline as another specimen taken from a far larger mass, though I must confess that what difference there is in this latter is in the direction of the structure characteristic of natural rocks. The presence or absence of water appears to me a very probable explanation of some differences. When there is evidence of its presence in a liquid state during the consolidation of the rock, we can scarcely hesitate to conclude that it must have had some active influence; but in the case of true volcanic rocks the presence of liquid water is scarcely probable. That much water is present in some form or other is clearly proved by the great amount of steam given off from erupted lavas. I can scarcely believe that it exists in a liquid state except at great depths, but it may possibly be present in a combined form or as a dissolved vapour under much less pressure, and the question is, whether this water may not have considerable influence on the growth of crystals formed prior to eruption, before it was given off as steam. I do not know one single fact which can be looked upon as fairly opposed to this supposition, and it is even to some extent supported by experiment. M. Daubrée informs me that the crystals of augite formed by him at a high temperature by the action of water have the solid character of those in volcanic rocks, and not the skeleton structure of those met with in slags. The conditions under which they were formed were however not sufficiently like those probably present during the formation of erupted lavas to justify our looking upon the explanation I have suggested as anything more than sufficiently plausible, in the absence of more complete experimental proofs.

Granitic Rocks.—I now proceed to consider rocks of another extreme type, which for distinction we may call the granitic. On the whole they have little or nothing in common with slags or with artificial products similar to slags, being composed exclusively of solid crystals, analogous in character only to slag-crystals of very different mineral nature. As an illustration I would refer to the structure of the products formed by fusing and slowly cooling upwards of a ton of the syenite of Grooby, near Leicester. Different parts of the resulting mass differ very materially, but still there is an intimate relation between them, and a gradual passage from one to the other. The most characteristic feature of those parts which are completely crystalline is the presence of beautiful feathery skeleton crystals of magnetite, and of long flat prisms of a triclinic felspar, ending in complex, fan-shaped brushes. There are no solid crystals of felspar, hornblende, and quartz, of which the natural rock is mainly composed, to the entire exclusion of any resembling those in the melted rock. As looked upon from the point of view taken in this address, the natural and artificial products have no structural character in common, so that I think we must look for other conditions than pure igneous fusion to explain the greatly modified results. We have not to look far for evidence of a well-marked difference in surrounding circumstances. The quartz in the natural rock contains vast numbers of fluid cavities, thus proving that water was present, either in the liquid state or as a vapour so highly compressed that it afterwards condensed into an almost equal bulk of liquid. In some specimens of granite there is indeed clear proof that the water was present as a liquid, supersaturated with alkaline chlorides, like that inclosed in the cavities of some minerals met with in blocks ejected from Vesuvius, which also have to some extent what may be called a granitic structure.

In the case of one very exceptional and interesting granite, there is apparently good proof that the felspar crystallised out at a temperature above the critical point of water—that is to say, at a temperature higher than that at which water can exist as a liquid under any pressure—and it caught up highly compressed steam, comparatively, if not entirely, free from soluble salts; whereas the quartz crystallised when the temperature was so far lowered as to be below the critical point, and the water had passed into a liquid, supersaturated with alkaline chlorides, which have crystallised out as small cubes in the fluid-cavities, just as in the case of minerals in some of the blocks ejected from Vesuvius.

Confining our attention, then, to extreme cases, we thus see that rocks of the granitic type differ in a most characteristic manner from the products of artificial igneous fusion, both in the structure of the crystals and in containing liquid water inclosed at the time of their formation. The question then arises

whether these differences were due to the presence of the liquid water, or whether its presence and the characteristic structure were not both the effects of the great pressure of superincumbent rocks. I do not see how this can be decided in a perfectly satisfactory manner, but must confess that I am inclined to believe that, whilst great pressure was necessarily the reason why the water did not escape as vapour, the presence of liquid water during final consolidation must have had a very considerable influence in modifying the structure of the rock, and had a great share in developing what we may call the granitic type.

It would be very instructive to follow out the gradual passage from one extreme type to another far more completely than is possible on the present occasion. The most interesting examples of rocks intermediate between the granitic and volcanic types that I have been able to examine in adequate detail are the various Cornish elvans and other quartz felsites, which furnish all but a complete passage from pitch-stone to granite. Some specimens prove that quartz may crystallise out from and inclose a perfectly glassy base, without a trace of liquid water, and at the same time other specimens prove equally well that, as we approach the granitic type, *the quartz was not deposited from* a glassy solvent, but inclosed more or less water. In the few intermediate cases there appears to be evidence of the conjoint presence of uncombined water and melted stony matter. On the whole, if we take into consideration only the external form of the larger crystals, rocks of the granitic type are very much as though the crystals met with in truly volcanic rocks had been strained out from the glassy or fine-grained base, and the intermediate spaces filled with quartz. The internal structure of the crystals is however very different, the cavities in one class containing glass, and in the other water. This most essential and characteristic difference proves that rocks of the true granitic type cannot have been formed simply by the more complete crystallisation of the general base of the rock. If the crystals in granite were analogous to those developed in volcanic rocks, and the only essential difference were that the residue crystallised out more slowly and completely, so as to give rise to a more coarsely crystallised base, the crystals first formed ought not, as I think, to differ so essentially as that in one case they should inclose only glass, and in the other only water. Taking all into consideration, we can therefore scarcely suppose that the crystals in granitic rocks were deposited from a truly-melted dry glassy solvent, like those in volcanic rocks or in slags.

General Results.—I have, I trust, now said enough to show that the objects here described may be conveniently separated into three well-marked groups, viz. artificial slags, volcanic rocks, and granitic rocks. My own specimens all show perfectly well-marked and characteristic structures, though they are connected in some cases by intermediate varieties. Possibly such connecting links might be more pronounced in other specimens that have not come under my notice. I must, however, base my conclusions on what I have been able to study in an adequate manner, by examining my own preparations, and leave it for others to correct any error into which I may have been led from lack of more numerous specimens. In any case the facts seem abundantly sufficient to prove that there must be some active cause for such a common, if not general difference in the structural character of these three different types. The supposition is so simple and attractive that I feel very much tempted to suggest that this difference is due to the presence or absence of water as a gas or as a liquid. In the case of slags it is *not* present in any form. Considering how large an amount of steam is given off from erupted lavas, and that, as a rule, no fluid-cavities occur in the constituent minerals, it appears to me very plausible to suppose that those structures which are specially characteristic of volcanic rocks are in great measure, if not entirely, due to the presence of *associated* or *dissolved vapour*. The fluid-cavities prove that water was sometimes, if not always, present as a *liquid* during the consolidation of granitic rocks, and we can scarcely hesitate to conclude that it must have had very considerable influence on the rock during consolidation. Still, though these three extreme types appear to be thus characterised by the absence of water or by its presence in a state of vapour or liquid, I think we are scarcely in a position to say that this difference in the conditions is more than a plausible explanation of the differences in their structure. At the same time I do not know any facts that are opposed to this conclusion, and we should perhaps not greatly err in thus correlating the structures, even though the water was not the essential and active cause of the differences.

Confining our attention to the more important crystalline constituents which are common to the different types, we may say that the chief structural characters of the crystals are as follows:—

a. Skeleton crystals.
b. Fan-shaped groups.
c. Glass cavities.
d. Simple crystals.
e. Fluid cavities.

These different structural characters are found combined in different ways in the different natural and artificial products, and for simplicity I will refer to them by means of the affixed letters.

The type of the artificial products of fusion may generally be expressed by $a + b$ or $b + c$; that is to say, it is characterised by skeleton crystals and fan-shaped groups, or by fan-shaped groups and glass-cavities. In like manner, the volcanic type may be expressed occasionally by $b + c$, but generally by $c + d$, and the granitic by $d + e$. These relations will be more apparent if given in the form of a table as follows:—

Slag type	$\begin{cases} a + b \\ \quad b + c \end{cases}$
Volcanic type	$\begin{cases} b + c \\ \quad c + d \end{cases}$
Granitic type	$d + e$

Hence it will be seen that there is a gradual passage from one type to the other by the disappearance of one character and the appearance of another, certain characters in the meanwhile remaining common, so that there is no sudden break, but an overlapping of structural characteristics. It is, I think, satisfactory to find that, when erupted rocks are examined from such a new and independent point of view, the general conclusions to which I have been led are so completely in accord with those arrived at by other methods of study.

Conclusion.—And now I feel that it is time to conclude. I have necessarily been compelled to give only a general account of the subject, and perhaps for want of adequate description many facts may appear more complex than they really are. Some are indeed of anything but simple character, and their full explanation is perhaps beyond our present power. The greater part are, however, much more simple and easy to observe than to describe; and, even if I have failed to make everything as plain as I could wish, I hope that I have succeeded in making the principal points sufficiently clear to show that the structure of slags and analogous artificial products throws much light on the structure and origin of the various groups of erupted rocks. I feel that very much still remains to be learned, and, as I think, could be learned by the further extension of this method of inquiry. What strikes me most is the great necessity for the more complete appreciation of experimental methods of research; but to carry out the experiments necessary to clear up the essential difficulties of the subject would, I fear, be a most difficult undertaking. In the meantime all that we can do is to compare the structure of known artificial products with that of natural rocks, and to draw the best conclusions we can from the facts, as viewed in the light of our present knowledge of chemistry and physics. My own impression is that there is still much to be learned respecting the exact conditions under which some of our commonest rocks were formed.

SECTION D

BIOLOGY

Opening Address by Dr. A. C. L. G. Günther, M.A., Ph.D., F.R.S., President of the Section

Sixteen years ago, at the meeting of the British Association at Bath, the duty which I am endeavouring to discharge to-day was intrusted to my predecessor and old friend, the late Dr. John Edward Gray. In the address which he then delivered before this section he spoke on "Museums, their Use and Improvement;" and he, who had devoted a whole lifetime to the formation and management of one of the greatest zoological collections in the world, was well qualified to give an opinion and advice on this subject. Indeed, when I read now what he then insisted on as a necessary change in the system of museums, I feel compelled to pay a passing tribute to his memory.

Zoology, geology, botany were to him not distinct and independent studies; the views advanced by Lamarck, by Treviranus,

viz., that our knowledge of these sciences would remain fragmentary and one-sided as long as they were not studied in their mutual relations, found in him one of the earliest advocates in this country. Against all opposition he tried to unite the zoological and palæontological collections in the British Museum, giving up this attempt only after having convinced himself of the impracticability of the scheme; and he readily joined the band of men who demanded that a museum should be not merely a repository for the benefit of the professed student and specialist, but serve in an equal measure for the recreation of the mass of the people and for their instruction in the principles of biology. This was the spirit in which he worked; and in the last years of his life he had the satisfaction of being able to say that there was no other collection in existence more accessible and more extensively used than the one under his charge.

I am encouraged to return to-day to the same subject because I have daily the opportunity of observing that the public more and more comprehend the use of museums, and that they appreciate any real improvement, however slight. Paragraphs, leaders, articles published in the public journals and periodicals, references made in speeches or addresses, questions put in the Houses of Parliament whenever an opportunity offers—all testify that the progress of museums is watched with interest. Not long ago a Royal Commission entered deeply and minutely into the subject, and elicited a mass of evidence and information invaluable in itself, though you may differ from some of the conclusions and views expressed in their final Report. Biological science has made rapid strides: not only do we begin to understand better the relations of the varieties of living forms to each other, but the number of the varieties themselves that have been made known has also been increased beyond all expectation, and the old repositories have everywhere been found too narrow to house the discoveries of the last forty years. Therefore you find that the United States, Austria, Prussia and Saxony, Denmark and Holland, France and Great Britain, have erected, or are building anew, their national museums, not to mention the numerous smaller museums, which are more or less exclusively devoted to some branch of biological science.

The purposes for which museums are formed are threefold:—(1) To diffuse instruction among, and offer rational amusement to, the mass of the people; (2) to aid in the elementary study of biology; and (3) to supply the professed student of biology or the specialist with as complete materials for his scientific researches as can be obtained, and to preserve for future generations the materials on which those researches have been based.

Although every museum has, as it were, a physiognomy of its own, differing from the others in the degree in which it fulfils one, or two, or all three of those objects, we may divide museums into three classes, viz.:—

(1) National, (2) Provincial, and (3) strictly Educational museums—a mode of division which may give to those of this assembly who are not biologists an idea of what we mean by the term "species." The three kinds pass into each other, and there may be hybrids between them.

The museum of the third class, the strictly *Educational institution*, we find established chiefly in connection with universities, colleges, medical and science schools. Its principal object is to supply the materials for teaching and studying the elements and general outlines of biology; it supplements, and is the most necessary help for, oral and practical instruction, which always ought to be combined with this kind of museum. The conservation of objects is subservient to their immediate utility and unrestricted accessibility to the student. The collection is best limited to a selection of representatives of the various groups or "types," arranged in strictly systematic order, and associated with preparations of such parts of their organisation as are most characteristic of the group. Collections of this kind I have seen arranged with the greatest ingenuity, furnishing the student with a series of demonstrations which correspond to the plan followed in some elementary text-book. This, however, is not sufficient for practical instruction; besides the exhibited permanent series, a stock of well-preserved specimens should be kept for the express purpose of allowing the student to practise dissection and the method of independent examination. And in this latter I am inclined to include the method of determining to what order, family, genus, or species any given object should be referred. By such practice alone can the student learn to understand the relative value of taxonomic characters and acquire the elementary knowledge indispensable for him in the future.

Finally, in the educational museum should be formed a series of all the animals and plants, which are of economic value or otherwise of importance to man.

The proposal to unite living and extinct forms in one series, which has been urged by eminent men with such excellent reasons, might be tried in the educational museum with great advantage to the student, as the principal objections that are brought forward against this plan being carried out in larger collections, do not apply here.

A museum which offers to the teacher and student the materials mentioned, fulfils its object; its formation does not require either a long time or heavy expense; but the majority of these institutions outgrow in time their original limits in one or the other direction; and if such additions do not interfere with the general arrangement of the museum, they neither destroy its character, nor do they add to its value as a strictly educational institution.

The principal aim of a *Provincial* Museum ought, in my opinion, to be popular instruction. I do not mean that it should be merely a place for mild amusement and recreation, but that it should rank equal with all similar institutions destined to spread knowledge and cultivate taste among the people. To attain this aim it should contain an arranged series of well-preserved specimens representing as many of the remarkable types of living forms as are obtainable; a series of useful as well as noxious plants and animals; of economic products derived from the animal and vegetable kingdoms; and last (but not least), a complete and accurately-named series of the flora and fauna of the neighbourhood. The majority of provincial museums with which I am acquainted are far from coming up to this ideal. One of the first principles by which the curator of such a museum should be guided is to admit into his collection no specimen unless it be well mounted and a fair representation of its species. He has not the excuse of his colleague in charge of a large museum, who has to retain those monsters which are literally his *bêtes-noires*, viz., specimens to which a history is attached, and the removal of which would sooner or later be resented by some of his fellow-labourers. The only too frequent presence of such badly-mounted specimens in provincial museums is not always the fault of the curator. The slender means with which he is provided are generally insufficient to encourage taxidermists to bestow the necessary amount of skill and time on their work. Besides, taxidermy is an art which depends as much on natural gift as drawing or modelling, and as long as we are obliged to be satisfied with receiving into our collections mediocre specimens, mediocre stuffers will take up taxidermy as a trade without there being one who is naturally qualified for it.

The direct benefit of a complete collection of the flora and fauna of the district in which the provincial museum is situated, is obvious and cannot be exaggerated. The pursuit of collecting and studying natural history objects gives to the persons who are inclined to devote their leisure hours to it, a beneficial training for whatever their real calling in life may be: they acquire a sense of order and method; they develop their gift of observation; they are stimulated to healthy exercise. Nothing encourages them in this pursuit more than a well-named and easily accessible collection in their own native town, upon which they can fall back as a pattern and an aid for their own. This local collection ought to be always arranged and named according to the plan and nomenclature adopted in one of those numerous monographs of the British fauna and flora in which this country excels; and I consider its formation in every provincial museum to be of higher importance than a collection of foreign objects.

The majority of provincial museums contain not only biological collections, but, very properly, also collections of art and literature; it is no part of my task to speak of the latter, but before I proceed to the next part of my address, I must say that nothing could more strikingly prove the growing desire of the people for instruction than the erection of the numerous free libraries and museums now spread over the country. The more, the healthier their rivalry, the safer their growth will be, especially if they avoid depending on aid from the State or placing themselves in the hands of a responsible minister—if they remain what they are—municipal institutions—the children and pride of their own province.

However great, however large a country or a nation may be, it can have in reality only one *National* Museum, truly deserving of the name. Yours is the British Museum; those of Scotland and Ireland can never reach the same degree of completeness, though there is no one who wishes more heartily than I do that they may approach it as closely as conditions permit. The

most prominent events in the recent history of the British Museum (to which I must confine the remainder of my remarks) are well known to the majority of those present;—that the question either of enlarging the present building at Bloomsbury, or of erecting another at South Kensington for the collections of natural history, was fully discussed for years in its various aspects; that, finally, a Select Committee of the House of Commons reported in favour of the expediency of the former plan; that the Standing Committee of the Trustees, than whom there is no one better qualified to give an opinion, took the same view; and that, nevertheless, the Government of the time decided upon severing the collections and locating the natural history in a separate building as the more economical plan.

The building was finished this year at a cost of 400,000*l.*, exclusive of the amount paid for the ground on which it is erected. It is built in the Romanesque or round-arched Gothic style, terra-cotta being almost exclusively employed in its construction. It consists of a basement, ground-floor, and two storeys, and is divided into a central portion, and a right and left wing. Its principal (southern) façade is 675 feet long. As you enter the portal, you come into a cathedral-like hall called the "Index Museum," 120 feet long, 97 feet wide, and 68 feet high; behind this there is a large side-lighted room for the British fauna. On each side of the hall there is a side-lighted gallery each 278 feet long by 50 feet in width; seven other galleries of various widths, and therefore adapted for various exhibitions, join at right angles the long gallery of the ground floor. The first and second storeys are occupied by galleries similar to the main galleries of the ground-floor.

The collections are distributed in this building thus:—The western wing is occupied by Zoology, the eastern by the three other departments, viz., the ground-floor by Geology, the first-floor gallery by Mineralogy, and the second-floor gallery by Botany. The central portion is, as mentioned above, divided into the room for British Zoology and into the "Index Museum," that is "an apartment devoted to specimens selected to show the type-characters of the principal groups of organised beings." The basement consists of a number of spacious, well-lit rooms, well adapted for carrying on the different kinds of work in connection with such large collections.

There is no doubt that the building fulfils the principal condition for which it was erected, viz., space for the collections. The zoological collections gain more than twice as much space as they had in the old building, the geological and minerological about thrice, and the botanical more four times. This increase of space will enable the keeper of the last-named department to bring the collections correlated with each other into close proximity, and to prepare a much greater number of objects for exhibition than was possible hitherto. The mineralogical department, already so admirably arranged in the old building, has now been supplied with the space requisite for a collection of rocks, with a laboratory and goniometrical room. Geology is now in a position to exhibit a great part of the invertebrata, which hitherto had to be deposited in private studies, besides devoting one or two of the new galleries to a stratigraphical series. On the zoological side we have been great gainers (not with regard to the proportion of space), but inasmuch as we were more impeded by the crowded state of our collections than any of the other departments. We are enabled to avoid the exhibition of heterogeneous objects in the same room or gallery; mammals, birds, reptiles, fishes, mollusks, insects, echinoderms, corals, and sponges have each a smaller or larger gallery to themselves. With the exception of the specimens preserved in spirits, the study-series can be located in contiguity with, or at least close vicinity to, the exhibition-series. There is ample and convenient accommodation for the students, who may work in a spacious room centrally situated, and arranged for their exclusive use at four other different localities immediately adjoining the several branches of the collection.

I believe that some of the members of the British Association will feel somewhat disappointed that the zoological and botanical collections on the one hand, and the palæontological on the other, continue to be kept distinct. Who will, who can doubt that the two branches of biological science would be immensely benefited by being studied in their natural mutual relations? and that palæontology more especially would have made surer progress if its study had been conducted with more direct application to the series of living forms? But to study the series of extinct and living forms in their natural connection, is one thing, and to incorporate in a museum the collection of fossils with that of recent forms, is another. The latter proposal, so excellent in theory, would offer in its practical execution so many and insuperable difficulties, that we may well hesitate before we recommend the experiment to be tried in so large a collection as the British Museum. I have mentioned above that in a small collection such an arrangement may be feasible to a certain degree; but in a large collection you cannot place skins, bones, spirit preparations, and stones in the same room, or perhaps in the same case, exposing them to the same conditions of light and temperature, without injuring either the one or the other. Each kind of those objects requires for its preservation special considerations and special manipulations; and by representing them in each of the several departments you would have to double your staff of skilled manipulators with their apparatus, which means multiplying your expenses. Departmental administration generally, and especially the system of acquisition by purchase or exchange, would become extremely complicated, and could not be carried on without a considerably greater expenditure in time and money. Thus, even if the old departmental division were abandoned for one corresponding to the principal classes of the animal kingdom, each of the new departments would still continue to keep, for considerations of conservation, those different kinds of objects, at least locally, separate. The necessity of this has been so much felt in the British Museum, that the Trustees resolved to store the spirit specimens at South Kensington, in a building specially adapted for the purpose, and separated from the main building, as the accumulation of many thousand gallons of spirits is a source of danger which not many years ago threatened the destruction of a portion of the present building in Bloomsbury.

I could never see that by the juxtaposition of extinct and living animals the student would obtain particular facilities for study, or that the general public would derive greater benefit than they may obtain, if so inclined, from one of the numerous popular books. They would not be much the wiser if the *Archæopteryx* were placed in a passage leading from the reptile- to the bird-gallery. And it certainly cannot be said that the separation of living and extinct organisms, so universally adopted in the old museums, has been a hindrance to the progress of our knowledge of the development of the organic world; this knowledge originated and advanced in spite of museums' arrangements. What lies at the bottom of the desire for such a change amounts, in reality, to this, that museums should be the practical exponents of the principle that zoologists and botanists should not be satisfied with the study of the recent fauna and flora, and that palæontologists should not begin their studies or carry on their researches without due and full reference to living forms. To this principle every biologist will most heartily subscribe; but the local separation of the various collections in the British Museum will not offer any obstacles whatever to its being carried out. The student can take the specimens, if not too bulky, from one department to the other; he may examine them in the gallery without interference on the part of the public; or he may have all brought to a private study, and, in fact, be in the same position with regard to the use of the collections as those who have charge of them. A plan which has been already initiated in the old building will probably be further developed in the new, viz., to distribute in the palæontological series such examples of important living types as will aid the visitor in comprehending the nature and affinities of the creatures, of which he sees only the fragmentary remains.

With regard to the further arrangement of the collections in the new building, it has been long understood that the exhibition of all the species, or even the majority of them, is a mistake, and that, therefore, two series of specimens should be formed, viz.:—one for the purposes of advanced scientific study—the study-series; and the other comprising specimens illustrative of the leading points both of popular and scientific interest; this latter—the exhibition series—being intended to supply the requirements of the beginner in the study of natural history and of the public. As the zoological collections are better adapted for exhibition than the others, the following remarks refer principally to them. The bulk of our present exhibition-series is the growth of many years; and to convert it into one which fulfils its proper purpose is a gradual and slow process, nor can it be expected to reveal its character until it has been removed into the new locality. The exhibition will be probably found more liberal than may be deemed necessary by some of my fellow-labourers; but if a visitor should, on leaving the galleries, "take nothing with him but sore feet, a bad

headache, and a general idea that the animal kingdom is a mighty maze without plan," I should be inclined to believe that this state of bodily and mental prostration is the visitor's, and not the curator's fault. The very fact that the exhibition series is intended for a great variety of people, renders it necessary to make a liberal selection of specimens; and I simply follow the principle of placing in it all those objects which, in my opinion, the public can understand and appreciate, and which, therefore, must contribute towards instruction. The public would receive but an inadequate return for keeping up a national museum if they were shown, for instance, a dozen so-called "types" of the family of parrots or humming-birds; they require a good many more to see what nature can produce in splendour and variation of colour, in grotesqueness of form; or to learn that whilst one of these groups of birds is spread over all the countries of the tropical zone, the other is limited to a portion of a single continent. To render such an exhibition thoroughly useful, two additional helps are required, viz., a complete system of explanatory labels, and a popularly-written and well-illustrated handbook, which should not only serve as a guide to the more important and interesting specimens, but give a systematic outline of the all-wise plan which we endeavour to trace in God's creation.

There is one part of the museum which I intend to treat in a different manner from the rest; and that is the collection of British animals. For the same reasons for which I have in a former part of this address insisted on district faunas being fully represented in provincial museums, I consider a complete exhibition of the British fauna to be one of the most important objects of the National Museum. Its formation is, strange as it may appear to many of you, still a desideratum, and a task which will occupy many years. It will not be easy (especially when you are in danger of infringing an Act of Parliament) to form a complete series of British birds, showing their change of plumage, their young, their eggs, their mode of nidification; it is a long work to collect the larvæ and chrysalides of insects, and to mount the caterpillars with their food-plants; and we shall require the co-operation of many a member of the British Association when we extend the collection to the marine animals and their metamorphoses. But all the trouble, time, and labour spent will be amply repaid by the direct benefits which all classes will derive from such a complete British collection.

My time is becoming short, and yet I find that I am far from having completed the task I had set to myself. Therefore let me briefly refer only to a few points which, of late, have much agitated those who feel a direct or indirect interest in the progress of the National Museum. In the first place, we must feel deeply concerned in everything relating to the conservation of the collections. If the objects could speak to you, as they do to those familiar with their history, many of them would tell you of the long hours of patient inquiry spent upon them; many might point with pride at the long pages written about them—alas! not always with the even temper which renders the study of natural science a delight and a blessing; others would remind you of having been objects of your wonder when you saw them depicted in scientific books, or in some household work; whilst not a few could tell you pitiful tales of the enthusiastic collector who, braving the dangers of a foreign climate, sacrificed health or life to his favourite pursuit. Collections thus obtained, thus cherished, representing the labours of thousands of men, and intended to instruct hundreds of thousands, are worth preserving, displaying, and cultivating. No cost has been spared in housing them; let no cost be spared in providing proper fittings to receive them, a sufficient staff to look after them, and the necessary books to study them.

What we chiefly require in a well-constructed exhibition-case is that it should be as perfectly dust-proof as possible, that it should lock well and easily, and yet that it should be of a light structure. Every one who has gone through a gallery of our old-fashioned museums must have noticed how much those broad longitudinal and transverse bars of the wooden frame of the front of a case interfere with the inspection of the objects behind them, hiding a head here, a tail there, or cutting an animal into two more or less unequal portions. Ill-constructed cases have brought zoological collections as much into bad repute as bad stuffers; and if it be thought that a pound could be saved in the construction of a case, that pound will probably entail a permanent expense of a pound a year. Now all the requisites of a good exhibition-case can be obtained by using metal wherever it can be substituted for wood; and although its use is more expensive than that of wood, you will join with me in the hope that no mistaken desire of economy will prevail now, as the time has arrived to furnish our priceless collections with adequate fittings.

Probably all of those present are aware that the formation of a natural history library has been urged almost from the very first day on which the removal of the Natural History Collections to South Kensington was proposed. But the cost and extent of such a library have been very variously estimated. And I am sorry to say that it is, I believe, owing to expressions of opinion on the part of those who ought to know better, that the cost of this library was considerably underrated when the removal to South Kensington was determined upon. We cannot blame the Government that they hesitated for years before they acceded to the pressing representations of the Trustees of the British Museum to begin with its formation, when they were told by naturalists that the cost of such a library would be something between 10,000*l.* and 20,000*l.* I could hardly believe my eyes when I read, only a few weeks ago, in the leader of a weekly periodical specially devoted to science, "that had the Trustees put aside 1,000*l.* a year for this purpose, when it was first determined to remove the Natural History Collections ten years ago, there would have been by this time in existence a library fully adequate to the purpose." The writer must have either a very poor idea of the objects and work of a national museum, or an imperfect knowledge of the extent of the literature of natural history. 10,000*l.* might suffice to purchase a good ornithological library, and 1,000*l.* would purchase the annual additions to all the various branches of natural history; but the former sum would be much too small if the purchase of those works only were intended which are required for the technical work of naming animals, plants, fossils, and minerals. A better calculation was made by the Select Committee of the House of Commons on the British Museum in 1860, who stated that the formation of a natural history library would "cost about 30,000*l.* at the present time" (1860). Considering that twenty years have elapsed since, and that this part of the literature has shown year by year a steady increase, we must put our estimate considerably higher than the writer of that article.

With the aid of some of my friends who know, from their daily occupation, the market value of natural history works, I made a calculation some years ago, and we came to the conclusion that a complete natural history library will cost 70,000*l.*, and, unpalatable as this statement may be to those who have advocated the removal of the natural history collections, and therefore must be held responsible for this concomitant expense, it will be found to be true. It will be satisfactory to you to learn that the Government have at last sanctioned the expenditure of half that amount.

Now, in my opinion, such a library formed in connection with the National Museum should not be reserved for the use of the officials, but I would recommend that it should be accessible to the general class of students in the same manner as any other part of the collections. It is for this reason that I wish to see it rendered as perfect as possible with respect to the older publications (many of which are getting scarcer year by year) as well as to the most recent. Whether or not a similarly perfect collection of natural history books exists in some other place in London, is another question with which I am not concerned. It is evident that a general national library ought to contain a perfect set of books on natural history, irrespective of other claims; but to have natural history collections in one place, and the books relating to them in another miles away, will produce as much inconvenience as is experienced by the person who puts the powder into the one barrel of his gun and the shot into the other.

If the British Museum (for the collections will remain united under this old time-honoured name, though locally separated) continues to receive that support from the Government to which it is justly entitled, I have no doubt that it will not only fulfil all the aims of a national collection, but that it will be also able to give to the kindred provincial institutions the aid which has recently been claimed on their behalf. Under an Act of Parliament which was passed in the previous session, and which empowers the Trustees to part with duplicate specimens, several of those museums have already received collections of zoological objects. But I consider it my duty to caution those who are in charge of those museums to be careful as to the manner in which they avail themselves of this opportunity. Well-preserved duplicates of the rarer and more valuable vertebrate animals are very scarce in the British Museum; the funds for purchase being much too small to permit of the acquisition of duplicates. What

we possess of this kind of duplicates are generally deteriorated specimens, and therefore ought not to be received by provincial museums. On the other hand, our invertebrate series, especially of mollusks and insects, will always offer a certain number of well-preserved duplicate specimens, and a sufficient inducement for provincial museums to select their desiderata.

It has been suggested that as the British Museum has correspondents and collectors in almost every part of the globe, and has therefore greater facilities for obtaining specimens than any other institution, it should systematically acquire duplicates, and form a central repository, from which provincial museums could draw their supplies. If the necessary funds to carry out this scheme were granted, I cannot see any objection to it on the part of the British Museum which, on the contrary, would probably derive some benefit. But there is one, and in my opinion a very serious, objection, viz., that this scheme would open the door to the employment of curators of inferior qualifications; it would relieve the curator of a provincial museum of an important part of his duty, viz., to study for himself the requirements of his museum, the means of meeting them, and to become well acquainted with the objects themselves. A curator who has to be satisfied with the mechanical work of displaying and preserving objects acquired, prepared, and named for him by others takes less interest in the progress of his museum than he whose duty it would be to *form* a collection; he is not the person in whose charge the museum will flourish.

In speaking of the claims of Provincial Museums on the National Museum, the kindred Colonial institutions should not be forgotten. We owe to them much of our knowledge of the natural history of the Colonies; they are the repositories of the collections of the temporary and permanent surveys which have been instituted in connection with them; and they have concentrated and preserved the results of manifold individual efforts, which otherwise most likely would have been lost to science. The British Museum has derived great benefit from the friendly relations which we have kept up with them; and, therefore, they are deserving of all the aid which we can possibly give them, and which may lessen the peculiar difficulties under which they labour in consequence of their distance from Europe.

I am painfully aware that, in the remarks which I have had the honour of making before you, I have tried the patience of some, and not satisfied the expectations of others. But so much I may claim: that the views which I have expressed before you as my own are the results of many years' experience, and, therefore, should be worthy of your consideration; and that I am guided by no other desire than that of seeing the museums in this country taking their proper place in regard to biology, and as one of the most important aids in the instruction of the people.

NOTES

In mediæval ages Rheims was a seat of learning, and in 1547 the Cardinal of Lorraine established there a university, which flourished until it was suppressed at the French Revolution. But although the present Republican Government has instituted in this ancient city a school of medicine, the liberal arts are little cultivated by the inhabitants, who are mostly engaged in commercial and manufacturing occupations. Rheims possesses the greatest wine trade in the world and the richest woollen manufactories in France. So, although the French Association has met with a very handsome reception, the local budget of scientific contributions was very meagre indeed, except in the sections of anthropology and archæology, which were a local success. M. Cotteau gave an address describing the geological character of the Rheims district, and illustrated by the local exhibition which had been arranged in one of the halls of the Lycée by M. Perron. M. Lemoine, Professor in the School of Medicine of Rheims, exhibited a rich collection of objects of palæontological interest which had been formed by him from the surrounding district. This was exceptionally rich in objects of the cretaceous period, mostly of polished stone, and wonderfully preserved in the caves so numerous in the cretaceous formation, and which are now utilised to protect against variations of temperature an immense quantity of bottled wine destined to be sent to all parts of the world. An excursion, specially interesting for archæologists, was organised to Epernay, where M. Baye, a rich proprietor, had collected in his château a number of curiosities belonging to the Carlovingian periods. Two other special excursions were organised, the first to the ruins of old Courcy Castle and St. Gobain, the largest glass foundry in France, where a large lump was cast in presence of the visitors, and the second to St. Menehould, which was supposed in former times to be the key of French independence. The most attractive excursion was undoubtedly to the caves where champagne is manufactured by the old process, which was scientifically described by M. François, a chemist of Châlons-sur-Marne. A demonstration of the principles of the operation was given in the caves of Pommery, where Madame Pommery kindly permitted the visitors to make a practical test of the quality of her celebrated produce. Synoptical tables had been prepared exhibiting the progress of the manufacture. The superiority of the champagne manufactured in Rheims and vicinity is attributed not only to the long experience of the workmen and the excellence of the receipts used, but to the perfect equality of temperature maintained in the old galleries where it is stored. Some of these are several acres in area, and are quite full of bottles. After the final meeting a general excursion was made to the celebrated grotto of Han in Belgium. The two lectures by M. Perier on "Transformism," and M. Garel on "Radiant Matter," were delivered, at the solicitation of the local committee for their information; the lecturers confined themselves to the clear enunciation of known facts, and to experiments already well known to the scientific world. M. Javal gave a public lecture on the Hygiene of the Eye, and M. Richet on the Symptoms of Somnambulism. About 500 members were present at the meeting this year, exclusive of local members. Among foreign visitors were Professors Sylvester and Hennessy. At the final session M. Janssen was elected president for 1882, when the meeting will be held at La Rochelle, and M. Emile Trelat will be general secretary; they will act as vice-president and vice-secretary respectively for the session of 1881, which will be held at Algiers in the first week after Easter. The president of the Algiers session will be M. Chauveau, Professor at the Veterinary School of Lyons, and the secretary will be M. Maunoir, general secretary of the French Geographical Society. A very large attendance is anticipated, as a diminution of 50 per cent. on the fares is expected, and the visit will take place at an exceptionally advantageous season. A general committee has been formed, having at its head M. Tomel, senator of Oran, and director of the newly-created School of Sciences. The Governor-General will be honorary president, and M. MacCarthy, president of the Algiers Society of Natural Sciences, has been nominated by the General Committee of Rheims president of the Section of Geography. The Rheims authorities and citizens have done everything within their power to welcome their guests, and the meeting has been on the whole successful.

From an additional Circular sent us from the American Association we see that nearly all the railway lines connected with Boston, the place of meeting, offer great facilities for the conveyance of members. Some of the companies indeed give those attending the meeting free tickets, while the others issue tickets at one-half the usual rates. Is it too much to expect similar advantages from English companies? Has the attempt ever been made?

A very interesting annual meeting of the Entomological Club of the American Association was to be held at Boston on Tuesday. Among other subjects to be brought forward, Mr. A. R. Grote was to speak of generic characters in the Noctuidæ; Mr. E. P. Austin hoped to exhibit some interesting series from his extensive collection of North American Coleoptera; Mr. Wm. Saunders to discuss Insectivorous Birds, their merits and demerits; Rev. H. C. McCook to read a paper on the Honey Ants of the Garden of the Gods, Colorado; Mr. S. H.

Scudder to exhibit interesting fossil insects, and illustrations of New England Butterflies; Dr. J. L. Le Conte to present an essay on Lightning Bugs, and give a list of Coleoptera hatched from a few hickory twigs; and Dr. H. A. Hagen to present papers on the Hessian Fly, on the anatomy of *Productus deceptus*, and on a new worm parasitic on insects.

THE third International Congress of Geography meets at Venice from the 15th to the 22nd of September, 1881, under the patronage of King Humbert. The accompanying exhibition will be opened on September 1, and will not be closed before October 1. The Congress will be divided into seven groups: 1. Mathematical, Geodetic, and Topographical Geography. 2. Hydrography and Maritime Geography. 3. Physical, Meteorological, Geological, Botanical, and Zoological Geography. 4. Historical, Ethnographical, and Philological Geography. 5. Economical, Commercial, and Statistical Geography. 6. Methodology; Geographical Education. 7. Exploration. Further information may be obtained by addressing "Al Comitato ordinatore del 3° Congresso Geografico Internazionale, 26, Via del Collegio Romano, Roma."

THE Sixth Annual Conference of the Cryptogamic Society of Scotland will be held in Glasgow, on September 27–30, and October 1 and 2, when all persons interested in cryptogamic botany are invited to attend. A detailed prospectus of the meetings, excursion, and show may be had on application to the Local Secretaries, on and after September 6. Fellows and others from a distance who purpose attending the Conference are requested to send intimation thereof as soon as possible to the Secretary, to whom also intimation of papers to be read should be sent. Fellows are requested to bring or send specimens of interest in any branch of cryptogamic botany for exhibition at the meeting and show. The Secretary is Dr. F. Buchanan White, Perth, and the Local Secretaries Mr. W. J. Milligan, 180, West Regent Street, and Mr. A. Turner, 122, Hospital Street, Glasgow.

THE annual meeting of the Mineralogical Society of Great Britain will be held at Swansea, in the Unitarian School-room, High Street, on Friday, August 27, at 2.30 p.m. The Council will meet at 2 p.m. All communications intended for this meeting should be addressed to the Secretary, Mr. J. H. Collins, F.G.S., at the Reception Rooms, British Association, Swansea.

WE understand that the long-expected first volume of Prof. Arthur Gamgee's "Text-book of Physiological Chemistry" may be expected to appear in the middle of September. This volume, which will be published by Macmillan and Co., deals with the Chemistry of the Tissues, and is to be succeeded in the space of a few months by a second and concluding volume, treating of the Chemical Processes Associated with the Animal Functions. Dr. Gamgee's work is, we are informed, a more elaborate treatise than has hitherto appeared on this branch of science. It deals with the subject from the point of view of the physiologist and the physician rather than from that of the pure chemist; it is indeed an advanced treatise, dealing with those departments of physiology and pathology which involve a study of chemical facts, and not, as all text-books of physiological chemistry, save those of Lehmann and Kühne, have been, a work treating of one branch of Applied Chemistry. The work is well illustrated; it contains a very full and complete account of the whole literature of each subject treated of, and besides being a systematic treatise, is intended to serve as a practical guide for the student of physiological chemistry.

IN Mr. Wallace's forthcoming work—"Island Life," no less than five chapters are devoted to geological subjects which he considers to be of fundamental importance for the study of questions of distribution,—such as the permanence of continents and oceans, glacial epochs and mild arctic climates, and the measurement of geological time. A complete and in many respects a novel solution of the problem of geological climates is attempted; and as the distribution of both animal and vegetable forms is dealt with this volume will probably interest a wide class of readers.

MR. R. BULLEN NEWTON, assistant naturalist under Prof. Huxley in the Museum of Practical Geology, Jermyn Street, has received an appointment in the geological department of the British Museum.

A BALLOON ascent was made at Cherbourg, on the occasion of the *fête* given by the Municipality to M. Grévy, by MM. Perron and Capt. Gauthier. The general direction of the wind being from the land to the sea, a government steamer was sent out to secure the safety of the aëronauts if necessary. Before starting not less than thirty pilot-balloons were sent up to ascertain the superposition of the aërial currents. It was proved that at 400 metres the wind was blowing from the sea. After having travelled for more than an hour in the direction of Portsmouth, the aëronauts opened their valve and returned safely on shore. More than a hundred thousand spectators witnessed the experiment. The culminating point of the ascent was an altitude of 1,500 metres, where the travellers could see the English coast, the whole of the Isle of Wight, &c. The scenery is stated to have surpassed description. Some very curious observations were made on the colours of the sea. In the places where the water is very deep it looks quite inky, and the curves of level are so clearly manifested that they bear comparison with equidistant lines worked on ordnance maps. When travelling at so great an altitude ships can be detected with some difficulty; but smoke can be seen even when the smoke-producing steamer can hardly be perceived with the naked eye.

AT a recent meeting of the Asiatic Society of Bengal, Mr. L. Schwendler gave an instance of a Langur monkey (*Semnopithecus entellus*) having been taught to do useful work. Mr. Schwendler's "trustworthy informant" was Babu B. Pyne, a member of the Government Telegraph Department. The Babu says:—"Some years ago I had a Langur which, when standing erect, measured fully 2 feet 6 inches. The animal was very powerful, and could easily pull a punkha measuring eight feet in length. It was a male, and even when young showed a disposition to be highly savage. The older it got the more savage it became. Seeing the great power this monkey had, I wanted to utilise it, and therefore intended to employ it for the purpose of pulling punkhas. The teaching I effected in the following manner:—The monkey was tied by the waist close to a strong pole, so that it could not move either backwards or forwards, or right or left. Both hands were tied to a rope attached to a punkha, which was regularly pulled from the other side by a man. Thus the animal had to sit in one place, and could only move its hands up and down with the punkha rope. In this way the monkey in a comparatively short time learnt to pull the punkha by itself, and was so employed by me for several years. It always kept in first-rate health, enjoyed its work immensely, and did it equally well, if not better, than a cooly. During the rains it suffered from fever, and ultimately died. Putting now this trained monkey in the place where the man used to pull the punkha, and a new Langur in the place where the trained monkey formerly sat, I attempted to teach successively *four* more monkeys, two of which were females. I succeeded perfectly in teaching the males, but was quite unsuccessful with the females." Mr. Schwendler said there is a certain amount of intelligence required to do this work, since the arms, in their up and down movements, have to keep time with the swinging punkha. Mr. Schwendler mentioned some other instances in which the display of intelligence by monkeys had

been noticed. In particular he mentioned a case in which a monkey, which had sustained a fall from trusting to a rotten branch while swinging on a tree, had been observed afterwards to examine the branches of the tree, and to break off those which it found to be rotten. Some discussion ensued as to whether the action of the monkey in this case was the result of intelligence, and some of the members present were of opinion that it might have been the result simply of anger caused by the fall. Mr. Schwendler, however, stated that he had for long made the habits of animals a study, and that he was convinced of the fact that monkeys were possessed of much intelligence; and he vouched for the authenticity of the statements made in the paper read regarding the monkeys which were taught to pull a punkha.

THE *Times* Geneva correspondent telegraphs as follows:—"An interesting geological discovery has been made in the neighbourhood of Solothurn. On removing a mass of superincumbent sand and gravel to prepare for some quarrying operations, the rock beneath was found to be quite smooth and intersected with old water channels. The excavation being continued, a number of enormous holes filled with great stones were laid bare. These holes, like those in the famous Gletcher Garten at Lucerne, are due to the action of water, which, flowing through rifts in the glacier that ages past covered the rock, set in movement the stones beneath, whereby the 'Giant's Rattles,' as they are called, were hollowed out; but while the rock at Lucerne is sandstone, the formation at Solothurn is hard limestone and quartz."

AT Judicarien and Riva, in the Tyrol, a rather smart shock of earthquake was felt on the 12th inst.

A CORRESPONDENT writes in reference to our Notes regarding the successes of the ladies in the recent London University Examination (NATURE, vol. xxii. pp. 346 and 374), calling attention to the fact that the position of the successful candidates in the respective divisions of the lists referred to (*i.e.*, the Pass Lists of the 1st B.A. and 1st B.Sc. Examinations) is determined by the alphabetical order of their names, and is therefore accidental. This does not refer to the Honours Lists, which have since been published, and in which the candidates *are* arranged in order of merit.

FROM a report drawn up by Don Mariano Barcena, Director of the Central Meteorological Observatory of Mexico, the *Gardeners' Chronicle* learns that it is proposed to establish a large number of stations throughout Mexico for the uniform record of observations on the temperature, pressure, rainfall, vegetation, &c. Should this project be properly inaugurated and continued, it will be of the greatest service to science. The observers will likewise report on the state of the crops, prices of grain, and other commodities, &c., as affected by the weather.

MR. BRYCE-WRIGHT writes to the *Times* that numbers of false turquoises have during the last two weeks come from Vienna and are still arriving? Their detection is somewhat difficult, the backs of every specimen having been pecked out and the holes filled with a black cement, to imitate the matrix of La Vieille Roche. They are, however, a little lighter than the real turquoise, the specific gravity being 2·4, while that of the genuine stone is 2·6 to 2·8. The easier method of distinguishing them is to use a penknife to the false matrix, which can easily be removed, revealing the artificial perforations.

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus*) from India, presented respectively by Mr. H. G. Wainwright and Mr. Cecil Peele; two Tcheli Monkeys (*Macacus tcheliensis*) from Shanghai, China, presented by Dr. Bushell; a Brown Capuchin (*Cebus fatuellus*) from Guiana, presented by Mr. Percy E. Scrutton; a West Indian Agouti (*Dasyprocta cristata*) from the West Indies, presented by Mr. W. H. Braithwaite; a Spotted Salamander (*Salamandra maculosa*), European, an Axolotl (*Siredon mexicanus*) from Mexico, presented by Dr. Gibbs, F.Z.S.; a Common Cormorant (*Phalacrocorax carbo*), British, deposited; a Straw-necked Ibis (*Carphibis spinicollis*), a Maned Goose (*Bernicla jubata*) from Australia, an Elate Hornbill (*Buceros elatus*) from West Africa, two Brown Mynahs (*Acridotheres fuscus*) from India, purchased.

OUR ASTRONOMICAL COLUMN

THE SATELLITES OF SATURN.—Mr. Marth has published (*Astron. Nach.*, No. 2,328) his ephemeris of the five interior satellites of Saturn, with the usual fulness of detail. For *Mimas* he now assumes accelerated motion, leaving it to be decided by further observation whether this hypothesis is the correct one to account for the discrepancies which have been recently remarked between his predictions and observation in the case of this difficult object. Mr. Marth's times of greatest elongations of *Mimas* now accord within 0·2h. with those deduced from the circular elements which we have adopted on several occasions for predictions in this column, and which were founded upon a very approximate discussion of measures at the Naval Observatory, Washington, in the years 1874-77. Without some such hypothesis as accelerated motion, however, these elements will not represent the observations even as late as Lassell's, and it has been only with the view of facilitating to some extent the identification of the satellite about this epoch that they have been from time to time employed. They give the following times of elongations, which may be compared with Mr. Marth's:—

East Elongations	h. m.	*West Elongations*	h. m.
Aug. 30 ...	15 15 G.M.T.	Sept. 7 ...	15 30 G.M.T.
31 ...	13 52	8 ...	14 7
Sept. 1 ...	12 29	9 ...	12 44
2 ...	11 6	10 ...	11 21
3 ...	9 43	11 ...	9 58

THE BINARY-STAR α CENTAURI.—Mr. Tebbutt communicates to the *Observatory* measures of this object made at Windsor, N.S.W., in the first half of the present year; duly weighted the mean result is:—

1880·311 ... Position, 186°·53; Distance, 5″·16.

Dr. Doberck's elements give the angle less by 2°·9, and the distance also less by 0″·21. An able investigation on the parallax of this star, with a new determination of the orbit by Mr. W. L. Elkin of Strassburg has just appeared.

THE GREAT COMET OF 1880.—Dr. B. A. Gould, the director of the National Observatory of the Argentine Republic at Cordoba, has passed through London during the last week. He describes the appearance of the Southern Comet of February, of which he has put upon record the longest series of observations as involving very great difficulty in fixing accurate positions with the telescope, while with the naked eye there was an equal difficulty in saying where the tail originated, there being no nucleus, or *head*, to use the old term, worthy of the name.

If a systematic search for comets had been organised in the southern hemisphere (shall we say had southern astronomers been so far ahead of their northern *confrères*?) possibly the comet might have been detected before perihelion, and some most interesting results would have accrued. The reader may perhaps like to see the track which the comet must have followed in its approach to the sun, which the subjoined places will sufficiently indicate:—

12h. G.M.T.	Right Ascension.	Declination.	Distance from Earth.	Intensity of Light.
1879, Dec. 28 ...	51°·0 ...	−73°·5 ...	0·630 ...	2·3
1880, Jan. 2 ...	9·1 ...	69·8 ...	0·611 ...	3·1
7 ...	346·3 ...	59·9 ...	0·621 ...	4·0
12 ...	334·8 ...	48·8 ...	0·660 ...	5·2
17 ...	327·4 ...	38·2 ...	0·727 ...	7·4
22 ...	321·1 ...	−28·5 ...	0·824 ...	14·7

The last column contains the values of $\frac{1}{r^2 . \Delta^2}$, and may be of questionable application in this instance.

A FRAGMENT OF PRIMEVAL EUROPE

WHEN the history of the growth of the European area is traced backward through successive geological periods, it brings before us a remarkable persistence of land towards the north. The stratified formations bear a generally concurrent testimony to the existence of a northern source whence much of their sediment was derived, even from very early geological times. In their piles of consolidated gravel, sand, and mud, their unconformabilities and their buried coast-lines, they tell of some boreal land which, continually suffering denudation, but doubtless at intervals restored and augmented by upheaval, has gradually extended over the whole of the present European area. The chronicles of this most interesting history are at best imperfect, and have hitherto been only partially deciphered. They naturally assume an increasingly fragmentary and obscure character in proportion to their antiquity. Nevertheless traces can still be detected of the shores against which the oldest known sedimentary accumulations were piled. The shores have of course been deeply buried under the deposits of subsequent ages. But the whirligig of time has once more brought them up to the light of day by stripping off the thick piles of rock beneath which they have lain preserved during so vast a cycle of geological revolutions. I shall here describe a fragment of this earliest land, and allude to some of the geological problems which it suggests.

In the north-west of Scotland, along the seaboard of the counties of Ross and Sutherland, a peculiar type of scenery presents itself, which reappears nowhere else on the mainland. Whether the traveller approaches the region from the sea or from the land, he can hardly fail to be struck by this peculiarity, even though he may have no specially geological eye for the discrimination of rock-structures. Seen from the westward or Atlantic side, as, for example, when sailing into Loch Torridon, or passing the mouths of the western fjords of Sutherlandshire, the land rises out of the water in a succession of bare rounded domes of rock, crowding one behind and above another, as far as the eye can reach. Not a tree or bush casts a shadow over these folds of barren rock. It might at first be supposed that even heather had been unable to find a foothold on them. Grey, rugged, and verdureless, they look as if they had but recently been thrust up from beneath the waves, and as if the kindly hand of nature had not yet had time to clothe them with her livery of green. Strange however as this scenery appears when viewed from a distance, it becomes even stranger when we enter into it, and more especially when we climb one of its more prominent heights and look down upon many square miles of its extent. The whole landscape is one of smoothed and rounded bosses and ridges of bare rock, which, uniting and then separating, inclose innumerable little tarns (Fig. 1). There are no definite lines of hill and valley; the country consists, in fact, of a seemingly inextricable labyrinth of hills and valleys, which, on the whole, do not rise much above, nor sink much below, a general average level. Over this expanse, with all its bareness and sterility, there is a singular absence of peaks or crags of any kind. The domes and ridges present everywhere a rounded, flowing outline, though here and there their outline has been partially defaced by the action of the weather.

The rocks that have assumed this external contour are the Fundamental, Lewisian, or Laurentian gneiss, which, as Murchison first showed, form the platform whereon the rest of the stratified rocks of Britain lie. They do not, however, cover the whole surface of these north-western tracts. On the contrary, they form a broken fringe from Cape Wrath to the Island of Raasay, coming out boldly to the Atlantic in the northern half of its course, but throughout the southern portion retiring chiefly towards the heads of the bays and sea-lochs, and even extending inland to the head of Loch Maree. The reason of this want of continuity is to be found in the spread of later formations over the gneiss. At the base of these overlying deposits comes a mass of dark red sandstone and conglomerate (classed as Cambrian by Murchison and his associates), which, in gently inclined or horizontal strata, sweeps across the platform of gneiss, rising here and there into solitary cones or groups of cones fully 3,400 feet above the sea. No contrast in Highland scenery is more abrupt and impressive than that between the ground occupied by the old gneiss and that covered by this overlying sandstone group. So sharp is the line of demarcation between the two tracts that it can be accurately followed by the eye even at a distance of several miles. Where the sandstone supervenes, the tumbled sea of bare grey gneiss is succeeded by smooth heathy slopes, through which the flat or gently-inclined parallel edges of the beds protrude in successive lines of terrace. As the ground rises into conical mountains, the covering of heather grows more and more scant, but the same terraced bars of rock continue to rise even to the summits, so that these vast solitary cones, standing apart on their platform of gneiss, have rather the aspect of rudely symmetrical pyramids than the free, bold sweep of crag and slope so characteristic of other Scottish mountains.

The depth of these sandstones must amount to several thousand feet. Even in single mountains a thickness of more than three thousand four hundred feet can be taken in at a glance of the eye from base to summit. Yet when this massive formation is followed along the belt of country in which it lies it is found to thin out rapidly and even for some distance to disappear. Such a disappearance might arise either because the formation was not continuously deposited or because it was unequally worn down before the next formation was accumulated upon it. Evidently the solution of this question will have an important bearing on any reconstruction of the early geography of the region.

Above the red sandstones and creeping across them transgressively lies the deep pile of white quartzites, limestones, and schists which Peach's discovery of recognisable fossils in them at Durness showed to be of Lower Silurian age. Another well-marked contrast of scenery is presented where these rocks abut upon those just described. The quartzites rise into long lines of bare white hills which, as the rock breaks up under the influence of the weather, are apt to be buried under their own *débris* even up to the summits. Here and there outlying patches of the white rock may be seen gleaming along the crests of the dark sandstone mountains like fields of snow or nascent glaciers. Quartzites, limestones, and schists dip away to the east and pass under the vast series of younger schists which form most of the rest of the Scottish Highlands. This order of succession, first established by Murchison, can be demonstrated by innumerable lines of natural section. I have myself traced it through the mountainous country from Cape Wrath to Skye, and in many traverses across Sutherland and Ross. I have sought for evidence of the reappearance of the old or fundamental gneiss of the north-west, and have ransacked every Highland county in the search, but have never found the least trace of that rock beyond its limits in Sutherland and Ross. Its distinctive gneisses and other crystalline masses, so wonderfully unlike anything else in the Highlands, never reappear to the east. And that strange mammillated, bossy surface is found in the north-west alone.

To realise what the appearance of the old gneiss at the present surface means we must bear in mind that it was first buried under several thousand feet of red sandstone, that the area was then further submerged until the vast pile of sediment was deposited out of which the High-

lands have been formed, that these sedimentary accumulations—how many thousand feet thick we cannot yet tell—were subsequently over the Highland area crumpled and metamorphosed into crystalline schists, and that finally towards the west the ancient platform of gneiss was once more ridged up and gradually bared of its superincumbent load of rock, until now at length some portions of it have been once more laid open to the air.

There is thus a special historical interest in this fragment of the old gneiss country. It is a portion of the

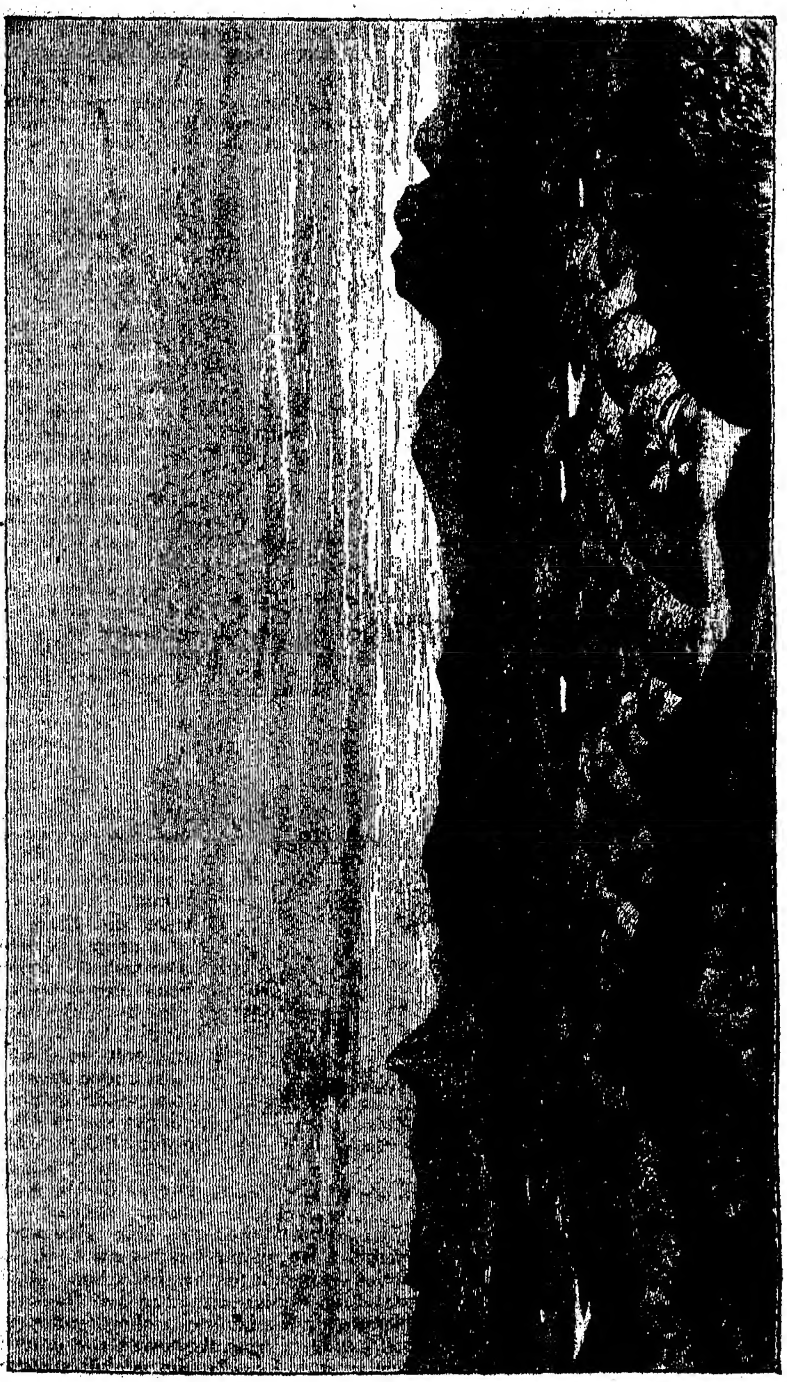

FIG. 1.—View of the ancient platform of gneiss looking eastward from above Scourie, Sutherlandshire. The hill to the left (one bird) is Arkle (2,580 feet), composed of quartzite resting on the fundamental gneiss, and dipping eastward; the conical mountain Stack (2,364 feet, marked here by two birds) consists of the old gneiss—the highest elevation reached by this rock on the mainland. The gneiss sweeps southward and underlies the great conical mountain of Queenaig (2,653 feet, four birds), while in the distance (three birds) are seen the quartzite heights of Ben More Assynt (3,235 feet).

earliest European surface of which as yet we know anything—a surface in chronological comparison with which the Alps are of quite modern date. For many years past I have at intervals wandered over it, finding in its undulations of bare rock a fascination which a fairer landscape might fail to exert. Each visit suggests some fresh problem, if it does not cast light on earlier difficulties. One of the questions which must particularly engage the attention of every observant traveller in Western Sutherland and Ross is the origin of that extraordinary contour

presented by the gneiss. A very slight examination shows that every dome and boss of rock is ice-worn. The smoothed polished and striated surface left by the ice of the glacial period is everywhere to be recognised. Each hummock of gneiss is a more or less perfect *roche moutonnée*. Perched blocks are strewn over the ground by thousands. In short, there can hardly be anywhere else in Britain a more thoroughly typical piece of glaciation.

An obvious answer to the question of the origin of the peculiar configuration of this gneiss country is to refer it to the action of the last ice-sheet which covered Britain. That the gneiss was powerfully ground down by that ice is sufficiently manifest. But if the peculiar bossy surface is to be thus explained we are confronted by the difficulty that the ice must have acted far more effectively on the gneiss than on any other rock in the region. Yet there is nothing in the configuration of the ground to make the erosion greater on the gneiss than on the red sandstone or quartzites and schists. The same side of a sea-loch may be seen to present slopes both of gneiss and sandstone; the gneiss is always worn into smooth domes, ridges, and hollows; but the sandstone retains its parallel bands of rocky terrace. The difference is evidently not due to any greater glacial abrasion of the gneiss. The area of high ground above the gneiss platform in Sutherlandshire is comparatively small. As shown in Fig. 1 it rises somewhat steeply from the west, its chief area and drainage lying towards the east. I have visited those tracts of the Highlands where the rocks approach nearest to the type of the ancient gneiss, and where the conditions have been most favourable for intense glaciation. No more promising locality for a comparison of this kind could be found than the deep defiles of Glen Shiel and Kintail. The rocks have there been extremely metamorphosed and have been exposed to the action of ice descending from some of the highest uplands in the West of Scotland. Yet we look in vain among them for any semblance of the bare bossy surface of the old gneiss.

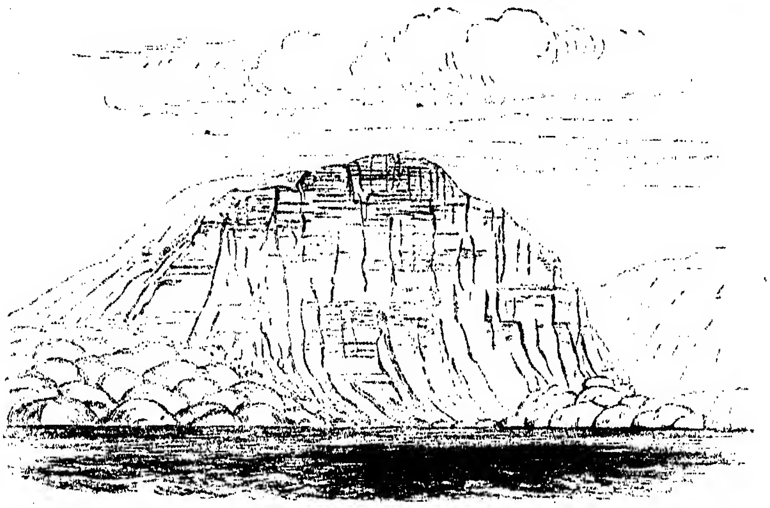

Fig. 2.—Ben Shieldag, Loch Torridon—a hill of flat Cambrian red sandstone resting upon an uneven hummocky surface of the old gneiss.

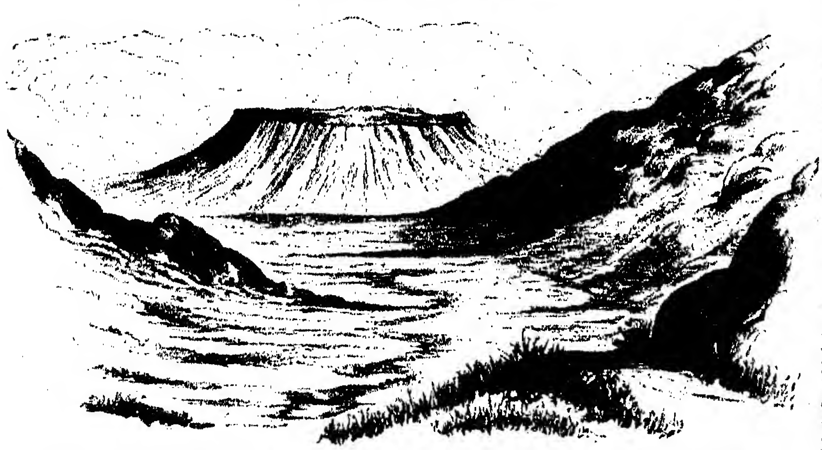

Fig. 3.—View of outlier of Cambrian breccia and sandstone among gneiss hills near Gairloch.

A further difficulty arises when we reflect that in the general erosion of the country the gneiss, being covered by later formations, would be the last to be attacked, and in so far as it was so covered, must have been exposed to the erosive action of the ice for a shorter time than the overlying rocks. We might therefore have presumed that instead of being more, it would have been less trenchantly worn down than these. Its great toughness and durability, which have enabled it to retain the ice-impress so faithfully, must have given it considerable powers of resistance to the grinding action of the glacier.

Every fresh excursion into these northern wilds has increased my difficulty in accounting for the peculiar contours of the gneiss ground by reference merely to the work of the Glacial period. A recent visit, however, seems at last to have thrown some light on the matter. I had long been familiar with the fact that the platform of gneiss on which the red sandstones and conglomerates were laid down abounded in inequalities even at the time of the deposit of these strata. Its uneven surface rose here and there into high ridges and cones, of which Stack is a diminished representative, and sank into depressions now occupied by thick masses of sandstone. But I have lately observed that not only do these larger features pass under the sandstone, but that the minor domes and bosses of gneiss do so likewise. On both sides of Loch Torridon, for example, the hummocky outlines of the gneiss can be seen emerging from under the overlying sandstones (Fig. 2). On the west side of Loch Assynt similar junctions are visible. But some of the most impressive sections occur in the neighbourhood of Gairloch. Little more than a mile to the north of the church the road to Poolewe descends into a short valley surrounded with gneiss hills. From the top of the descent the eye is at once arrested by a flat-topped hill standing in the middle of the valley at its upper end, and suggesting some kind of fortification; so different from the surrounding hummocky declivities of gneiss is its level grassy top, flanked by wall-like cliffs rising upon a glacis-slope of *débris* and herbage (Fig. 3). Closer examination shows that the little eminence is capped with a coarse reddish breccia made

up of fragments from the surrounding gneiss. The stones in this deposit are for the most part perfectly angular, and are sometimes stuck on end in the mass. They underwent but little re-arrangement after they were thrown down, though occasional lenticular seams of red sandstone running through the rock serve to prove that it is lying as a flat cake on the gneiss. My friend Mr. Norman Lockyer accompanied me in the examination of this hill. We searched long for a striated stone among the component materials of the breccia, but the matrix was too firm to allow us to bare and extract any of the pebbles or boulders. We traced, however, the characteristic rounded bossy surface of the gneiss until it passed under the breccia, and were convinced that, could the outlier of breccia be stripped off, the same kind of surface would be found below it as on the gneiss above and around. The valley in which this little fragment of a once more extensive deposit of breccia lies certainly existed as a hollow in Cambrian times. From the narrowness of its present outlet, which has been cut by the escaping streamlet, and from the nature of the breccia, we may infer with some plausibility that the hollow was filled with water, and may have been a lake. It was almost certainly a rock-basin, surrounded with hills of gneiss that had been worn into undulating dome-shaped hummocks.

Behind the new hotel at Gairloch the ground rises steeply into a rocky declivity of the old gneiss. Along the base of these slopes the gneiss (which is here a greenish schist) is wrapped round with a breccia of remarkable coarseness and toughness. We noticed some blocks in it fully five feet long. It is entirely made up of angular fragments of the schist underneath, to which it adheres with great tenacity. Here again rounded and smoothed domes of the older rock can be traced passing under the breccia, as at *a* in Fig. 4. On the coast immediately to the south of the new Free Church a series of

FIG. 4.—Sections of the junction of the fundamental gneiss and overlying Cambrian breccia. Gairloch.

instructive sections again lays bare the worn undulating platform of gneiss, with its overlying cover of coarse angular breccia (*b* in Fig. 4).

On these far northern shores, then, there still remain fragments of the surface on which our oldest sedimentary accumulations were deposited. These fragments are found to bear in their smoothed hummocky contours a striking resemblance to the surface which geologists now always associate with the action of glacier-ice. There can at least be no doubt that they are denuded surfaces. The edges of the vertical and twisted beds of gneiss and schist have been smoothly bevelled off. These rocks, however, would never have assumed such a contour if exposed merely to ordinary sub-aërial disintegration. They would have taken sharp craggy outlines like those which are here and there gradually replacing the ice-worn curves of the *roches moutonnées*. They have certainly been ground by an agent that has produced results which, if they were found in a recent formation, would, without hesitation, be ascribed to land-ice. The breccia, too, is quite comparable to moraine-stuff. Without wishing at present to prejudge a question on which I hope yet to obtain further evidence, I think we have in the meantime grounds for concluding that in the north-west of Scotland there is still traceable a fragment of the earliest known land-surface of Europe, that this primeval country had a smooth undulating aspect not unlike that of the west of Sutherland at the present time, that it contained rock-hollows, some of them filled with water, that into these hollows piles of coarse angular detritus were thrust, that around and beneath the tracks where this detritus accumulated the gneiss was worn into dome-shaped forms strongly suggestive of the operation of land-ice, and that though the ice of the last Glacial Period undoubtedly ground down the platform of gneiss, bared as it was of the overlying formations, it found a surface already worn into approximately the same forms as those which it presents to-day.

ARCH. GEIKIE

EXCRETION OF WATER BY LEAVES[1]

IN the pamphlet referred to below Dr. Moll gives a detailed account of his investigations upon the excretion of drops of water by leaves, of which an outline was given in the *Botanische Zeitung* for January 23 of the present year.

The question with which he more especially deals is as to whether this excretion is a function which is performed by all leaves, or whether it is confined to such leaves only as possess specially modified organs. The method which he employed in his researches is to place the leaves under the most favourable condition for the excretion of drops by diminishing as far as possible their transpiration, and by supplying them with water. Under ordinary circumstances the excretion of drops is due to the action of the root-pressure; but Dr. Moll substitutes for this, in his experiments, the pressure of a column of mercury, in order to have this important factor in the problem completely under control.

The results, which are of considerable interest, may be briefly stated as follows: out of sixty plants experimented on, the leaves of twenty-nine excreted drops without becoming injected, that is, without their intercellular spaces becoming filled with water; thirteen leaves became injected and excreted drops, and eighteen became injected but did not excrete at all. It appears that the age of the leaf has a very evident influence upon the excretion of drops, for whereas the young leaves of a plant, such as *Sambucus nigra* or *Platanus occidentalis*, for instance, readily excrete drops without becoming injected, the older leaves of the same plant become injected and excrete scarcely at all. Under these circumstances it is quite possible and even probable, as Dr. Moll himself suggests, that of the eighteen plants the leaves of which became only injected, some at least were capable of excretion at an earlier period. It is only definitely stated of Hedera, Syringa, and Taxus that their leaves do not excrete at all.

As to the organs of excretion, it is effected in eight out of the forty-two cases by means of water-pores, but in four of these cases it is effected also by ordinary stomata; in eight other cases it was found to be effected by stomata, and in three cases it took place at portions of the surface which possessed neither water-pores nor stomata. These last cases are carefully distinguished by Dr. Moll from those in which an excretion took place over the whole surface of the leaf in consequence of excessive pressure.

From these observations it appears that most leaves, at least so long as they are comparatively young, are capable of excreting water in drops when it is supplied to them in excess, and further, that this excretion is effected by certain organs (*Emissarien* the author calls them) which may be water-pores, or ordinary stomata, or limited areas of the surface which are histologically undifferentiated. The effect of this excretion is to prevent the injection of the leaves when the root-pressure is great, a condition which would obviously interfere with the circulation of air in the intercellular spaces, and therefore with the function of the leaf. Dr. Moll suggests that possibly some definite correlation exists between the presence of excretory organs and the existence of root-pressure in a plant; for instance, according to Hofmeister ("Flora," 1862), no root-pressure can be detected in Conifers,

[1] "Untersuchungen über Tropfenausscheidung und Injection bei Blättern," von Dr. J. W. Moll. (Amsterdam, 1880.)

and the author has failed to find any excretory organs in their leaves. It may be added, in conclusion, that these organs can excrete not only water but solutions of substances such as tannin, and the juice of Phytolacca berries. Further, Dr. Moll's observations tend to confirm the view that the wood is the channel by which water is conveyed to the leaves from the roots.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, June 17.—"On the Constants of the Cup Anemometer," by the Rev. T. R. Robinson, D.D., F.R.S., &c. In a previous paper the author detailed experiments made by attaching anemometers to a whirling machine, and the conclusions to which they led. He was however doubtful of the accuracy of the method, and proposed one depending on the action of natural wind. He has tried this, and he thinks successfully. Two instruments of the Kew type, differing only in friction, were established 22 feet asunder on the roof of the house and 16 feet above it: the number of turns made by each, and the time, were recorded by a chronograph, and from these, v and v', the velocity in miles per hour of the centres of the cups was known.

The friction of one of these (K) was constant; that of the other (E) was varied by applying to a disk on its axle Prony's brake, which was connected with a spring balance whose tension was recorded during the time of experiment by a pencil moved by clockwork. Thus the mean friction was obtained. It ranged from 353 grains to 4,982.

The equation of an anemometer's motion is

$$V^2 + v^2 - 2Vvx - \frac{f}{a} = 0$$

where V is the unknown velocity of the wind, a and x two constants which are to be determined. Each observation gives two equations in which there are four unknown quantities, for it is found that the value of V changes from one instrument to another. This is partly owing to eddies caused by the buildings, but also in great measure to irregularity of the wind itself. It is however also found that these wind-differences are as likely to have + as − signs, and therefore it may be expected that their sum will vanish in a large number of observations. The ordinary methods of elimination fail here even to determine with precision a single constant, and he has proceeded by approximation.

Assuming the value of a given by the actual measurements in his paper = 15·315 at 30″ and 32° for 9-inch cups, and that there is no resistance as v^2 except that in the equation, and assuming an approximate value for x, we can compute V and V′. The difference between these must be due to an error in x and to w the wind error, and taking the sum of a series we have

$$S(V' - V) + Sw = \Delta x \times S(e - e'); \; e \text{ being } -\frac{V}{\sqrt{x^2 - 1 + \frac{f'}{av'^2}}}.$$

If the observations are sufficiently numerous $Sw = 0$, with the assumed $x + \Delta x$ thus found, recompute the V till the sum of V′ − V is insensible, and the final x will give V with a high degree of probability. Twenty-one observations gave a value of x considerably larger than what was obtained with the whirling machine, and of course the limiting factor (that when v' is so large that $\frac{f'}{av'}$ may be neglected). It is for the Kew type 9″ cups 24″ arms = 2,831. In this series the differences are so evidently casual as to show that neither a or x change with v.

With this x, K gives the true value of V at it; therefore if any other type be substituted for E′ it is easy to find its x, for its a is as area of cups, its f' is known, and assuming its x' and computing as before, we get similarly its Δx. He tried five different types and obtained very unexpected results, for he found that the x varied as some inverse function of the diameter of the cups and of the arms. He gives its values.

No. 1.	Original instrument	12″ cups	23·17 arms,	x = 1·5880,	limit	2·812
,, 2.	Kew	9 ,,	24, ,,	1·5919,	,,	2·831
,, 3.	,, ...	9 ,,	12, ,,	1·7463,	,,	3·035
,, 4.	,, ...	9 ,,	8, ,,	2·1488,	,,	4·052
,, 5.	,, ...	4 ,,	26·75, ,,	1·8587,	,,	3·485
,, 6.	,, ...	4 ,,	10·67, ,,	2·5798,	,,	4·956

No. 6 is similar to No. 2, and it might be expected that their constants would be equal. The cause of these differences is partly the eddies caused by the cups being more powerful when the arms are short, but still more the presence of high powers of the arm and diameter occurring in the expressions of the mean pressures on the concave and convex surfaces of the hemispheres. In the present state of hydrodynamics we cannot assign these expressions, but we know enough to see that such powers may be present.

As each type of anemometer has its own constants, the author would suggest to meteorologists the propriety of confining themselves to one or two forms. For fixed instruments he considers the Kew one as good as any, and would wish to see it generally adopted. For portable ones he has no experience except with Casella's 3″ cups 6″ arms, which he found very convenient; he has not however determined its constants. Some selection of the sort seems necessary if it is wished to have an uniform system of wind-measures.

Entomological Society, August 4.—J. W. Dunning, M.A., F.L.S., vice-president, in the chair.—Sir Sidney Saunders forwarded for exhibition four living specimens of *Prosopis rubicola*, all stylopised females recently bred from larvæ extracted from briars received from Epirus, and contributed notes thereon.—Miss E. A. Ormerod exhibited a soft gall-like formation found on *Rhododendron ferrugineum*, but believed to be of fungoid growth.—Mr. Billups exhibited a specimen of *Heptaulacus villosus* from Box Hill.—Mr. H. J. Elwes communicated a paper on the genus *Colias*.—Mr. W. L. Distant read a paper entitled "Notes on Exotic Rhynchota," with descriptions of new species.

THE CRUISE OF THE "KNIGHT ERRANT"

IT was accepted by us as one of the general conclusions from the temperature observations made on board the *Challenger* that the normal vertical arrangement of temperature in the ocean is somewhat in this wise. The water is warmest at the surface; from the surface it cools rapidly for the first hundred fathoms or so; it then cools more slowly down to five or six hundred fathoms; and then extremely slowly to the bottom, where the minimum temperature is reached.

I need not here enter into detail as to the causes of this normal condition, which have already been fully discussed.[1] I may state however, generally, that the temperature of the upper strata is raised by solar radiation, and its distribution is affected by currents and by many other local causes; and that the water which has been cooled down in the polar seas until it has acquired a high specific gravity, flows along the bottom and into the deepest abysses to which it has access.

This normal vertical distribution of temperature is by no means universal or even general; it exists only in those parts of the ocean which are continuous throughout their entire depth with a polar sea. No ocean is thus continuous with the Arctic Sea; a wide belt apparently under these normal temperature conditions surrounds the South Pole or the south polar land nearly if not entirely, but the gulf-like northward extensions of the water-hemisphere, the Atlantic and the Pacific, show a distribution of temperature to a certain extent abnormal, and in some seas which occupy more restricted areas, the deviation from the normal conditions is excessive. In oceans where the thermometer sinks steadily from the surface to the bottom, that is to say, in those under normal conditions, the bottom temperature at anywhere near 2,500 fathoms is a little below the freezing point. The Atlantic Ocean is divided into three areas; in one of these, an area extending from the Antarctic Sea along the coast of South America to ten degrees or so north of the Equator, the temperature sinks at the usual rate to 31°·5 F. at the bottom (2,900 fathoms). In another, the eastern basin, extending along the coasts of Europe and Africa, the temperature sinks steadily to 35°·5 at a depth of about 2,000 fathoms, and this temperature extends to the bottom (3,150 fathoms); in the third area, the western basin, off the West Indies and the coast of North America, the temperature falls to 35° at 2,000 fathoms, and this temperature is again continuous to the bottom (3,475 fathoms). As extreme instances of this abnormal condition, in the Celebes Sea, which attains a depth of 2,600 fathoms, the minimum temperature—38°·5 F.—is reached between 700 and 800 fathoms; the Banda Sea, with a depth of 2,800 fathoms, reaches its minimum temperature of 37° F. at 900 fathoms; and the Sulu Sea, which is at least 2,550 fathoms deep, has a uniform temperature of 50°·5 F. from a depth of 400 fathoms to the bottom.

[1] "Hydrographic Proceedings of the Voyage of H.M.S. *Challenger*." Report on Temperatures by Staff-Commander Tizard, R.N. (London, 1876); "The Atlantic," by Sir C. Wyville Thomson, F.R.S., vol. ii. p. 300, *et seq.* (London: Macmillan and Co., 1877.)

The combined results of our soundings and serial temperature determinations led us to conclude that those ocean basins in which the water is of a uniform temperature from a certain depth to the bottom are inclosed within a continuous barrier of a height corresponding to the depth at which the fall in temperature ceases; and that consequently no water at a temperature lower than the isotherm of that depth can pass into them. Suppose such a barrier to rise, as it does rise, in the Atlantic between the south-western and the eastern basins to a height of 2,000 fathoms below the surface, a sounding on the west side to the depth of 2,500 fathoms close to the barrier would give a temperature a little below 32° F., while the thermometer at the same depth on the other side of the barrier would register 35°·5 F. In this way we may have very different temperatures at the same depth, close to one another and apparently under absolutely similar circumstances, and from our experience we should be inclined to accept the existence of continuous barriers as the almost universal explanation of such phenomena.

Of course any generalisation such as I have indicated partakes more or less of the character of a speculation. It is impossible to trace out the entire line of the barrier limiting an ocean basin and to prove its continuity.

In discussing this matter during the cruise of the *Challenger*, Staff-Commander Tizard and I had often in our minds the singular instance of contiguous areas of widely different temperature conditions which had been examined by Dr. Carpenter and myself in the *Lightning* and the *Porcupine* in the years 1868 and 1869.

In the channel between the north coast of Scotland and the Shetland Islands, and the banks and islands of the Faroe group, the average maximum depth is from 500 to 600 fathoms. An abrupt line of demarcation divides this channel into two portions, one of which my colleague Dr. Carpenter called the *cold* and the other the *warm* area.[1] The temperature of the water to a depth of 200 fathoms is much the same in the two areas; in the *cold area*, which occupies nearly the whole of the channel, extending in a north-easterly direction from a line joining Cape Wrath and the Faroe fishing banks, the temperature at 250 fathoms is 34° F., and 30°·5 at the bottom (640 fathoms); in the *warm area* which stretches south-westwards from the same line, the thermometer registers 47° F. at 250 fathoms, and 42° F. at the bottom (600 fathoms).

When the phenomenon was first observed, we concluded than an indraught of cold water, passing southwards from the Spitzbergen Sea, welled into the Faroe Channel, and was met at its mouth and banked in by the north-easterly extension of the Gulf Stream, forming along the line of contact and partial mixture a "cold wall," comparable with that described as occurring in the Strait of Florida between the cold water of the Labrador Current and the Gulf Stream near its origin. This view however presented many difficulties, and on reconsidering the matter

[1] "Preliminary Report by Dr. W. B. Carpenter, V.P.R.S., of Dredging Operations in the Seas to the North of the British Islands, carried on in H.M. steam-vessel *Lightning*," by Dr. Carpenter and Dr. Wyville Thomson, Professor of Natural History in Queen's College, Belfast (*Proceedings* of the Royal Society of London, vol. xvii.). "Preliminary Report of the Scientific Exploration of the Deep Sea in H.M. Surveying-vessel *Porcupine* during the Summer of 1869, conducted by Dr. Carpenter, V.P.R.S., Mr. J. Gwyn Jeffreys, F.R.S., and Prof. Wyville Thomson, LL.D., F.R.S. (*Proceedings* of the Royal Society of London, vol. xviii.)

it now seemed certain that if our generalisation with regard to the cause of great differences in bottom temperatures within short distances be correct, a submarine ridge rising to within about 200 fathoms of the surface must extend across the mouth of the channel between the coast of Scotland and the Faroe banks. We recognised this as a test case which we might probably be able to examine thoroughly, as it was within our easy reach and on a sufficiently small scale; and I determined to take the first opportunity of making a careful survey of the channel with Capt. Tizard's co-operation, if possible before the *Challenger* temperature results were finally discussed.

I was prevented by various circumstances from taking any active steps in this direction until last year, when the Hydrographer of the Admiralty kindly consented to arrange another opportunity for sounding the Faroe Channel. I was obliged again to postpone the undertaking on account of a severe illness, and it was not until the early part of the present summer that I felt well enough to renew my application. I then wrote the following letter to the Hydrographer:—

"*Bonsyde, Linlithgow, June* 16, 1880

"DEAR CAPTAIN EVANS,—As you are aware, during our cruise in H.M.S. *Lightning*, in the year 1868, Dr. Carpenter and I found to our surprise that the channel between the Faroe Island and the coast of Scotland consisted of two very distinct 'areas,' the deep water in the two divisions differing in temperature to a marked degree. Consequent upon the difference of temperature, the faunæ of the two areas were also different. The 'warm' area was separated from the 'cold' by a distinct line of demarcation running apparently from about Cape Wrath past the Island of Rona, and as far as the southern Faroe fishing banks. During the voyage of the *Challenger* we met on many occasions with an abrupt change in the deeper temperatures along a definite line, and we arrived at the general conclusion that the phenomenon depended in all cases upon the interruption of the flow of an undercurrent by a raised submarine ridge. The instance between Scotland and Faroe still, however, remains the most conspicuous as well as the most accessible, and it is very important for us before concluding the Report of the *Challenger* Expedition, to have an opportunity of checking with our greatly increased knowledge our earlier observations.

"I have carefully considered what would be the minimum amount of work required for this purpose, and I now write to ask if you could, with the sanction of their Lordships, authorise Capt. Tizard, now surveying on the west coast, to run north to Stornoway and sound out the line indicated. This would occupy a month, or perhaps a little more.

"As remarkable differences in the distribution of marine animals accompany these differences in temperature, I should greatly regret if we had not a few casts of the trawl on each side of the line, but any additional expense involved for this purpose I will gladly meet. I regret greatly that my present state of health prevents my committing myself to accompany the vessel during the whole time, but I will be at Stornoway during the survey, and my chief assistant, Mr. Murray, is prepared to go. I should think that about the middle of July would be the best time for the trip, if that time would be convenient. Trusting for your assistance to the kind interest you have always taken in our work, believe me very truly yours,

"C. WYVILLE THOMSON"

I give this letter in full to show that our anticipations were very definite, although they were founded entirely upon the comparison of serial temperature soundings.

Their Lordships agreed to my proposal, and on July 22, 1880, I joined the *Knight Errant* at Oban, and proceeded to Gairloch, and thence to Stornoway, where we arrived at mid-day on Saturday, the 24th. The weather was delightful, and the Minch as smooth as glass; when we reached Stornoway, however, the barometer had begun to fall, and continued sinking steadily with a rising breeze from the north-east. After coaling on Monday forenoon, the vessel left Stornoway Harbour at 1 p.m. with a rather unfavourable weather forecast. I meant to have gone with her on this trip but I was advised to give up the idea, and the civilians who accompanied Capt. Tizard were Mr. Murray, our indefatigable assistant Mr. Frederick Pearcey, with my son as a supernumerary. Taking the island of North Rona as a point of departure, during Tuesday the 27th, and Wednesday the 28th, the *Knight Errant* ran a sectional line of soundings, the distance between the soundings averaging ten miles, between the shallow water on the Scottish coast and the bank to the south-west of the Faroe Islands. Fourteen soundings on this line gave the following depths and bottom temperatures:—

	Depth, fathoms.	Temp. °		Depth, fathoms.	Temp. °
1	88	49·5	8	405	46·0
2	178	49·6	9	355	43·8
3	400	45·8	10	270	43·5
4	560	45·2	11	335	41·0
5	540	46·0	12	245	41·8
6	300	47·5	13	120	47·5
7	305	46·5	14	130	46·0

The line was therefore entirely in the *warm area*, and no perceptible amount of water from the cold area could be shown to pass in this direction towards the Atlantic.

Capt. Tizard then proceeded a little way to the north-eastward, and commenced running a second line, parallel to the first and about eight miles from it, back towards the Scottish coast. Soundings were continued on the second line at the same average distances as before on Wednesday and Thursday morning, when, the barometer falling rapidly and the sea running high with a gale from the north-east, it was thought prudent to bear up for Stornoway, which they reached on Friday after a somewhat anxious twenty-four hours.

On Tuesday, August 3, the weather looking somewhat better, the *Knight Errant* left Stornoway and carried a sectional line north-north-west from Rona towards the last sounding; they completed the second line of soundings on the evening of Wednesday, the 4th inst. On this line twelve soundings gave depths and bottom temperatures according to the following table:—

	Depth, fathoms.	Temp. °		Depth, fathoms.	Temp. °
1	370	35·5	7	285	45·8
2	375	31·0	8	255	48·0
3	375	31·0	9	460	46·0
4	285	32·5	10	202	48·2
5	210	47·0	11	145	49·5
6	260	47·5	12	93	50·0

All these soundings therefore, with the exception of Nos. 1, 2, and 3, which were across the ridge in the *cold area*, and No. 9, which was in the deep water of the *warm area*, gave a depth of under 300 fathoms, and were consequently on the ridge.

On August 10 the *Knight Errant* went out again and got several fairly successful hauls of the trawl and a serial temperature-sounding in the *warm area*, returning on Thursday the 12th, and she left Stornoway for the fourth time on Monday, August 16, when the party landed on Rona and gave it a cursory examination. They then steamed towards the deep water of the *cold area*, and on Tuesday the 17th they trawled successfully, and took a serial temperature-sounding in 540 fathoms. They returned to Stornoway for the last time on the evening of Thursday, and left on the following day for Greenock, where they arrived on Monday, the 23rd.

The observations made by Capt. Tizard in the *Knight Errant* have fully corroborated the results of the *Lightning* and *Porcupine* as to the facts of the abnormal distribution of temperature in the Faroe Channel. They have also established the existence of a submarine ridge rising to within 300 fathoms of the surface, in the position in which such a ridge is required to satisfy the conditions of the doctrine of the interference of continuous barriers with the distribution of deep-sea temperatures. Thus far they may be regarded as entirely successful.

The highest line of the ridge has probably not been found, and the details of temperature have yet to be traced out more accurately along the line and for a short distance on either side. I consider that it would be of the greatest interest to work this case out fully as a striking example, within a few miles of our own shore, of a physical phenomenon of importance from its wide occurrence.

The *Knight Errant* was found quite unsuitable for such work; a small steamer of ordinary strength, with stowage for coals for a fortnight's steaming, and with sails to enable her to lie to in a breeze, could do all that is required within a month or six weeks of the ordinary variable weather of these seas.

Although the solution of this temperature problem was the principal object of this summer's trip, I wished greatly to make some additional observations on the nature of the faunæ on the two sides of the ridge, and I was especially anxious to procure some fresh specimens of sponges as material for the structural part of the memoir in which I am engaged with Prof. Franz Eilhart Schultze on the Hexactinellidæ of the *Challenger* Expedition.

The Admiralty declined to give us any material assistance in this direction, but they allowed me to take the gear on board and to get a cast of the trawl or dredge in the intervals of sounding, or when the sounding work was over. I accordingly provided 1,000 fathoms of 2½ inch dredge-rope and other necessary appliances, and Messrs. Henderson, ship-builders, Glasgow, kindly lent us an excellent steam-winch, which was fitted on deck and was of the greatest service both in sounding and trawling. Owing to the boisterous weather and insufficiency of the vessel, this part of our undertaking was not very successful. I got none of the coveted sponges, but two or three hauls of the trawl were taken in each area, and a number of highly-characteristic abyssal forms were procured, including some deep-sea fishes, several crustaceans, and a number of gigantic pycnogonids, some interesting echinoderms, including *Porocidaris*, *Asthenosoma*, *Phormosoma*, *Pourtalesia*, *Rhizocrinus*, and others; some corals, and many curious rhizopods. As the vessel has not yet returned, I take these names from Mr. Murray's rough notes.

Enough has been done to give further evidence, if such were needed, that a small district on the northern slope of the coast of Scotland will afford a richer harvest to a properly-organised dredging-excursion than perhaps any other spot on the earth. The whole area is singularly productive, and it is bisected by a narrow line, on the one side of which the warm sea at a depth of 500 to 600 fathoms vies in abundance and variety of abyssal forms with the favoured patches off Inosima and Zebu; while on the other side of the line, within a distance of a few miles, we find an epitome of the fauna of the depths of the Arctic Sea.

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

A Fragment of Primeval Europe

The paper in Nature, vol. xxii. p. 400, by Prof. Archibald Geikie, on the glacial phenomena of the north-west coast of Scotland, contains on many points a most true and graphic description of a most peculiar and a most interesting country. But I demur to its accuracy on one of the main features to which he refers. The amount of glaciation on the hills of Laurentian gneiss, as represented in the sketch on p. 401, is inordinately exaggerated. I know that country well, both in its general aspect and in its details, and no part of it presents such a scene of symmetrically rounded hills, like the huts of Caffres in Zululand, as that depicted in the sketch.

It is true that all the lower hills are more or less strongly glaciated. But they are also full of low cliffs, and precipitous rocks upon the sides of the glens, and the whole character of the glaciation is such as to suggest the action of heavy floating ice such as that of the "Palæocrystic Sea," and which acted only upon surfaces specially exposed.

Ben Stack, which is 2,364 feet high, and is composed of the same rock, is not rounded at all, and on the north-west face is full of great precipices along which no glaciation can be seen.

It is perfectly true that the same glaciation which is common on the exposed surfaces of the gneiss cannot be traced on the Cambrian sandstones which overlie it. But this is probably due to the obliteration of the ice-marks by subsequent atmospheric action, which tells rapidly and powerfully on the sandstones, whilst it is almost inoperative on the intensely hard and tough Laurentian gneiss.

That this is the true explanation of the difference now presented by the two rocks, is evident from the fact that the next rock in the ascending series, namely, the white quartzites, do retain surfaces in abundance which are splendidly glaciated. I know no spot in Scotland where the polished surfaces due to glaciation are seen on a greater scale than on the top of the white quartzites which cap the mountain of Queenaig in Assynt. This is a classical area in geology—a sketch of it forming the frontispiece of Murchison's "Siluria." The road from Inchnadamf to Kylescue and Scourie passes over a plateau formed of this quartzite, and the beds of white rock, highly glaciated, shine for miles through the heather.

The glaciation which left these surfaces must have passed over the sandstones also. But the rock was not of a material calculated to retain the marks.

Nevertheless I am not prepared to deny that possibly the gneiss of Sutherland may have been doubly glaciated—once in the glacial epoch as hitherto known to geology, and also at some former epoch inconceivably remote, when similar conditions had prevailed.

If well glaciated surfaces of the gneiss can be distinctly traced

passing under the Cambrian conglomerates, such evidence would go a great way. I have examined some spots where the Cambrian conglomerate has left cakes sitting on the gneiss, and at these spots I should say decidedly that there was no proof of the glaciation of the subjacent rock.

That there may be such evidence at other points is very possible; and if Mr. Geikie can establish it he will have made a discovery of high interest in geology. ARGYLL

August 27

New Red Star

MR. ORMOND STONE, writing from Mount Lookout, U.S., lately informed me that on August 6 he found a very red star, 6·5 mag. in 19h. 10m. ±, and − 16° 7′ ±. I observed it last night, when it appeared, according to my estimation, of no more than 7·5–8 magnitude. In colour it ranks among the most remarkable red stars, and as it is also, very probably, a variable, I would recommend it to the close attention of observers. It agrees approximately in R.A. with the well-known variable T Sagittarii, but differs in more than a degree of declination from that star, of which I find the place in my *Red Star Catalogue* to be α, 19h. 9m. 19s.; and δ, −17° 10′·7 for 1880. In about that position last night I found a small colourless star not more than 10 or 11 magnitude. JOHN BIRMINGHAM

Millbrook, Tuam, August 29

Locusts and Coffee Trees

MR. S. B. O'LEARY of this city has favoured me with extracts from a letter written by a relation of his residing on a plantation near Antigua-Guatemala, and containing information about the locust-plague, by which lately the crops of Indian corn and a great many coffee plantations in that country have been destroyed. The insect is called *Chapulin* (*Gryllus miles*, Drury?), and appeared first in the department of Chiquimula, in the eastern part of Guatemala, close to Honduras. Thence it spread over all the warmer parts of the Republic, avoiding the higher and cooler regions. The loss must be very considerable; one gentleman, Don Gregorio Revuelto, in the department of Suchitepeque, lost in one night 70,000 trees, without there being left one single leaf. In April a swarm, supposed to be four leagues broad and about 300 metres long, approached the estate belonging to the writer of the letter, but fortunately could be partly driven away with noise and smoke.

These facts are interesting, as it has not been observed hitherto that locusts, in such a degree, attack the coffee-tree.

Carácas, August 2 A. ERNST

Intellect in Brutes

A VERY interesting instance of animal intelligence has been recently reported in one of our newspapers, and may appear sufficiently remarkable to merit more extended notice. A large and destructive fire lately took place upon the shores of the East River opposite to New York, between which city and Long Island this channel passes. The occasion was the spread of naphtha from a burning oil-ship, which instantly became a trail of fire from which the flames swept into well-filled lumber-yards covered with pine boards, and thence to the loaded barges which lined the docks along the river front, and extended up the banks of a small neighbouring creek.

By the rapid and uncontrolled advance of the conflagration over this wide area the families and occupants of the barges and in the lumber-yards were driven away and forced to seek safety in flight. A Newfoundland dog belonging to the grounds, and at that time roaming amongst the lanes of lumber, found himself imprisoned by a swiftly-contracting arc of flame, with the river on one side as the single avenue of escape. Unlike the beasts in the notable dilemma of Baron Munchausen, these opposed elements refused to leap over the back of their prey, and, extinguishing each other, permit him to escape.

The dog jumped into the water and headed for the opposite (the New York) shore. Although pursued by men in boats and lured by cries and calls from the shores, he steadily kept on his course, and after a long and difficult trip landed on the New York side of the water. From the shore he reached one of the avenues which run lengthwise through New York, and finally found his way to the 34th Street ferry, which lay at a considerable distance below the point of his landing. The dog, following the lumber-waggons, had often crossed from one shore to the other by means of this ferry, and now recognised in his present extremity, he easily secured a single passage.

Once returned to the Long Island side, he regained his old quarters, having by this circuitous route baffled the fire and regained his home. L. P. GRATACAP

CHATEL, Jersey, must send a more precise address.

THUNDERSTORMS[1]

III.

THE name *thunderbolt*, which is still in use, even by good writers, seems to have been introduced in consequence of the singular effects produced when lightning strikes a sandhill or sandy soil. It bores a hole often many feet in length, which is found lined throughout with vitrified sand. The old notion was that an intensely hot, solid mass, whose path was the flash of lightning, had buried itself out of sight, melting the sand as it went down. It is quite possible that this notion may have been strengthened by the occasional observation of the fall of aerolites, which are sometimes found, in the holes they have made, still exceedingly hot. And at least many of the cases in which lightning is said to have been seen in a perfectly clear sky are to be explained in the same way. Every one knows Horace's lines—

> "Diespiter
> Igni corusco nubila dividens
> Plerumque, per purum tonantes
> Egit equos volucremque currum."

But Virgil's remark is not so commonly known. He is speaking of prodigies of various kinds, and goes on:—

> "Non alias coelo ceciderunt plura sereno
> Fulgura; nec diri toties arsere cometae."

It is very singular that he should thus have associated comets and meteorites, which quite recent astronomical discovery has shown to have a common origin.

Another remarkable peculiarity, long ago observed, is the characteristic smell produced when lightning strikes a building or a ship. In old times it was supposed to be sulphurous; nowadays we know it to be mainly due to ozone. In fact, all the ready modes of forming ozone which are as yet at the disposal of the chemist depend upon applications of electricity. But besides ozone, which is formed from the oxygen of the air, there are often produced nitric acid, ammonia, and other compounds derived from the constituents of air and of aqueous vapour. All these results can be produced on a small scale in the laboratory.

Hitherto I have been speaking of lightning discharges similar in kind to the ordinary electric spark, what is commonly called *forked* or *zig-zag* lightning. Our nomenclature is very defective in this matter, and the same may be said of the chief modern European languages. For, as Arago remarks, by far the most common form of lightning flash observed in thunderstorms is what we have to particularise, for want of a better term, as *sheet-lightning*. He asserts that it occurs thousand-fold as often as forked lightning; and that many people have never observed the latter form at all! It is not at all easy to conceive what can be the nature of sheet-lightning, if it be not merely the lighting up of the clouds by a flash of forked lightning not directly visible to the spectator. That this is, at least in many cases, its origin is evident from the fact that its place of maximum brightness often takes the form of the *edge* of a cloud, and that the *same* cloud-edge is occasionally lit up several times in quick succes-

[1] Abstract of a lecture, delivered in the City Hall, Glasgow, by Prof. Tait. Continued from p. 366.

sion. You will remember that we are at present dealing with the appearances observed *in* a thunderstorm, so that I do not refer to that form of sheet-lightning which commonly goes by the name of *summer-lightning*, and which is not, audibly at least, followed by thunder.

The next remarkable feature of the storm is the thunder, corresponding, of course, on the large scale, to the snap of an electric spark. Here we are on comparatively sure ground, for sound is very much more thoroughly understood than is electricity. We speak habitually and without exaggeration of the *crash* of thunder, the *rolling* of thunder, and of a *peal* of thunder; and various other terms will suggest themselves to you as being aptly employed in different cases. All of these are easily explained by known properties of sound. The origin of the sound is in all cases to be looked for in the instantaneous and violent dilatation of the air along the track of the lightning flash, partly, no doubt, due to the disruptive effects of electricity of which I have already spoken, but mainly due to the excessive rise of temperature which renders the air for a moment so brilliantly incandescent. There is thus an extremely sudden compression of the air all round the track of the spark, and a less sudden, but still rapid, rush of the air into the partial vacuum which it produces. Thus the sound-wave produced must at first be of the nature of a bore or breaker. But as such a state of motion is unstable, after proceeding a moderate distance the sound becomes analogous to other loud but less violent sounds, such as those of the discharge of guns. Were there few clouds, were the air of nearly uniform density, and the flash a short one, this would completely describe the phenomenon, and we should have a thunder *crash* or thunder *clap* according to the greater or less proximity of the seat of discharge. But, as has long been well known, not merely clouds but surfaces of separation of masses of air of different density, such as constantly occur in thunderstorms, *reflect* vibrations in the air; and thus we may have many successive echoes, prolonging the original sound. But there is another cause, often more efficient than these. When the flash is a long one, all its parts being nearly equidistant from the observer, he hears the sound from all these parts simultaneously; but if its parts be at very different distances from him, he hears *successively* the sounds from portions farther and farther distant from him. If the flash be much zig-zagged, long portions of its course may run at one and the same distance from him, and the sounds from these arrive simultaneously at his ear. Thus we have no difficulty in accounting for the *rolling* and *pealing* of thunder. It is, in fact, a mere consequence, sometimes of the reflection of sound, sometimes of the finite velocity with which it is propagated. The usual rough estimate of five seconds to a mile is near enough to the truth for all ordinary calculations of the distance of a flash from the observer.

The extreme distance at which thunder is heard is not great, when we consider the frequent great intensity of the sound. No trustworthy observation gives in general more than about nine or ten miles, though there are cases in which it is possible that it may have been heard fourteen miles off. But the discharge of a single cannon is often heard at fifty miles, and the noise of a siege or naval engagement has certainly been heard at a distance of much more than 100 miles. There are two reasons for this: the first depends upon the extreme suddenness of the production of thunder; the second, and perhaps the more effective, on the excessive variations of density in the atmosphere, which are invariably associated with a thunderstorm. In certain cases thunder has been propagated, for moderate distances from its apparent source, with a velocity far exceeding that of ordinary sounds. This used to be attributed to the extreme suddenness of its production; but it is not easy, if we adopt this hypothesis, to see why it should not occur in all cases. Sir W. Thomson has supplied a very different explanation, which requires no unusual velocity of sound, because it asserts the production of the sound *simultaneously* at all parts of the air between the ground and the cloud from which the lightning is discharged.

We now come to an exceedingly strange and somewhat rare phenomenon, to which the name of *fire-ball* or *globe-lightning* has been given. As we are as yet unable to produce anything of this kind by means of our electrical machines, some philosophers have tried to cut the Gordian knot of the difficulty by denying that any such thing can exist. But, as Arago says, "*Où en serions nous, si nous nous mettions à nier tout ce qu'on ne sait pas expliquer?*" The amount of trustworthy and independent evidence which we possess as to the occurrence of this phenomenon is such as must convince every reasonable man who chooses to pay due attention to the subject. No doubt there is a great deal of exaggeration, as well as much imperfect and even erroneous observation, in almost all of these records. But the existence of the main feature (the fire-*ball*) seems to be proved beyond all doubt.

The most marked peculiarities of this species of lightning-discharge are its comparatively long duration and its comparatively slow motion. While a spark, or lightning-flash, does not last longer than about a millionth part of a second, if so long, globe-lightning lasts from one to ten seconds, sometimes even longer, so that a sufficiently self-possessed spectator has time carefully to watch its behaviour. The general appearance is that of a luminous ball, which must be approximately spherical, because it always appears circular in outline, slowly and steadily descending from a thundercloud to the ground. It bursts with a loud explosion, sometimes before reaching the ground, sometimes as it impinges, and sometimes after actually rebounding. Its size varies from that of a child's head to a sphere of little less than a yard in diameter. On some occasions veritable flashes of lightning were seen to proceed from large fire-balls as they burst. It is difficult to imagine what these balls can be if they be not a species of natural Leyden jar very highly charged. If it be so, no ordinary lightning-rod can possibly prevent danger from it; and we may thus be able to explain the very few cases in which damage has been done by lightning to thoroughly protected buildings. To guard against this form nothing short of a pretty close net-work of stout copper wires would suffice. Meanwhile I give a brief sketch of *two* out of the long series of descriptions of such phenomena which Arago has patiently collected. The first is given on the authority of Babinet, who was deputed by the Academy of Sciences to make inquiries into the case.

Shortly, but not immediately, after a loud peal of thunder, a tailor who was sitting at his dinner saw the paper ornament which covered his fire-place blown down as if by a gentle breeze, and a globe of fire, about the size of a child's head, came gently out and moved slowly about at a slight elevation above the floor. It appeared bright rather than hot, and he felt no sensation of warmth. It approached him like a little kitten which desired to rub itself in play against his legs; but he drew his feet away, and by slow and cautious movements avoided contact with it. It remained several seconds near his feet, while he leaned forward and carefully examined it. At last it rose vertically to about the level of his head, so he threw himself back in his chair and continued to watch it. It then became slightly elongated, and moved obliquely towards a hole pierced to the chimney about a yard above the mantelpiece. This hole had been made for the chimney of a stove which was used in winter. "But," as the tailor said, "the globe could not *see* the hole, for paper had been pasted over it." The globe went straight for the hole, tore off the paper, and went up the chimney. After the lapse of time which, at the rate at which he had seen it moving, it would have required to get to the

top of the chimney, a terrific explosion was heard, and a great deal of damage was done to the chimney and the roofs around it.

The next is even more striking: In June, 1849, in the evening of one of the days when cholera was raging most formidably in Paris, the heat was suffocating, the sky appeared calm, but summer lightning was visible on all sides. Madame Espert saw from her window something like a large red globe, exactly resembling the moon when it is seen through mist. It was descending slowly towards a tree. She at first thought it was a balloon, but its colour undeceived her; and while she was trying to make out what it was she saw the lower part of it take fire ("*Je vis le feu prendre au bas de ce globe*"), while it was still some yards above the tree. The flames were like those of paper burning slowly, with sparks and jets of fire. When the opening became twice or thrice the size of one's hand, a sudden and terrific explosion took place. The infernal machine was torn to pieces, and a dozen flashes of zig-zag lightning escaped from it in all directions. The *débris* of the globe burned with a brilliant white light and revolved like a catherine-wheel. The whole affair lasted for at least a minute. A hole was bored in the wall of a house, three men were knocked down in the street, and a governess was wounded in a neighbouring school, besides a good deal of other damage.

I have never seen one myself, but I have received accounts of more than one of them from competent and thoroughly credible eye-witnesses. In particular on a stormy afternoon in November, 1868, when the sky was densely clouded over, and the air in a highly electrical state, there was heard in Edinburgh one solitary short, but very loud, clap of thunder. There can be no doubt whatever that this was due to the explosion of a fire-ball, which was seen by many spectators, in different parts of the town, to descend towards the Calton Hill, and to burst whilst still about a hundred feet or so above the ground. The various accounts tallied in most particulars, and especially in the very close agreement of the positions assigned to the ball by spectators viewing it from different sides, and in the intervals which were observed to elapse between the explosion and the arrival of the sound.

The remaining phenomena of a thunderstorm are chiefly the copious fall of rain and of hail, and the almost invariable lowering of the barometer. These are closely connected with one another, as we shall presently see.

(To be continued.)

THE BRITISH ASSOCIATION

WE had but just time before going to press last week to indicate the general arrangements made for the reception at Swansea of the British Association. We have now to chronicle the events of the meeting which, although small, has not been destitute of many points of interest. The actual number of members and associates in attendance has been smaller than is shown by the returns for many previous years. This is probably accounted for by the geographical isolation of Swansea and the smallness of its population; but there are doubtless other collateral causes—such, for example, as the coincidence of the meeting of the Iron and Steel Institute at Düsseldorf—which have contributed to discourage a large attendance.

At the General Committee meeting on August 25 the Report of the Council for the year 1879-80 was presented.

The Council having been requested by the General Committee at Sheffield to take such further action as regards the correspondence with the Treasury about the Natural History Collections as they should think desirable in the interests of science, prepared and sent to the Secretary of the Treasury, in reply to his letter of July 22, 1879, the following letter:—

"*British Association for the Advancement of Science,*
"*22, Albemarle Street, London, W., June 8, 1880*

"SIR,—The letter of the Council of this Association, of March 25, 1879, respecting the administration of the Natural History Collections, and your reply thereto of July 22, have been laid before the British Association, at the meeting held at Sheffield in August last, when the subject was again referred to the Council.

"On the part of the Council I am now requested to inform you that they learn with satisfaction that the action of Her Majesty's Government, in passing the British Museum Act of 1878, does not prejudice the question of the future administration of the Natural History Collections at South Kensington, but that the subject is still under the consideration of the Lords Commissioners of Her Majesty's Treasury.

"Under these circumstances the Council of the Association must again express their hope that, when the period arrives, as it must shortly do, for the settlement of the question, the recommendations of the Royal Commission on Science will have their full weight and importance accorded to them.

"If, however, the Lords Commissioners of Her Majesty's Treasury are prepared, as they would seem to indicate, to constitute a Special Standing Committee, or Sub-Committee, of the Trustees of the British Museum, for the management of the Natural History Collections, the Council of the Association are of opinion that such a form of government, though not the form suggested by the Royal Commission on Science, might possibly be so organised as to be satisfactory both to the public and to men of science.

"Trusting that the Lords Commissioners will do the Council the favour of considering these observations on a subject which keenly interests many members of the British Association,

"I have the honour to be, sir,
"Your obedient servant,
"G. J. ALLMAN,
"*President of the British Association for the Advancement of Science.*

"SIR R. R. W. LINGEN, K.C.B., &c., &c."

The receipt of this letter has been acknowledged.

The Council have elected Prof. Cornu, of Paris, and Prof. Boltzmann, of Vienna, Corresponding Members since the Sheffield meeting.

The president's address was very well received; and suffered nothing from the extempore style adopted by Prof. Ramsay, who held his audience to the end. The presidential addresses of the sections were of an unusually high order, and happily no hitch occurred this year to necessitate the delay of any of them beyond the day and hour fixed for their delivery. We reprinted some of them last week, and others will be found in our columns to-day. Of papers in the different sections there has not been, perhaps, as plentiful a supply as in other years, Section G exhibiting a decided lack. There has been certainly a less amount of illustration by diagrams and experiments in the Section meetings than is usual, though several papers in Section A were accompanied by the exhibition of new forms of apparatus. The Neanderthal skull exhibited by Prof. Schaffhausen of Bonn in Section D drew an inquisitive crowd of admirers. The excursions to the local centres of industry—the Dowlais Works, the Landore Steel Works, and the various copper and tin works thrown open by the courtesy of their proprietors—were deservedly popular. Some of these specially invited the notice of Section G, which on the very first day of meeting adjourned for a visit to Dowlais. The promoters of the new East Dock have not omitted to seek for possible shareholders in the members of the Association.

The Saturday excursions to Milford, Gower, St.

David's, &c., were attended by a fair number of visitors, but the exertions of the Excursion Committees had made more than ample accommodation for the limited number of excursionists. The excursions announced for to-day were numerous, and of an interesting character; but several of them have been withdrawn, in consequence of the smallness of the number of applications.

The first of the two evening *soirées* was a reception by the Mayor of Swansea, and was enlivened by some excellent music by a local chorus and orchestra. There were a number of exhibits of machinery in motion, and of products of local industries.

The second of the *soirées* was held on the evening of Tuesday, the 31st, and was more particularly devoted to scientific apparatus. The temporary pavilion in Burrows Square, in which these entertainments were given, was illuminated by the light of the Jamin candle lately described in NATURE, giving an agreeable and brilliant light, though somewhat unsteady, under the disadvantageous conditions under which it had to be set up and worked.

The evening lectures cannot be said to have been largely patronised, although perhaps the geographical difficulties of the town may have accounted to some extent for this state of things. Prof. Boyd Dawkins's discourse on "Primæval Man," excellently delivered and admirably illustrated, was very attentively listened to and enthusiastically applauded. Mr. F. Galton's lecture on "Mental Imagery" was illustrated by diagrams of some of the singular generic photographs with which he has identified his name; great amusement being evoked by the exhibition of the face of a "generalised" Welsh Dissenting minister, compounded from photographs of sundry Nonconformist divines of Swansea. Mr. F. Seebohm lectured on the North-east Passage to a small but very attentive audience of working men on Saturday evening, dwelling more particularly on the heroic exploits of Nordenskjöld and of Capt. Willing.

At the meeting of the General Committee on Monday arrangements were made for the holding next year at York of the jubilee gathering of the Association. The proceedings were unusually interesting and enthusiastic.

Sir John Lubbock was chosen as President, the Vice-Presidents being His Grace the Archbishop of York, and those Past-Presidents of the Association who were living when it was founded in 1831. As Presidents of the Sections the following have been chosen, all of whom are Past-Presidents of the Association:—Mathematics and Physics, Sir William Thomson; Chemistry, Prof. Williamson; Geology, Prof. Ramsay; Biology, Prof. Owen; Geography, Sir J. Hooker; Mechanics, Sir Wm. Armstrong.

After a stout competition between Southampton, Nottingham, and Southport, the first-mentioned of these places was selected for the meeting of 1882.

At the final meeting of the Association on Wednesday, the following grants were made:—

A—Mathematics and Physics	£
Prof. G. C. Foster—Electrical Standards	100
Mr. G. H. Darwin—Lunar Disturbance of Gravity	30
Prof. Everett—Underground Temperatures	20
Dr. Joule—Mechanical Equivalent of Heat	40
Dr. O. J. Lodge—High Insulation Key	5
Sir Wm. Thomson—Seismic Experiments	30
Sir Wm. Thomson.—Tidal Observation	10
Mr. J. M. Thomson.—Inductive Capacity of Crystals and Paraffin	10
B—Chemical Science	
Dr. Gladstone.—Specific Refractions	10
Lord Rayleigh.—Spectrum Analysis	10
C—Geology	
Prof. Duncan—Fossil Polyzoa	10
Mr. J. Evans—Geological Record	100
Prof. E. Hull—Underground Waters	£10
Prof. A. C. Ramsay—Earthquake in Japan	25
Dr. Sorby—Metamorphic Rocks	10
D—Biology	
Dr. M. Foster—Scottish Zoological Station	50
Dr. M. Foster—Naples Zoological Station	75
Mr. Godwin Austen—Natural History of Socotra	50
Prof. Gwyn Jeffreys—Exploration of Sea Bed North of Hebrides	50
General Pitt Rivers—Anthropological Notes	20
Dr. Pye Smith.—Elimination of Nitrogen during Bodily Exercise	50
Mr. P. L. Sclater.—Natural History of Timor Laut	50
Mr. Stainton.—Zoological Record	100
F—Statistics and Economic Science	
Mr. F. Galton.—Estimation of Weights and Heights of Human Beings	30
G—Mechanical Science	
Mr. Bramwell.—Patent Laws	5
Mr. J. Glaisher.—Wind Pressure	5
Prof. O. Reynolds.—Steering Steamships	5

SECTION A

MATHEMATICS AND PHYSICS

OPENING ADDRESS BY PROF. W. GRYLLS ADAMS, M.A., F.R.S., PRESIDENT OF THE SECTION

IT has been said by a former President of this Section of the British Association that the president of a Section ought to occupy your time, not by speaking of himself or his own feelings, but by a review "more or less extensive of those branches of science which form the proper business of his section." He may give a rapid sketch of the progress of mathematical science during the year, or he may select some one special subject, or he may take a middle course, neither so extensive as the first nor so limited as the second.

There are many branches of science which have always been regarded as properly belonging to our section, and the range is already wide; but it is becoming more and more true every day that the sciences which are dealt with in other sections of the Association are becoming branches of Physics, *i.e.*, are yielding results of vast importance when the methods and established principles of Physics are applied to them. I wish to direct your attention to investigations which are being made in that fertile region for discovery, the "border land" between Chemistry and Physics, where we have to deal with the constitution of bodies, and where we are tempted to speculate on the existence of matter and on the nature of the forces by which the different parts of it are bound together, or become so transformed that all resemblance to their former state is lost. It is not long since the theory of exchanges became thoroughly recognised in the domain of Radiant Heat, and yet it is already recognised and accepted in the theory of Chemical Combination. Just as the molecules of a body which remains at a constant temperature are continuously giving up their heat motion to surrounding molecules, and getting back from them as much motion of the same kind in return, so in a chemical compound which does not appear to be undergoing change, the combining molecules are continuously giving up their chemical or combining motions to surrounding molecules, and receiving again from them as much combining motion in return. We may say that each molecule is, as far as we can see, constantly dancing in perfect time with a partner, and yet is continuously changing partners. When such an idea of chemical motion is accepted, we can the more easily understand that chemical combination means the alteration of chemical motion which arises from the introduction of a new element into the space already occupied, and the consequent change in the motion of the new compound as revealed to us in the spectroscope. We can also the more readily understand that in changing from the old to the new form or rate of motion there may be a development of energy in the shape of heat-motion which may escape or become dissipated wherever a means of escape presents itself. We know from the experiments of M. Favre that as much heat is absorbed during the decomposition

of an electrolyte as is given out again by the combination of the substances composing it.

We are making rapid strides towards the exact determination of those relations between the various modes of motion or forms of energy which were so ably shadowed forth, and their existence established long ago, by Sir William Grove in his "Correlation of the Physical Forces," where, in stating the conclusion of his comparison of the mutual interchange of physical forces, he distinctly lays down the principles of energy in this statement: "Each force is definitely and equivalently convertible into any other; and where experiment does not give the full equivalent, it is because the initial force has been dissipated, not lost, by conversion into other unrecognised forces. The equivalent is the limit never practically reached."

The laws of Faraday, that (1) when a compound is electrolysed the mass of the substance decomposed is proportional to the quantity of electricity which has produced the change, and that (2) the same current decomposes equivalent quantities of different substances, *i.e.*, quantities of their elements in the ratio of their combining numbers, have given rise to several determinations of the relation between chemical affinity and electromotive force. In a paper lately communicated to the Physical Society, Dr. Wright has discussed these several determinations, and has given an account of a new determination by himself. The data at present extant show that when one gramme of hydrogen unites with 7·98 grammes of oxygen, there are about 34,100 units of heat given out, making the latent heat of dissociation of one gramme of water equal to 3,797 units. The results obtained are compared with the heat given out by the combustion of hydrogen and oxygen, and the value of the mechanical equivalent of heat is deduced from these determinations.

The value obtained by Dr. Wright, which depends on the value of Clark's standard cell, and therefore depends upon the value of the ohm, agrees fairly well with Joule's determination from the heat produced by an electric current in a wire, but is greater than Joule's value as obtained from his water-friction experiments. This may be accounted for by supposing an error in the value of the ohm or B.A. unit, making it too large by 1·5 or 2 per cent. Kohlrausch has also made comparisons of copies of the B.A. unit with standard coils, and comes to the conclusion that the B.A. unit is 1·96 per cent. too large. On the other hand, Prof. Rowland, in America, has made a new determination, and finds that according to his calculations the B.A. unit is nearly 1 per cent. too small. These differences in the values obtained by different methods clearly point to the necessity for one or more new determinations of the unit, and I would venture to suggest that a determination should be made under the authority of this Association, by a committee appointed to carry out the work. And it is not sufficient that this determination should be made once for all, for there is reason to think that the resistance of standard coils alters with time, even when the material has been carefully selected. It has been found that coils of platinum silver which were correct copies of the standard ohm have become so altered, and have their temperature coefficients so changed, that there are doubts as to the constancy of the standards themselves. Pieces of platinum-silver alloy cut from the same rod have been found to have different temperature coefficients. The value ·031 for 1° C. is given by Matthiessen for this alloy, yet two pieces of wire drawn from the same rod have given, one ·021 per cent. and the other ·04 per cent. for 1° C. Possibly this irregularity in the platinum-silver alloys may be due to something analogous to the segregation which Mr. Roberts has found to take place in copper-silver alloys in their molten state, and which Matthiessen in 1860 regarded as mechanical mixtures of allotropic modifications of the alloy.

A recommendation has been made that apparatus for determining the ohm should be set up in London, and that periodically determinations be made to test the electrical constancy of the metals and alloys used in making coils. A committee should be authorised to test coils and issue certificates of their accuracy, just as is done by the Kew Committee with regard to meteorological instruments. The direct relation between Heat and Chemical work has been established, and the principles of Conservation of Energy been shown to be true in Chemistry by the experiments of Berthelot and of Thomsen, so that we may say that when a system of bodies passes through any succession of chemical changes, the heat evolved or absorbed when no external mechanical effect is produced depends solely upon the initial and final tates of the system of bodies, whatever be the nature or the order of the transformations. The extension of this principle to the interaction of the molecules and atoms of bodies on one another is of vast importance in relation to our knowledge of the constitution of matter, for it enables us to state that each chemical compound has a distinct level or potential which may be called its own, and that when a compound gives up one of its elements to another body, the heat evolved in the reaction is the difference between the heat of formation of the first compound and that of the resulting product.

We have become accustomed to regard matter as made up of molecules, and those molecules to be made up of atoms separated from one another by distances which are great in comparison with the size of the atom, which we may regard as the smallest piece of matter that we can have any conception of. Each atom may be supposed to be surrounded by an envelope of ether which accompanies it in all its movements. The density of the ether increases rapidly as an atom is approached, and it would seem that there must be some force of attraction between the atom and its ether envelope. All the atoms have motions of translations in all possible directions, and according to the theories of Maxwell and Boltzmann, and the experiments of Kundt, Warburg, and others on the specific heat of vapours, in *one-atom* molecules in the gaseous state there is no motion of rotation. According to the theory of Pictet, the liquid state, being the first condensation from the gaseous state, must consist of at least two gaseous atoms combined. These two atoms are bound to one another through their ether envelopes. Then the solid state results from the condensation of a liquid, and so a solid molecule must consist of at least two liquid molecules, *i.e.* at least four gaseous molecules, each surrounded by an atmosphere of ether. M. Pictet imagines these atoms to be centres of attraction; hence in the solid with four such centres the least displacement brings into action couples tending to prevent the molecule from twisting as soon as external forces act upon it. All the molecules constituting a solid will be rigidly set with regard to one another, for the least displacement sets in action a couple or an opposing force in the molecules on one another.

Let us now follow the sketch which M. Pictet has given of changes which we may consider it to undergo when we expend energy upon it. Suppose a solid body is at absolute zero of temperature, which may be regarded as the state in which the molecules of a body are in stable equilibrium and at rest, the application of heat gives a vibratory motion to the molecules of the solid, which increases with the temperature, the mean amplitude of vibration being a measure of the temperature. We may regard the sum of all the molecular forces as the specific heat of the body, and the product of the sum of all the molecular forces by the mean amplitude of the oscillations; *i.e.* the product of the specific heat and the temperature will be the quantity of heat or the energy of motion of the body. As more and more heat is applied, the amplitude of vibration of the molecules increases until it is too great for the molecular forces, or forces of cohesion, and the melting point of the solid is reached. Besides their vibratory motion, the molecules are now capable of motions of translation from place to place among one another. To reduce the solid to the liquid state, *i.e.* to make the amplitude of vibration of the molecules sufficient to prevent them from coming within the sphere of the forces of cohesion, requires a quantity of heat which does not appear as temperature or molecular motion, and hence it is termed the latent heat of fusion. The temperature remains constant until the melting is complete, the heat being spent in bursting the bonds of the solid. Then a further application of heat increases the amplitude of vibration, or raises the temperature of the liquid at a rate depending on its specific heat until the succession of blows of the molecules overcomes the external pressure and the boiling-point is reached An additional quantity of heat is applied which is spent in changing the body to a gas, *i.e.*, to a state of higher potential, in which the motion of translation of the molecules is enormously increased. When this state is attained, the temperature of the gas again begins to increase, as heat is applied, until we arrive at a certain point, when dissociation begins, and the molecules of the separate substances of which the body is composed have so large an amplitude of vibration that the bond which unites them can no longer bring them again into their former positions. The potential of the substances is again raised by a quantity which is proportional to its chemical affinity. Again, we may increase the amplitude of vibration, *i.e.*, the temperature of the molecules, and imagine the possibility of higher and higher degrees of dissociation.

If temperature means the amplitude of vibration of the molecules, then we might expect that only those bodies which have their temperatures increased by the same amount when equal amounts of heat are applied to them can possibly combine with one another; and so the fact that the increase of temperature bears a fixed ratio to the increase of heat may be the cause in virtue of which bodies can combine with one one another. Were other bodies to begin to combine together at any definite temperature, they would immediately be torn to pieces again when the temperature is even slightly raised, because the amplitudes of vibration of their molecules no longer remain the same. This idea of temperature is supported by the fact that a combining molecule of each substance requires the same amount of heat to raise its temperature by the same number of degrees, the atomic weights being proportional to the masses of the combining molecules. The celebrated discovery of Faraday, that in a voltameter the work done by an electric current always decomposes equivalent quantities of different substances, combined with the fact that in the whole range of the physical forces work done is equivalent to the application of heat, is quite in accordance with the view that no molecule can combine with another which has not its amplitude of vibration altered by the same amount when equal quantities of heat are applied to both. As soon as we get any divergence from this state of equal motions for equal increments of heat, then we should expect that a further dissociation of molecules would take place, and that only those which are capable of moving together can remain still associated.

Just as in the change of state of a body from the solid to the liquid, or from the liquid to the gas, a great amount of heat is spent in increasing the motion of translation of the molecules without altering the temperature, so a great amount of heat is spent in producing dissociation without increasing the temperature of the dissociated substances, since the principle of conservation of energy has been shown by M. Berthelot to hold for the dissociation of bodies. We may conveniently make use of the term latent heat of dissociation for, the heat required to dissociate a unit of mass of a substance.

We may thus sum up the laws of physical and chemical changes :—

1. All the physical phenomena of change of state consist in the subdivision of the body into molecules or particles identical with one another.

2. The reconstitution of a body into a liquid or a solid being independent of the relative position of the molecules, only depends on the pressure and temperature.

3. Dissociation separates bodies into their elements, which are of different kinds, and the temperature remains constant during dissociation.

4. The reunion of dissociated bodies depends on the relative position of the elements, and so depends on the grouping of the molecules. The atomic weight being the mass of a molecule as compared with hydrogen, the specific volume, *i.e.*, the atomic weight divided by the density, is the volume or *mean free path* of a molecule.

Building up his theory of heat on these principles, M. Pictet arrives at a definite relation between the atomic weight of a body, its density, its melting-point, and its coefficient of expansion, which may be stated thus—

The volume of a solid body will be increased as the temperature rises by an amount which is proportional to the number of molecules in it, and inversely as its specific heat. At a certain temperature peculiar to each body, the amplitude of the heat oscillation is sufficient to melt the solid, and we are led to admit that for all bodies the intermolecular distance corresponding to fusion ought to be the same. The higher the point of fusion of a body, the shorter, on this theory, must be its heat vibrations. The product of the length of *swing* (the heat oscillations) by the temperature of fusion ought to be a constant number for all solid bodies.

A comparison of the values of the various quantities involved in these statements shows a very satisfactory agreement between theory and experiment, from which it appears that for many different substances the product of the length of swing by the temperature of fusion lies between 3·3 and 3·7 for most substances. Not many values of the latent heat of dissociation have been made. In order to determine it, say, for the separation of oxygen and hydrogen, we should have to determine the amount of work required to produce a spark in a mixture of oxygen and hydrogen, and to measure the exact amount of water or vapour of water combined by the spark as well as the range of temperature through which it had passed after its formation. Very few such determinations have been made.

Our usual mode of producing heat is by the combination of the molecules of different substances, and we are limited in the production of high temperatures, and in the quantity of available heat necessary to dissociate any considerable quantity of matter. If we heat vapours or gases, we may raise their temperatures up to a point corresponding to the dissociation of their molecules, and we are limited in our chemical actions to the temperatures which can be obtained by combining together the most refractory substances, as we are dependent on this combination for our supply of heat.

The combination of carbon and hydrogen with oxygen will give us high temperatures, so that by the oxyhdrogen blow-pipe most of the salts and oxides are dissociated. The metalloids bromine, iodine, sulphur, potassium, &c., are the results of the combination of two or more bodies bound together by internal forces much stronger than the affinity of hydrogen or carbon for oxygen, for approximately they obey the law of Dulong and Petit.

For higher temperatures, in order to dissociate the most refractory substances, we require the electric current, either a continuous current, as in the electric arc from a battery or a dynamo-machine, or, more intense still, the electrical discharges from an electrical machine or from an induction coil.

This electric current may be regarded as the most intense furnace for dissociating *large* quantities of the most refractory substances, and the electric spark may be regarded as something very much hotter than the oxyhydrogen blow-pipe, and therefore of service in reducing very small quantities of substances which will yield to no other treatment. The temperature of the electric arc is limited, and cannot reach above the temperature of dissociation of the conductor, and in the case of the constant current, which will not leap across the smallest space of air unless the carbons have first been brought in contact, the current very soon ceases when the point of fusion has been reached. Yet in the centre of the arc we have the gases of those substances which form the conductor; and, as Prof. Dewar has shown, we have the formation of acetylene and cyanogen and other compounds, and therefore must have attained the temperature necessary for their formation, *i.e.* the temperature of their dissociation. The temperature of the induction spark, or, at least, its dissociating power, is higher than that of the arc. We know that the spark will pass across a space of air or a gaseous conductor, and we are limited by the dissociation of the gaseous conductor, and get only very small quantities of the dissociated substances, which immediately recombine, unless they are separated. If the gases formed are of different densities they will diffuse at different rates through a porous diaphragm, and so may be obtained separated from one another. As the molecules of bodies vibrate they produce vibrations of the ether particles, the period of the oscillations depends on the molecules of the body, and these periodic vibrations are taken up by their ether envelopes and by the luminiferous ether, and their wave-length determined by means of the spectroscope. The bright-line spectrum may be regarded as arising from the vibratory motions of the atoms. As the temperature is increased, the amplitudes of oscillation of the molecules and of the ether increase, and from the calculations of Lecoq de Boisbaudran, Stoney, Soret, and others, it would appear that many of the lines in the spectra of bodies may be regarded as harmonics of a fundamental vibration. Thus Lecoq de Boisbaudran finds that in the nitrogen spectrum the blue lines seen at a high temperature correspond to the double octave of certain vibrations, and that, at a lower temperature, red and yellow lines are seen which correspond to a fifth of the same fundamental vibrations.

The bright-line spectrum may be regarded as arising from the vibratory motions of the atoms. A widening of the lines may be produced at a higher temperature by the backward and forward motions of the molecules in the direction of the observer. A widening of the lines may also be produced by increase of pressure, because it diminishes the free path of the molecules, and the disturbances of the ether arising from collisions become more important than vibrations arising from the regular vibrations of the atoms.

Band spectra, or chanelled space spectra, more readily occur in the case of bodies which are not very readily subject to chemical actions, or, according to Professors Liveing and Dewar, in the case of cooler vapours near the point of liquefaction.

The effects of change of temperature on the character of spectra is very well illustrated by an experiment of M. Wiedemann with mixtures of mercury with hydrogen or nitrogen in a Geissler's tube. At the ordinary temperature of the air the spectrum of hydrogen or nitrogen was obtained alone; but on heating the tube in an air-bath the lines of mercury appeared and became brighter as the temperature rose, and at the same time the hydrogen lines disappeared in the wider portion of the tube and at the electrodes. The hydrogen or nitrogen lines disappeared first from the positive electrode and in the luminous tuft, and as the temperature rose disappeared altogether. With nitrogen in a particular experiment, up to 100° C., the nitrogen lines were seen throughout the tube, but from 100° to 230° the nitrogen lines appear towards the negative pole, and the mercury lines are less bright at the negative than at the positive pole, while at about 230° C. no nitrogen lines appear. The experiments of Roscoe and Schuster, of Lockyer and other observers, with potassium, sodium, and other metalloids in vacuum tubes, from which hydrogen is pumped by a Sprengel pump, also show great changes in the molecular condition of the mixture contained in the tubes when they are heated to different temperatures. The changes of colour in the tube are accompanied by changes in the spectrum. Thus, Lockyer finds that when potassium is placed in the bottom of the tube, and the spark passes in the upper part of it, as the exhaustion proceeds and the tube is slightly heated, the hydrogen lines disappear, and the red potassium line makes its appearance; then as the temperature is increased, the red line disappears, and three lines in the yellowish-green make their appearance, accompanied by a change in the colour of the tube, and at a higher temperature, and with a Leyden jar joined to a secondary circuit of the induction coil, the gas in the tube becomes of a dull red colour, and with this change a strong line comes out in the spectrum, more refrangible than the usual red potassium line. In this case, on varying the conditions, we get a variation in the character of the spectrum, and the colours and spectra are different in different parts of the tube. In Lockyer's experiments, at the temperature of the arc obtained from a Siemens' dynamo-machine, great differences appear in different parts of the arc: for instance, with carbon poles in the presence of calcium, the band spectrum of carbon, or the carbon flutings and the lines of calcium, some of them reversed, are seen separated in the same way as mercury and hydrogen, the carbon spectrum appearing near one pole and the calcium near the other, the lines which are strongest near that pole being reversed or absorbed by the quantity of calcium vapour surrounding it. On introducing a metal into the arc, lines appear which are of different intensities at different distances from the poles, others are strong at one pole and entirely absent at or near the other, while some lines appear as broad as half-spindles in the middle of the arc, but are not present near the poles. Thus, the blue line of calcium is visible alone at one pole, the H and K line without the blue lines at the other.

We may probably regard these effects as the result, not of temperature alone, but must take into account that we have powerful electric currents which will act unequally on the molecules of different bodies according as they are more or less electro-positive. It would seem that we have here something analogous to the segregation which is observed in the melting of certain alloys to which I have already referred.

The abundance of material in some parts of the arc surrounding the central portion of it gives rise to reversal of the principal lines in varying thicknesses over the arc and poles, so that bright lines appear without reversal in some regions, and reversals or absorption lines without bright lines in others. The introduction of a substance into the arc gives rise to a flame of great complexity with regard to colour and concentric envelopes, and the spectra of these flames differ in different parts of the arc. Thus in a photograph of the flame given by manganese, the line at wave-length 4234·5 occurs without the triplet near 4030, while in another the triplet is present without the line 4234·5.

The lines which are reversed most readily in the arc are generally those the absorption of which is most developed in the flame; thus the manganese triplet in the violet is reversed in the flame, and the blue calcium line is often seen widened when the H and K lines of calcium are not seen at all. In consequence of the numerous changes in spectra at different temperatures, Mr. Lockyer has advanced the idea that the molecules of elementary matter are continually being more and more broken up as their temperature is increased, and has put forward the hypothesis that the chemical elements with which we are acquainted are not simple bodies, but are themselves compounds of some other more simple substances. This theory is founded on Mr. Lockyer's comparisons of spectra and the maps of Ångström, Thalén, Young, and others, in which there are coincidences of many of the short lines of the spectra of different substances. These short lines are termed basic lines, since they appear to be common to two or more substances. They appear at the highest temperatures when the longest lines of those substances and those which are considered the test of their presence are entirely absent.

Mr. Lockyer draws a distinction between weak lines, which are basic, *i.e.* which would permanently exist at a higher temperature in a more elementary stage, and other weak or short lines which would be more strongly present at a lower temperature, in a more complex stage of the molecules. Thus, in lithium, the red line is a low temperature line, and the yellow is feeble; at a higher temperature, the red line is weak, the yellow comes out more strongly, and the blue line appears; at a higher temperature still, the red line disappears, and the yellow dies away; whilst at the temperature of the sun the violet lithium line is the only one which comes out strongly. These effects are studied by first producing the spectrum of the substance in the Bunsen flames, and observing the changes which are produced on passing a spark through the flame; thus, in magnesium, a wide triplet or set of three lines (5209·8, b^1 and b^2) is changed into a narrow triplet (b^1, b^2, and b^4) of the same character. We have here what some observers regard as a recurrence of the same harmonic relation of the vibrations of the same body at a higher temperature.

If the so-called elements are compounds, they must have been formed at a very high temperature, and as higher and higher temperatures are reached the dissociation of these compound bodies will be effected, and the new line spectra, the real basic lines of those substances which show coincidences, will make their appearance as short lines in the spectra. In accordance with this view, Mr. Lockyer holds that the different layers of the solar atmosphere may be regarded as a series of furnaces, on the hottest of which, A, we have the most elementary forms of matter capable of existing only in its uncombined state; at a higher and cooler level, B, this form of matter may form a compound body, and may no longer exist in a free state at the lower temperature; as the cooler and cooler levels, C, D, and E, are reached, the substances become more and more complex and form different combinations, and their spectra become altered at every stage. Since the successive layers are not at rest, but in a state of disturbance, we may get them somewhat mixed, and the lines at the cooler levels D and E may be associated with the lines of the hotter levels; these would be basic or coincident lines in the spectra of two different compounds which exist at the cooler levels D and E. We might even get lines which are not present in the hottest furnace A coming into existence as the lines of compounds in B or C, and then extending among the lines belonging to more complex compounds which can only exist at a lower temperature, when they might be present as coincident weak lines in the spectra of several compound bodies. Thus Mr. Lockyer regards the calcium lines H and K of the solar spectrum as evidence of different molecular groupings of more elementary bodies. In the electric arc with a weak current the single line 4226 of calcium, which is easily reversed, is much thicker than the two lines H and K; but the three lines are equally thick with a stronger current and are all reversed. With a spark from a large coil and using a condenser the line 4226 disappears, and H and K are strong lines. In the sun, the absorption bands H and K are very broad, but the band 4226 is weak. Prof. Young, in his observation of the lines of the chromosphere, finds that H and K are strongly reversed in every important spot and in solar storms; but the line 4226, so prominent in the arc, was only observed three times in the chromosphere.

One of the most interesting features among the most recent researches in spectrum analysis is the existence of rhythm in the spectra of bodies, as has been shown by MM. Mascart, Cornu, and others, such as the occurrence and repetition of sets of lines, doublets, and triplets in the spectra of different substances and in different parts of the spectrum of the same body. Professors Liveing and Dewar, using the reversed lines in some cases for the more accurate determination of wave-lengths, have traced out the rhythmical character in the spectra of sodium, potassium, and lithium. They show that the lines of sodium and potassium form groups of four lines each, which recur in a regular sequence,

while lithium gives single lines, which, including the green line, which they show really to belong to lithium, though it was ascribed to cæsium by Thalén, also recur in a similar way. In these three metals the law of recurrence seems to be the same, but the wave-lengths show that the whole series are not simple harmonics of one fundamental, although between some of the terms very simple harmonic relations can be found. Between the lines G and H are two triplets of iron lines, which, according to Mr. Lockyer, do not belong to the same molecular grouping as most of the other lines. In many photographs of the iron spectrum these triplets have appeared almost alone. Also the two triplets are not always in the same relation as to brightness, the more refrangible being barely visible with the spark; combining this with Young's observations, in which some short weak lines near G appear in the chromosphere 30 times, while one of the lines of the less refrangible triplet only appears once, and with the fact that in the solar spectrum the more refrangible triplet is much the more prominent of the two, Mr. Lockyer is led to the conclusion that these two triplets are again due to two distinct molecular groupings.

There is one difficulty which must be taken account of in connection with Mr. Lockyer's theory with regard to the production of successive stages of dissociation by means at our command: (1) by combustion of different substances; (2) by an electric arc, which will probably give different temperatures according as it is produced by different dynamo-electric machines; (3) by the induction spark without; and (4) with a condenser.

At each stage of the process there must be a considerable absorption of heat to produce the change of state, and our supply of heat is limited in the electric arc because of the dissociation of the conductors, and more limited still in quantity in the electric spark or in the discharge through a vacuum tube. Also we should expect a recombination of the dissociated substances immediately after they have been first dissociated. Hence it seems easier to suppose that at temperatures which we can command on the earth, the dissociation of molecules by the arc or the spark is accompanied by the formation of new compounds, in the formation of which heat and light, and especially chemical vibrations, would be again given out, thus giving rise to new spectra, rather than to suppose that we can reach the temperature necessary for successive stages of dissociation.

To the lines C, F, the line near G, and *h* belonging to hydrogen, which have a certain rhythmical character, Mr. Lockyer adds D_3 and Kirchhoff's line "1474," regarding "1474" as belonging to the coolest or most complex form, rising to F at a higher temperature, which is again subdivided into C and G, using the spark without a condenser, which again gives *h* with the spark and condenser, which is again split up and gives D_3, a more simple line than *h*, in the Chromosphere. Professors Liveing and Dewar, on the other hand, trace a rhythmical character or ratio between three of the brightest lines of the Chromosphere, two of which are lines "1474" and "f" of Lorenzoni similar to the character of C, F, and *h* of hydrogen, and also trace a similar relation between the chromospheric line D_3 and "1474" to the ratio of the wave-lengths of F and the line near G. They infer the probability that these four lines are due to the same at present unknown substance, as had been suggested by Young with regard to two of them. The harmony of this arrangement is somewhat disturbed by the fact that D_3 lies on the wrong side of "1474" to correspond with the line near G of the hydrogen spectrum.

If we inquire what our sun and the stars have to say to these changes of spectra of the same substance at different temperatures, Dr. Huggins gives us the answer.

In the stars which give a very *white* light, such as Sirius or *a* Lyræ, we have the lines G and *h* of hydrogen and also H, which has been shown by Dr. Vogel to be coincident with a line of hydrogen; but the K line of calcium is weak in *a* Lyræ, and does not appear in Sirius. In passing from the white or hottest stars to the yellow stars like our sun, the typical lines diminish in breadth and are better defined, and K becomes stronger relatively to H, and other lines appear. In Arcturus we have a star which is probably cooler than our sun, and in it the line K is stronger in relation to H than it is in the solar spectrum, both being very strong compared with their state in the solar spectrum.

Professors Liveing and Dewar find that K is more easily reversed than H in the electric arc, which agrees with the idea that this line is produced at a lower temperature than H.

Besides the absence or weakness of K, the white stars have twelve strong lines winged at the edges, in which there are three of hydrogen, viz. G, *h*, and H, and the remaining nine form a group which are so related to one another that Dr. Huggins concludes they probably belong to one substance. Three of these lines are said by Dr. Vogel to be lines of hydrogen. Liveing and Dewar have made considerable progress in determining the conditions and the order of reversal of the spectral lines of metallic vapours. They have adopted methods which allow them to observe through greater thicknesses of vapour than previous observers have generally employed. For lower temperatures tubes of iron or other material placed vertically in a furnace were used, and the hot bottom of the tube was the source of light, the absorption being produced by vapours of metals dropped into the hot tube and filling it to a greater or less height. By this means many of the more volatile metals, such as sodium, thallium, iridium, cæsium, and rubidium, magnesium, lithium, barium, strontium, and calcium, each gave a reversal of its most characteristic line or pair of lines, *i.e.* the red line of lithium, the violet lines of rubidium and calcium, the blue line of strontium, the sharp green line of barium (5535), and no other lines which can certainly be ascribed to those metals in the elementary state.

For higher temperatures tubes bored out in blocks of lime or of gas carbon, and heated by the electric arc, were used. By keeping up a supply of metal and in some cases assisting its volatilisation by the admixture of a more volatile metal, such as magnesium, and its reduction by some easily oxidisable metal, such as aluminium, or by a current of coal gas or hydrogen, they succeeded in maintaining a stream of vapour through the tube so as to reverse a great many lines. In this way the greater part of the bright lines of the metals of the alkalies and alkaline earths were reversed, as well as some of the strongest lines of manganese, aluminium, zinc, cadmium, silver, copper, bismuth, and the two characteristic lines of iridium and of gallium. By passing an iron wire into the arc through a perforated carbon electrode they succeeded in obtaining the reversal of many of the lines of iron. In observing bright-line spectra they have found that the arc produced by a De Meritens machine arranged for high tenison gives, in an atmosphere of hydrogen, the lines C and F, although the arc of a powerful Siemens machine does not bring them out, and they have observed many metallic lines in the arc which had not been previously noticed. The temperature obtained by the De Meritens machine is thus higher than that obtained in the Siemens machine.

From observations on weighed quantities of sodium, alone and as an amalgam, introduced into a hot bottle of platinum filled with nitrogen, of which the pressure was varied by an air-pump, they conclude that the width of the sodium lines depends rather on the thickness and temperature of the vapour than upon the whole quantity of sodium present. Very minute quantities diffused into the cool part of the tube gave a broad diffuse absorption, while a thin layer of compressed vapour in the hot part of the tube give only narrow absorption lines. Professors Liveing and Dewar have observed the reversal of some of the well-known bands of the oxides and chlorides of the alkaline earth metals. The lines produced by magnesium in hydrogen form a rhythmical series extending all across the well-known B group, having a close resemblance in general character to the series of lines produced by an electric discharge in a vacuum tube of olefiant gas.

The series appears at all temperatures except when a large condenser is employed along with the induction coil, provided hydrogen is present as well as magnesium, while they disappear when hydrogen is excluded, and never appear in dry nitrogen or carbonic oxide.

From their experiments on carbon spectra they conclude with Ångström and Thalén that certain of the so-called "carbon bands" are due to some compound of carbon with hydrogen, probably acetylene, and that certain others are due to a compound of carbon with nitrogen, probably cyanogen.

They describe some ultra-violet bands: one of them coincides with the shaded band P of the solar spectrum which accompanies the other violet bands in the flame of cyanogen as well as in the arc and spark between carbon electrodes in the nitrogen. All the bands which they ascribe to a compound of carbon and nitrogen disappear when the discharge is taken in a non-nitrogenous gas, and they reappear on the introduction of a minute quantity of nitrogen.

They appear in the flame of hydrocyanic acid, or of cyanogen, even when cooled down as much as possible as shown by Watts,

or when raised to the highest temperature by burning the cyanogen in nitric oxide; but no flames appear to give these bands unless the burning substance contains nitrogen already united with carbon. As the views of Mr. Lockyer with regard to the multiple spectre of carbon have very recently appeared in the pages of NATURE, I need only say that these spectra are looked upon as supporting his theory that the different flutings are truly due to carbon, and that they represent the vibrations of different molecular groupings. The matter is one of very great interest as regards the spectra of comets, for the bands ascribed to acetylene occur in the spectra of comets without the bands of nitrogen, showing that either hydrocarbons must exist ready formed in the comets, in which case the temperature need not exceed that of an ordinary flame, or else nitrogen must be absent, as the temperature which would produce acetylene from its elements would also produce cyanogen, if nitrogen were present.

Quite recently, Professors Liveing and Dewar have, simultaneously with Dr. Huggins, described an ultra-violet emission spectrum of water, and have given maps of this spectrum. It is not a little remarkable that by independent methods these observers should have deduced the same numbers for the wave-lengths of the two strong lines at the most refrangible end of this spectrum.

Great attention has been paid by M. Mascart and by M. Cornu to the ultra-violet end of the solar spectrum. M. Mascart was able to fix lines in the solar spectrum as far as the line R (3179), but was stopped by the faintness of the photographic impression. Prof. Cornu has extended the spectrum still farther to the limit (2948), beyond which no further effect is produced, owing to complete absorption by the earth's atmosphere. A quartz-reflecting prism was used instead of a heliostat. The curvature of the quartz lens was calculated so as to give minimum aberration for a large field of view. The Iceland spar prism was very carefully cut. A lens of quartz was employed to focus the sun on the slit. Having photographed as far as possible by direct solar light, Prof. Cornu compared the solar spectrum directly by means of a fluorescent eye-piece with the spectrum of iron, and then obtained, by photography, the exact positions of the iron lines which were coincident with observed lines in the solar spectrum. M. Cornu states that the dark absorption lines in the sun and the bright iron lines of the same refrangibility are of the same relative importance or intensity in their spectra, indicating the equality between the emissive and the absorbing powers of metallic vapours; and he thinks that we may get by the comparison of bright spectra with the sun some rough approximation to the quantity of metallic vapours present in the absorption layers of the sun's atmosphere. He draws attention to the abundance of the magnetic metals—iron, nickel, and magnesium—and to the fact that these substances form the composition of most meteorites. M. Cornu has studied the extent of the ultra-violet end of the spectrum, and finds that it is more extended in winter than in summer, and that, at different elevations, the gain in length of the spectrum for increase of elevation is very slow, on account of atmospheric absorption, so that we cannot hope greatly to extend the spectrum by taking elevated observing stations. The limit of the solar spectrum is reached very rapidly, and the spectrum is sharply and completely cut off at about the line U (wave-length 2948). From photographs taken at Viesch in the valley of the Rhone, and at the Riffelberg, 1910 metres above it, M. Cornu finds the limits to be at wave-lengths 2950 and 2930 respectively.

In the actual absorption of bright-line spectra by the earth's atmosphere, M. Cornu observed among others three bright-lines of aluminium, which M. Soret calls 30, 31, and 32 (wave-lengths about 1988, 1930, and 1860), and he found that 32 could not be seen at the distance of 6 metres; but on using a collimator and reducing the distance to 1½ metres, the line 32 became visible, notwithstanding the absorption of the extra lens; at 1 metre, line 32 was brighter than 31, and at a quarter of a metre 32 was brighter than either 30 or 31. With a tube 4 metres in length between the collimator and prism ray 32 is not seen; but when the tube is exhausted, ray 31 gains in intensity and 32 comes into view, and gradually gets brighter than 31, whilst 30 changes very little during the exhaustion. With the same tube he found no appreciable difference between the absorption by air very carefully dried and by moist air, and concludes that this absorption is not due to the vapour of water, and it follows the law of pressure of the atmosphere which shows it to be due to the whole mass or thickness of the air. Also, M. Soret has shown that water acts very differently on the two ends of the spectrum, distilled water being perfectly transparent for the most refrangible rays, since a column of water of 116 c.m. allowed the ray 2060 in the spectrum of zinc to pass through; on the other hand, water is so opaque to the ultra-red rays that a length of 1 c.m. of it reduces the heat spectra of metals to half their length and one quarter of their intensity.

In concluding my address, I wish to draw attention to some of those magnetic changes which are due to the action of the Sun, and which are brought about by means of the ether which brings to us his radiant heat and light. In his discussion of the magnetic effects observed on the earth's surface, General Sabine has shown the existence of diurnal variations due to the magnetic action of the sun; also the magnetic disturbances, aurora and earth-currents, which are now again beginning to be large and frequent, have been set down to disturbances in the sun.

Although iron, when raised to incandescence, has its power of attracting a magnet very greatly diminished, we have no proof that it has absolutely no magnetic power left, and with a slight magnetic action the quantity of iron in the sun would be sufficient to account for the diurnal variations of the magnetic needle. During the last few weeks I have been engaged in examining the declination curves for the month of March, 1879, which have been kindly lent to the Kew Committee by the directors of the Observatories of St. Petersburg, Vienna, Lisbon, Coimbra, and Stonyhurst. Other curves are on their way from more distant stations, but have not yet been examined. On comparing them with the Kew curves for the same period, I find the most remarkable coincidences between the curves from these widely-distant stations. It was previously known that there was a similarity between disturbances at different stations, and in one or two cases a comparison between Lisbon and Kew had been made many years ago by Señor Capello and Prof. Balfour Stewart, but the actual photographic magnetic records from several stations have never been previously collected, and so the opportunity for such comparisons had not arisen. Allow me to draw attention to a few of the more prominent features of these comparisons which I have made. On placing the declination curves over one another, I find that in many cases there is absolute agreement between them, so that the rate of change of magnetic disturbances at widely-distant stations like Kew, Vienna, and St. Petersburg, is precisely the same; also similar disturbances take place at different stations at the same absolute time. It may be stated generally, for large as well as small disturbances, that the east and west deflections of the declination needle take place at the same time and are of the same character at these widely-distant stations.

There are exceptions to this law. Some disturbances occur at one or two stations and are not perceived at another station. Many instances occur, where, up to a certain point of time, the disturbances at all the stations are precisely alike, but suddenly at one or two stations the disturbance changes its character: for instance, on comparing Kew and St. Petersburg, we get perfect similarity followed by deflections of the needle opposite ways at the same instant, and in some such cases the maxima in opposite directions are reached at the same instant, showing that the opposite deflections are produced by the same cause, and that the immediate cause or medium of disturbance in such a case is not far off; probably it is some change of direction or intensity of the earth's magnetism arising from solar action upon it.

Generally, after an hour or two, these differences in the effects of the disturbance vanish, and the disturbances again become alike and simultaneous. In such cases of difference, if the curve tracing of the horizontal or the vertical force be examined, it is generally found that, at the very same instant of absolute time, with the beginning of these opposite movements there was an increase or a diminution in the horizontal force, and that the horizontal force continues to change as long as there is any difference in the character of the declination curves. It is clear then from these effects that the cause or causes of magnetic disturbances are in general far distant from the earth's surface, even when those disturbances are large; but that not unfrequently these causes act on magnetic matter nearer to the surface of the earth, and therefore at times between two places of observation, and nearer to one than another, thus producing opposite effects on the declination needle at those places; in such cases the differences are probably due to changes in the earth's magnetic force. Now,

if we imagine the masses of iron, nickel, and magnesium in the sun to retain even a slight degree of magnetic power in their gaseous state—and we know from the researches of Faraday that gases are some of them magnetic—we have a sufficient cause for all our terrestrial magnetic changes, for we know that these masses of metal are ever boiling up from the lower and hotter levels of the sun's atmosphere to the cooler upper regions, where they must again form clouds to throw out their light and heat, and to absorb the light and heat coming from the hotter lower regions; then they become condensed and are drawn again back towards the body of the sun, so forming those remarkable dark spaces or sun-spots by their downrush towards the lower levels.

In these vast changes, which we know from the science of energy must be taking place, but of the vastness of which we can have no conception, we have abundant cause for these magnetic changes which we observe at the same instant at distant points on the surface of the earth, and the same cause acting by induction on the magnetic matter within and on the earth may well produce changes in the magnitude or in the direction of its total magnetic force. These magnetic changes on the earth will influence the declination needles at different places, and will cause them to be deflected; the direction of the deflection must depend on the situation of the earth's magnetic axis or the direction of its motion with regard to the stations where the observations are made. Thus both directly and indirectly we may find in the Sun not only the cause of diurnal magnetic variations, but also the cause of these remarkable magnetic changes and disturbances over the surface of the Earth.

SECTION D

BIOLOGY

Department of Anatomy and Physiology

ADDRESS BY F. M. BALFOUR, M.A., F.R.S., VICE-PRESIDENT OF THE SECTION

IN the spring of the present year Prof. Huxley delivered an address at the Royal Institution, to which he gave the felicitous title of "The Coming of Age of the Origin of Species." It is, as he pointed out, twenty-one years since Mr. Darwin's great work was published, and the present occasion is an appropriate one to review the effect which it has had on the progress of biological knowledge.

There is, I may venture to say, no department of biology the growth of which has not been profoundly influenced by the Darwinian theory. When Messrs. Darwin and Wallace first enunciated their views to the scientific world, the facts they brought forward seemed to many naturalists insufficient to substantiate their far-reaching conclusions. Since that time an overwhelming mass of evidence has, however, been rapidly accumulating in their favour. Facts which at first appeared to be opposed to their theories have one by one been shown to afford striking proofs of their truth. There are at the present time but few naturalists who do not accept in the main the Darwinian theory, and even some of those who reject many of Darwin's explanations still accept the fundamental position that all animals are descended from a common stock.

To attempt in the brief time which I have at my disposal to trace the influence of the Darwinian theory on all the branches of anatomy and physiology would be wholly impossible, and I shall confine myself to an attempt to do so for a small section only. There is perhaps no department of biology which has been so revolutionised, if I may use the term, by the theory of animal evolution as that of Development or Embryology. The reason of this is not far to seek. According to the Darwinian theory the present order of the organic world has been caused by the action of two laws, known as the laws of heredity and of variation. The law of heredity is familiarly exemplified by the well-known fact that offspring resemble their parents. Not only, however, do the offspring belong to the same species as their parents, but they inherit the individual peculiarities of their parents. It is on this that the breeders of cattle depend, and it is a fact of every-day experience amongst ourselves. A further point with reference to heredity to which I must call your attention is the fact that the characters, which display themselves at some special period in the life of the parent, are acquired by the offspring at a corresponding period. Thus, in many birds the males have a special plumage in the adult state. The male offspring is not, however, born with the adult plumage, but only acquires it when it becomes adult.

The law of variation is in a certain sense opposed to the law of heredity. It asserts that the resemblance which offspring bear to their parents is never exact. The contradiction between the two laws is only apparent. All variations and modifications in an organism are directly or indirectly due to its environments; that is to say, they are either produced by some direct influence acting upon the organism itself, or by some more subtle and mysterious action on its parents; and the law of heredity really asserts that the offspring and parent would resemble each other if their environments were the same. Since, however, this is never the case, the offspring always differ to some extent from the parents. Now, according to the law of heredity, every acquired variation tends to be inherited, so that, by a summation of small changes, the animals may come to differ from their parent stock to an indefinite extent.

We are now in a position to follow out the consequences of these two laws in their bearing on development. Their application will best be made apparent by taking a concrete example. Let us suppose a spot on the surface of some very simple organism to become, at a certain period of life, pigmented, and therefore to be especially sensitive to light. In the offspring of this form the pigment-spot will reappear at a corresponding period; and there will therefore be a period in the life of the offspring during which there is no pigment-spot, and a second period in which there is one. If a naturalist were to study the life-history, or, in other words, the embryology, of this form, this fact about the pigment-spot would come to his notice, and he would be justified, from the laws of heredity, in concluding that the species was descended from an ancestor without a pigment-spot, because a pigment-spot was absent in the young. Now, we may suppose the transparent layer of skin above the pigment-spot to become thickened, so as gradually to form a kind of lens, which would throw an image of external objects on the pigment-spot. In this way a rudimentary eye might be evolved out of the pigment-spot. A naturalist studying the embryology of the form with this eye would find that the pigment-spot was formed before the lens, and he would be justified in concluding, by the same process of reasoning as before, that the ancestors of the form he was studying first acquired a pigment-spot and then a lens. We may picture to ourselves a series of steps by which the simple eye, the origin of which I have traced, might become more complicated; and it is easy to see how an embryologist studying the actual development of this complicated eye would be able to unravel the process of its evolution.

The general nature of the methods of reasoning employed by embryologists, who accept the Darwinian theory, is exemplified by the instance just given. If this method is a legitimate one, and there is no reason to doubt it, we ought to find that animals, in the course of their development, pass through a series of stages, in each of which they resemble one of their remote ancestors; but it is to be remembered that, in accordance with the law of variation, there is a continual tendency to change, and that the longer this tendency acts the greater will be the total effect. Owing to this tendency we should not expect to find a perfect resemblance between an animal, at different stages of its growth, and its ancestors; and the remoter the ancestors, the less close ought the resemblance to be. In spite, however, of this limitation, it may be laid down as one of the consequences of the law of inheritance that every animal ought, in the course of its individual development, to repeat with more or less fidelity the history of its ancestral evolution.

A direct verification of this proposition is scarcely possible. There is ample ground for concluding that the forms from which existing animals are descended have in most instances perished; and although there is no reason why they should not have been preserved in a fossil state, yet, owing to the imperfection of the geological record, palæontology is not so often of service as might have been hoped.

While, for the reasons just stated, it is not generally possible to prove by direct observation that existing forms in their embryonic state repeat the characters of their ancestors, there is another method by which the truth of this proposition can be approximately verified.

A comparison of recent and fossil forms shows that there are actually living at the present day representatives of a considerable proportion of the groups which have in previous times existed on the globe, and there are therefore forms allied to the ancestors of those living at the present day, though not actually

the same species. If therefore it can be shown that the embryos of existing forms pass through stages in which they have the characters of more primitive groups, a sufficient proof of our proposition will have been given.

That such is often the case is a well-known fact, and was even known before the publication of Darwin's works. Von Baer, the greatest embryologist of the century, who died at an advanced age but a few years ago, discussed the proposition at considerable length in a work published between the years 1830 and 1840. He came to the conclusion that the embryos of higher forms never actually resemble lower forms, but only the embryos of lower forms; and he further maintained that such resemblances did not hold at *all*, or only to a very small extent, beyond the limits of the larger groups. Thus he believed that, though the embryos of Vertebrates might agree amongst themselves, there was no resemblance between them and the embryos of any invertebrate group. We now know that these limitations of von Baer do not hold good, but it is to be remembered that the meaning *now* attached by embryologists to such resemblances was quite unknown to him.

These preliminary remarks will, I trust, be sufficient to demonstrate how completely modern embryological reasoning is dependent on the two laws of inheritance and variation, which constitute the keystones of the Darwinian theory.

Before the appearance of the "Origin of Species" many very valuable embryological investigations were made, but the facts discovered were to their authors merely so many ultimate facts, which admitted of being classified, but could not be explained. No explanation could be offered of why it is that animals, instead of developing in a simple and straightforward way, undergo in the course of their growth a series of complicated changes, during which they often acquire organs which have no function, and which, after remaining visible for a short time, disappear without leaving a trace.

No explanation, for instance, could be offered of why it is that a frog in the course of its growth has a stage in which it breathes like a fish, and then why it is like a newt with a long tail, which gradually becomes absorbed, and finally disappears. To the Darwinian the explanation of such facts is obvious. The stage when the tadpole breathes by gills is a repetition of the stage when the ancestors of the frog had not advanced in the scale of development beyond a fish, while the newt-like stage implies that the ancestors of the frog were at one time organised very much like the newts of to-day. The explanation of such facts has opened out to the embryologist quite a new series of problems. These problems may be divided into two main groups, technically known as those of phylogeny and those of organogeny. The problems of phylogeny deal with the genealogy of the animal kingdom. A complete genealogy would form what is known as a natural classification. To attempt to form such a classification has long been the aim of a large number of naturalists, and it has frequently been attempted without the aid of embryology. The statements made in the earlier part of my address clearly show how great an assistance embryology is capable of giving in phylogeny; and as a matter of fact embryology has been during the last few years very widely employed in all phylogenetic questions, and the results which have been arrived at have in many cases been very striking. To deal with these results in detail would lead me into too technical a department of my subject; but I may point out that amongst the more striking of the results obtained *entirely* by embryological methods is the demonstration that the Vertebrata are not, as was nearly universally believed by older naturalists, separated by a wide gulf from the Invertebrata, but that there is a group of animals, known as the Ascidians, formerly united with the Invertebrata, which are now universally placed with the Vertebrata.

The discoveries recently made in organogeny, or the genesis of organs, have been quite as striking, and in many respects even more interesting, than those in phylogeny, and I propose devoting the remainder of my address to a history of results which have been arrived at with reference to the origin of the nervous system.

To render clear the nature of these results I must say a few words as to the structure of the animal body. The body is always built of certain pieces of protoplasm, which are technically known to biologists as cells. The simplest organisms are composed either of a single piece of this kind, or of several similar pieces loosely aggregated together. Each of these pieces or cells is capable of digesting and assimilating food, and of respiring; it can execute movements, and is sensitive to external stimuli, and can reproduce itself. All the functions of higher animals can, in fact, be carried on in this single cell. Such lowly-organised forms are known to naturalists as the Protozoa. All other animals are also composed of cells, but these cells are no longer complete organisms in themselves. They exhibit a division of labour; some carrying on the work of digestion; some, which we call nerve-cells, receiving and conducting stimuli; some, which we call muscle-cells, altering their form—in fact, contracting in one direction—under the action of the stimuli brought to them by the nerve-cells. In most cases a number of cells with the same function are united together, and thus constitute a tissue. Thus the cells which carry on the work of digestion form a lining membrane to a tube or sac, and constitute a tissue known as a secretory epithelium. The whole of the animals with bodies composed of definite tissues of this kind are known as the Metazoa.

A considerable number of early developmental processes are common to the whole of the Metazoa.

In the first place every Metazoon commences its existence as a simple cell, in the sense above defined; this cell is known as the ovum. The first developmental process which takes place consists in the division or segmentation of the single cell into a number of smaller cells. The cells then arrange themselves into two groups or layers known to embryologists as the *primary germinal layers*. These two layers are usually placed one within the other round a central cavity. The inner of the two is called the hypoblast, the outer the epiblast. The existence of these two layers in the embryos of vertebrated animals was made out early in the present century by Pander, and his observations were greatly extended by von Baer and Remak. But it was supposed that these layers were confined to vertebrated animals. In the year 1849, and at greater length in 1859, Huxley demonstrated that the bodies of all the polype tribe or Cœlenterata—that is to say, of the group to which the common polype, jelly-fish, and the sea-anemone belong—were composed of two layers of cells, and stated that in his opinion these two layers were homologous with the epiblast and hypoblast of vertebrate embryos. This very brilliant discovery came before its time. It fell upon barren ground, and for a long time bore no fruit. In the year 1860 a young Russian naturalist named Kowalevsky began to study by special histological methods the development of a number of invertebrated forms of animals, and discovered that at an early stage of development the bodies of all these animals were divided into germinal layers like those in vertebrates. Biologists were not long in recognising the importance of these discoveries, and they formed the basis of two remarkable essays, one by our own countryman, Prof. Lankester, and the other by a distinguished German naturalist, Prof. Haeckel of Jena.

In these essays the attempt was made to show that the stage in development already spoken of, in which the cells are arranged in the form of two layers inclosing a central cavity, has an ancestral meaning, and that it is to be interpreted to signify that all the Metazoa are descended from an ancestor which had a more or less oval form, with a central digestive cavity provided with a single opening, serving both for the introduction of food and for the ejection of indigestible substances. The body of this ancestor was supposed to have been a double-walled sac formed of an inner layer, the hypoblast, lining the digestive cavity, and an outer layer, the epiblast. To this form Haeckel gave the name of gastræa or gastrula.

There is every reason to think that Lankester and Haeckel were quite justified in concluding that a form more or less like that just described was the ancestor of the Metazoa; but the further speculations contained in their essays as to the origin of this form from the Protozoa can only be regarded as suggestive feelers, which, however, have been of great importance in stimulating and directing embryological research. It is, moreover, very doubtful whether there are to be found in the developmental histories of most animals any traces of this gastræa ancestor, other than the fact of their passing through a stage in which the cells are divided into two germinal layers.

The key to the nature of the two germinal layers is to be found in Huxley's comparison between them, and the two layers in the fresh-water polype and the sea-anemone. The epiblast is the primitive skin, and the hypoblast is the primitive epithelial wall of the alimentary tract.

In the whole of the polype group, or Cœlenterata, the body remains through life composed of the two layers, which Huxley recognised as homologous with the epiblast and hypoblast of the Vertebrata; but in all the higher Metazoa a third germinal

layer, known as the mesoblast, early makes its appearance between the two primary layers. The mesoblast originates as a differentiation of one or of both the primary germinal layers; but although the different views which have been held as to its mode of origin form an important section of the history of recent embryological investigations, I must for the moment confine myself to saying that from this layer there take their origin—the whole of the muscular system, of the vascular system, and of that connective-tissue system which forms the internal skeleton, tendons, and other parts.

We have seen that the epiblast represents the skin or epidermis of the simple sac-like ancestor common to all the Metazoa. In all the higher Metazoa it gives rise, as might be expected, to the epidermis, but it gives rise at the same time to a number of other organs; and, in accordance with the principles laid down in the earlier part of my address, it is to be concluded that *the organs so derived have been formed as differentiations of the primitive epidermis.* One of the most interesting of recent embryological discoveries is the fact that the nervous system is, in all but a very few doubtful cases, derived from the epiblast. This fact was made out for vertebrate animals by the great embryologist Van Baer; and the Russian naturalist Kowalevsky, to whose researches I have already alluded, showed that this was true for a large number of invertebrate animals. The derivation of the nervous system from the epiblast has since been made out for a sufficient number of forms satisfactorily to establish the generalisation that it is all but universally derived from the epiblast.

In any animal in which there is no distinct nervous system it is obvious that the general surface of the body must be sensitive to the action of its surroundings, or to what are technically called stimuli. We know experimentally that this is so in the case of the Protozoa, and of some very simple Metazoa, such as the fresh-water Polype or Hydra, where there is no distinct nervous system. The skin or epidermis of the ancestor of the Metazoa was no doubt similarly sensitive; and the fact of the nervous system being derived from the epiblast implies that the functions of the central nervous system, which were originally taken by the whole skin, became gradually concentrated in a special part of the skin which was step by step removed from the surface, and finally became a well-defined organ in the interior of the body.

What were the steps by which this remarkable process took place? How has it come about that there are nerves passing from the central nervous system to all parts of the skin, and also to the muscles? How have the arrangements for reflex actions arisen by which stimuli received on the surface of the body are carried to the central part of the nervous system, and are thence transmitted to the appropriate muscles, and cause them to contract? All these questions require to be answered before we can be said to possess a satisfactory knowledge of the origin of the nervous system. As yet, however, the knowledge of these points derived from embryology is imperfect, although there is every hope that further investigation will render it less so? Fortunately, however, a study of comparative anatomy, especially that of the Cœlenterata, fills up some of the gaps left from our study of embryology.

From embryology we learn that the ganglion-cells of the central part of the nervous system are originally derived from the simple undifferentiated epithelial cells of the surface of the body. We further learn that the nerves are out-growths of the central nervous system. It was supposed till quite recently that the nerves in Vertebrates were derived from parts of the middle germinal layer or mesoblast, and that they only became secondarily connected with the central nervous system. This is now known not to be the case, but the nerves are formed as processes growing out from the central part of the nervous system.

Another important fact shown by embryology is that the central nervous system, and percipient portion of the organs of special sense, are often formed from the same part of the primitive epidermis. Thus, in ourselves and in other vertebrate animals the sensitive part of the eye, known as the retina, is formed from two lateral lobes of the front part of the primitive brain. The crystalline lens and cornea of the eye are, however, subsequently formed from the skin.

The same is true for the peculiar compound eyes of crabs or Crustacea. The most important part of the central nervous system of these animals is the supracesophageal ganglia, often known as the brain, and these are formed in the embryo from two thickened patches of the skin at the front end of the body. These thickened patches become gradually detached from the surface, remaining covered over by a layer of skin. They then constitute the supracesophageal ganglia; but they form not only the ganglia, but also the rhabdons or retinal elements of the eye—the parts in fact which correspond to the rods and cones in our own retina. The layer of epidermis or skin which lies immediately above the supracesophageal ganglia becomes gradually converted into the refractive media of the crustacean eye. A cuticle which lies on its surface forms the peculiar facets on the surface of the eye, which are known as the corneal lenses, while the cells of the epidermis give rise to lens-like bodies known as the crystalline cones.

It would be easy to quote further instances of the same kind, but I trust that the two which I have given will be sufficient to show the kind of relation which often exists between the organs of special sense, especially those of vision, and the central nervous system. It might have been anticipated *à priori* that organs of special sense would only appear in animals provided with a well-developed central nervous system. This, however, is not the case. Special cells with long delicate hairs, which are undoubtedly highly sensitive structures, are present in animals in which as yet nothing has been found which could be called a central nervous system; and there is every reason to think that the organs of special sense originated *pari passu* with the central nervous system. It is probable that in the simplest organisms the whole body is sensitive to light, but that with the appearance of pigment-cells in certain parts of the body, the sensitiveness to light became localised to the areas where the pigment-cells were present. Since, however, it was necessary that stimuli received by such organs should be communicated to other parts of the body, some of the epidermic cells in the neighbourhood of the pigment-spots, which were at first only sensitive, in the same manner as other cells of the epidermis, became gradually differentiated into special nerve-cells. As to the details of this differentiation, embryology does not as yet throw any great light; but from the study of comparative anatomy there are grounds for thinking that it was somewhat as follows:—Cells placed on the surface sent protoplasmic processes of a nervous nature inwards, which came into connection with nervous processes from similar cells placed in other parts of the body. The cells with such processes then became removed from the surface, forming a deep layer of the epidermis below the sensitive cells of the organ of vision. With these cells they remained connected by protoplasmic filaments, and thus they came to form a thickening of the epidermis underneath the organ of vision, the cells of which received their stimuli from those of the organ of vision, and transmitted the stimuli so received to other parts of the body. Such a thickening would obviously be the rudiment of a central nervous system, and it is easy to see by what steps it might become gradually larger and more important, and might gradually travel inwards, remaining connected with the sense-organ at the surface by protoplasmic filaments, which would then constitute nerves. The rudimentary eye would at first merely consist partly of cells sensitive to light, and partly of optical structures constituting the lens, which would throw an image of external objects upon it, and so convert the whole structure into a true organ of vision. It has thus come about that, in the development of the individual, the retina or sensitive part of the eye is first formed in connection with the central nervous system, while the lenses of the eye are independently evolved from the epidermis at a later period.

The general features of the origin of the nervous system which have so far been made out by means of the study of embryology are the following:—

1. That the nervous system of the higher Metazoa has been developed in the course of a long series of generations by a gradual process of differentiation of parts of the epidermis.

2. That part of the central nervous system of many forms arose as a local collection of nerve-cells in the epidermis, in the neighbourhood of rudimentary organs of vision.

3. That ganglion-cells have been evolved from simple epithelial cells of the epidermis.

4. That the primitive nerves were outgrowths of the original ganglion cells; and that the nerves of the higher forms are formed as outgrowths of the central nervous system.

The points on which embryology has not yet thrown a satisfactory light are:—

1. The steps by which the protoplasmic processes, from the primitive epidermic cells, became united together so as to form

a network of nerve-fibres, placing the various parts of the body in nervous communication.

2. The process by which nerves became connected with muscles, so that a stimulus received by a nerve-cell could be communicated to and cause a contraction in a muscle.

Recent investigations on the anatomy of the Cœlenterata, especially of jelly-fish and sea-anemones, have thrown some light on these points, although there is left much that is still obscure.

In our own country Mr. Romanes has conducted some interesting physiological experiments on these forms; and Prof. Schäfer has made some important histological investigations upon them. In Germany a series of interesting researches have also been made on them by Professors Kleinenberg, Claus, and Eimer, and more especially by the brothers Hertwig, of Jena. Careful histological investigations, especially those of the last-named authors, have made us acquainted with the forms of some very primitive types of nervous system. In the common sea-anemones there are, for instance, no organs of special sense, and no definite central nervous system. There are, however, scattered throughout the skin, and also throughout the lining of the digestive tract, a number of specially modified epithelial cells, which are no doubt delicate organs of sense. They are provided at their free extremity with a long hair, and are prolonged on their inner side into a fine process which penetrates the deeper part of the epithelial layer of the skin or digestive wall. They eventually join a fine network of protoplasmic fibres which forms a special layer immediately within the epithelium. The fibres of this network are no doubt essentially nervous. In addition to fibres there are, moreover, present in the network cells of the same character as the multipolar ganglion-cells in the nervous system of Vertebrates, and some of these cells are characterised by sending a process into the superjacent epithelium. Such cells are obviously epithelial cells in the act of becoming nerve-cells; and it is probable that the nerve-cells are, in fact, sense-cells which have travelled inwards and lost their epithelial character.

There is every reason to think that the network just described is not only continuous with the sense-cells in the epithelium, but that it is also continuous with epithelial cells which are provided with muscular prolongations. The nervous system thus consists of a network of protoplasmic fibres, continuous on the one hand with sense-cells in the epithelium, and on the other with muscular cells. The nervous network is generally distributed both beneath the epithelium of the skin and that of the digestive tract, but is especially concentrated in the disk-like region between the mouth and tentacles. The above observations have thrown a very clear light on the characters of the nervous system at an early stage of its evolution, but they leave unanswered the questions (1) how the nervous network first arose, and (2) how its fibres became continuous with muscles. It is probable that the nervous network took its origin from processes of the sense-cells. The processes of the different cells probably first met and then fused together, and becoming more arborescent, finally gave rise to a complicated network.

The connection between this network and the muscular cells also probably took place by a process of contact and fusion.

Epithelial cells with muscular processes were discovered by Kleinenberg before epithelial cells with nervous processes were known, and he suggested that the epithelial part of such cells was a sense-organ, and that the connecting part between this and the contractile processes was a rudimentary nerve. This ingenious theory explained completely the fact of nerves being continuous with muscles; but on the further discoveries being made which I have just described, it became obvious that this theory would have to be abandoned, and that some other explanation would have to be given of the continuity between nerves and muscles. The hypothetical explanation just offered is that of fusion.

It seems very probable that many of the epithelial cells were originally provided with processes, the protoplasm of which, like that of the Protozoa, carried on the functions of nerves and muscles at the same time, and that these processes united amongst themselves into a network. By a process of differentiation parts of this network may have become specially contractile, and other parts may have lost their contractility and become solely nervous. In this way the connection between nerves and muscles might be explained, and this hypothesis fits in very well with the condition of the neuro-muscular system as we find it in the Cœlenterata.

The nervous system of the higher Metazoa appears then to have originated from a differentiation of some of the superficial epithelial cells of the body, though it is possible that some parts of the system may have been formed by a differentiation of the alimentary epithelium. The cells of the epithelium were most likely at the same time contractile and sensory, and the differentiation of the nervous system may very probably have commenced, in the first instance, from a specialisation in the function of part of a network formed of neuro-muscular prolongations of epithelial cells. A simultaneous differentiation of other parts of the network into muscular fibres may have led to the continuity at present obtaining between nerves and muscles.

Local differentiations of the nervous network, which was no doubt distributed over the whole body, took place on the formation of organs of special sense, and such differentiations gave rise to the formation of a central nervous system. The central nervous system was at first continuous with the epidermis, but became separated from it and travelled inwards. Ganglion-cells took their origin from sensory epithelial cells provided with prolongations continuous with the nervous network. Such epithelial cells gradually lost their epithelial character, and finally became completely detached from the epidermis.

Nerves, such as we find them in the higher types, originated from special differentiations of the nervous network, radiating from the parts of the central nervous system.

Such, briefly, is the present state of our knowledge as to the genesis of the nervous system. I ought not, however, to leave this subject without saying a few words as to the hypothetical views which the distinguished evolutionist Mr. Herbert Spencer has put forward on this subject in his work on Psychology.

For Herbert Spencer nerves have originated, not as processes of epithelial cells, but from the passage of motion along the lines of least resistance. The nerves would seem, according to this view, to have been formed in any tissue from the continuous passage of nervous impulses through it. "A wave of molecular disturbance," he says, "passing along a tract of mingled colloids closely allied in composition, and isomerically transforming the molecules of one of them, will be apt at the same time to form some new molecules of the same type," and thus a nerve becomes established.

A nervous centre is formed, according to Herbert Spencer, at the point in the colloid in which nerves are generated, where a single nervous wave breaks up, and its parts diverge along various lines of least resistance. At such points some of the nerve-colloid will remain in an amorphous state, and as the wave of molecular motion will there be checked, it will tend to cause decompositions amongst the unarranged molecules. The decompositions must, he says, cause "additional molecular motion to be disengaged; so that along the outgoing lines there will be discharged an augmented wave. Thus there will arise at this point something having the character of a ganglion corpuscle."

These hypotheses of Herbert Spencer, which have been widely adopted in this country, are, it appears to me, not borne out by the discoveries to which I have called your attention to-day. The discovery that nerves have been developed from processes of epithelial cells, gives a very different conception of their genesis to that of Herbert Spencer, which makes them originate from the passage of nervous impulses through a tract of mingled colloids; while the demonstration that ganglion-cells arose as epithelial cells of special sense, which have travelled inwards from the surface, admits still less of a reconciliation with Herbert Spencer's view on the same subject.

Although the present state of our knowledge on the genesis of the nervous system is a great advance on that of a few years ago, there is still much remaining to be done to make it complete.

The subject is well worth the attention of the morphologist, the physiologist, or even of the psychologist, and we must not remain satisfied by filling up the gaps in our knowledge by such hypotheses as I have been compelled to frame. New methods of research will probably be required to grapple with the problems that are still unsolved; but when we look back and survey what has been done in the past, there can be no reason for mistrusting our advance in the future.

Department of Anthropology

Address by F. W. Rudler, F.G.S., Vice-President of the Section

After referring to the ethnologically mixed state of the population of South Wales, Mr. Rudler went on—What then

are the ethnical relations of the typical man of South Wales?

Nine people out of every ten to whom this question might be addressed would unhesitatingly answer that the true Welsh are Celts or Kelts.[1] And they would seek to justify their answer by a confident appeal to the Welsh language. No one has any doubt about the position of this language as a member of the Keltic family. The Welsh and the Breton fall naturally together as living members of a group of languages to which Prof. Rhys applies the term *Brythonic*, a group which also includes such fossil tongues as the old Cornish, the speech of the Strathclyde Britons, and possibly the language of the Picts and of the Gauls. On the other hand, the Gaelic of Scotland, the Irish, and the Manx arrange themselves as naturally in another group, which Prof. Rhys distinguishes as the *Goidelic* branch of the Keltic stock.[2] But does it necessarily follow that all the peoples who are closely linked together by speaking, or by having at some time spoken, these Keltic languages, are as closely linked together by ties of blood? Great as the value of language unquestionably is as an aid to ethnological classification, are we quite safe in concluding that all the Keltic-speaking peoples are one in race?

The answer to such a question must needs depend upon the sense in which the anthropologist uses the word Kelt. History and tradition, philology and ethnology, archæology and craniology, have at different times given widely divergent definitions of the term. Sometimes the word has been used with such elasticity as to cover a multitude of peoples who differ so widely one from another in physical characteristics that if the hereditary persistence of such qualities counts for anything, they cannot possibly be referred to a common stock. Sometimes, on the other hand, the word has been so restricted in its definition that it has actually excluded the most typical of all Kelts—the Gaulish Kelts of Cæsar. According to one authority the Kelt is short, according to another tall; one ethnologist defines him as being dark, another as fair; this craniologist finds that he has a long skull, while that one declares that his skull is short. It was no doubt this ambiguity that led so keen an observer as Dr. Beddoe to remark, nearly fifteen years ago, that "Kelt and Keltic are terms which were useful in their day, but which have ceased to convey a distinct idea to the minds of modern students."[3]

No anthropologist has laboured more persistently in endeavouring to evoke order out of this Keltic chaos than the late Paul Broca. What, let us ask, was the opinion of this distinguished anthropologist on the Keltic question?[4] Prof. Broca always held that the name of Kelt should be strictly limited to the Kelt of positive history—to the people, or rather confederation of peoples, actually seen by Cæsar in Keltic Gaul—and, of course, to their descendants in the same area. Every schoolboy is familiar with the epitome of Gaulish ethnology given by Julius in his opening chapter. Nothing can be clearer than his description of the tripartite division of Gaul, and of the separation between the three peoples who inhabited the country—the Belgæ, the Aquitani, and the Celtæ. Of these three peoples the most important were those whom the Romans called *Galli*, but who called themselves, as the historian tells us, *Celtæ*. The country occupied by the Keltic population stretched from the Alps to the Atlantic in one direction, and from the Seine to the Garonne in another; but it is difficult to find any direct evidence that the Kelts of this area ever crossed into Britain. Broca refused to apply the name of Kelt to the old inhabitants of Belgic Gaul, and as a matter of course he denied it to any of the inhabitants of the British Isles. Writing as late as 1877, in full view of all the arguments which had been adduced against his opinions, he still said: "Je continue à soutenir, jusqu'à preuve du contraire, ce que j'ai avancé il y a douze, ans dans notre première discussion sur les Celtes, savoir, qu'il n'existe aucune preuve, qu'on ait constaté dans les Iles-Britanniques l'existence d'un peuple portant le nom de Celtes."[1]

Nevertheless, in discussing the Keltic question with M. Henri Martin, he admitted the convenience, almost the propriety, of referring to all who spoke Keltic languages as *Keltic* peoples, though of course he would not hear of their being called Kelts. "On peut très bien les nommer les peuples celtiques. Mais il est entièrement faux de les appeler les *Celtes*, comme on le fait si souvent."[2] As to the eminent historian himself, I need hardly say that M. Martin adheres to the popular use of the word Kelt, and even goes so far as to speak of the county in which we are now assembled as "le Glamorgan, le pays aujourd'hui le plus celtique de l'Europe."[3]

Whether we use the word Kelt in its wide linguistic sense or in the narrower sense to which it has been reduced by the French anthropologists, it is important to remember that the Welsh do not designate, and never have designated themselves by this term or by any similar word. Their national name is *Cymry*, the plural of *Cymro*. My former colleague, the Rev. Prof. Silvan Evans, kindly informs me that the most probable derivation of this word is from *cyd-* (the *d* being changed to *m* for assimilation with the following *b*, like the *n* of its Latin cognate *con*) and *bro-*, "country," the old form of which is *brog*, as found in *Allobrogæ*, and some other ancient names. The meaning of *Cymry* is therefore "fellow-countrymen," or compatriots. Such a meaning naturally suggests that the name must have been assumed in consequence of some foreign invasion—possibly when the Welsh were banded together against either the Romans or the English. If this assumption be correct it must be a word of comparatively late origin.

At the same time, the similarity between *Cymry* and *Cimbri*—the name of those dread foes of the Romans whom Marius eventually conquered—is so close as to naturally suggest a common origin for the two names, if not for the people who bore the names.[4] The warlike Cimbri have generally been identified with the people who inhabited the Cimbric peninsula, the *Chersonesus Cimbrica*, now called Jutland. Whether they were connected or not with the *Kimmerioi*, who dwelt in the valley of the Danube and in the Tauric Chersonesus or *Crimea*, is a wider question with which we are not at the moment concerned. As to the ethnical relations of the Cimbri, two views have been current, the one regarding them as of Germanic, the other as of Keltic stock. Canon Rawlinson, in summing up the evidence on both sides, believes that the balance of opinion inclines to the Keltic view.[5] These Cimbri are described, however, as having been tall, blue-eyed, and yellow- or flaxen-haired men. Can we trace anything like these characters in the Cymry?

All the evidence which the ethnologist is able to glean from classical writers with respect to the physical characters and ethnical relations of the ancient inhabitants of this country may be put into a nutshell with room to spare. The exceeding meagreness of our data from this source will be admitted by any one who glances over the passages relating to Britain which are collected in the "Monumenta Historica Britannica." As to the people in the south, there is the well-known statement in Cæsar, that the maritime parts of Britain, the southern parts which he personally visited, were peopled by those who had crossed over from the Belgæ, for what purpose we need not inquire. Of the Britons of the interior, whom he never saw, he merely repeats a popular tradition which represented them as aborigines.[6] They may, therefore, have been Keltic tribes, akin to the Celti of Gaul, though there is nothing in Cæsar's words to support such a view.

Tacitus, in writing the life of his father-in-law, Agricola,

[1] Whether this word should be written Celt or Kelt seems to be a matter of scientific indifference. Probably the balance of opinion among ethnologists is in the direction of the former rendering. Nevertheless it must be borne in mind that the word "celt" is so commonly used nowadays by writers on prehistoric anthropology to designate an axe-head, or some such weapon, whether of metal or of stone, that it is obviously desirable to make the difference between the archæological word and the ethnological term as clear as possible. If ethnologists persist in writing "Celt," the two words differ only in the magnitude of an initial, and when spoken are absolutely indistinguishable. I shall therefore write, as a matter of expediency, "Kelt." It may be true, as Mr. Knight Watson has pointed out, that there was originally no justification for using the word "celt" as the name of a weapon, but it is too late in the day to attempt to oust so deeply-rooted a word from the vocabulary of the archæologists.

[6] "Britanniæ pars interior ab iis incolitur, quos natos in insula ipsi memoria proditum dicunt: maritima pars ab iis, qui prædæ ac belli inferendi causa ex Belgis transierant."—*De Bello Gallico*, lib. v. c. 12.

says that the Britons nearest to Gaul resembled the Gauls.[1] If he refers here to the sea-coast tribes in the south-east of Briton, the comparison must be with the Belgic and not with the Keltic Gauls. But his subsequent reference to the resemblance between the sacred rites of the Britons and those of the Gauls suggests that his remarks may be fairly extended to the inland tribes beyond the limits of the Belgic Britons, in which case the resemblance may be rather with the Gaulish Kelts. Indeed this inference, apart from the testimony of language, is the chief evidence upon which ethnologists have based their conclusions as to the Keltic origin of the Britons.

Our data for restoring the anthropological characteristics of the ancient Britons are but few and small. It is true that a description of Bunduica, or Boadicea, has been left to us by Xiphiline, of Trebizond; but then it will be objected that he did not write until the twelfth century. Yet it must be remembered that he merely abridged the works of Dion Cassius, the historian, who wrote a thousand years earlier, and consequently we have grounds for believing that what Xiphiline describes is simply a description taken from the lost books of an early historian who is supposed to have drawn his information from original sources. Now Boadicea is described in these terms: "She was of the largest size, most terrible of aspect, most savage of countenance, and harsh of voice, having a profusion of yellow hair which fell down to her hips."[2] Making due allowance for rhetorical exaggeration, making allowance too for the fact that in consequence of her royal descent she is likely to have been above the average stature, and even admitting that she dyed her hair, it is yet clear that this British queen must be regarded as belonging to the xanthous type—tall and fair. The tribe of the Iceni, over which this blonde amazon ruled, is generally placed beyond the limits of the Belgic Britons; though some authorities have argued in favour of a Belgic origin. If the latter view be correct, we should expect the queen to be tall, light-haired, and blue-eyed; for, from what we know of the Belgæ, such were their features. Cæsar asserts that the majority of the Belgæ were derived from the Germans.[3] But notwithstanding this assertion most ethnologists are inclined to ally them with the Celti, without, of course, denying a strong Teutonic admixture. Strabo says[4] that the Belgæ and Celti had the same Gaulish form, though both differed widely in physical characters from the Aquitanians. As to language, Cæsar's statement that the Belgic and Keltic differed, probably refers only to dialectical differences.[5] If a close ethnical relationship can be established between the Celti and the Belgæ, British ethnology clearly gains in simplification. To what extent the Belgic settlers in this country resembled the neighbouring British tribes must remain a moot point. According to Strabo[6] the Britons were taller than the Celti, with hair less yellow, and they were slighter in build. By the French school of ethnologists the Belgæ are identified with the Cymry, and are described as a tall fair people, similar to the Cimbri already mentioned; and Dr. Pritchard, the founder of English anthropology, was led long ago to describe the Keltic type in similar terms.[7]

Yet as we pass across Britain westwards, and advance towards those parts which are reputed to be predominantly Keltic, the proportion of tall fair folk, speaking in general terms, diminishes, while the short and dark element in the population increases, until it probably attains its maximum somewhere in this district. As popular impressions are apt to lead us astray, let us turn for accuracy to the valuable mass of statistics collected in Dr. Beddoe's well-known paper "On the Stature and Bulk of Man in the British Isles,"[8] a paper to which every student refers with unfailing confidence, and which will probably remain our standard authority until the labours of our own Anthropometric Committee are sufficiently matured for publication. Dr. Beddoe, summing up his observations on the physical characters of the Welsh as a whole, defines them as of "short stature, with good weight, and a tendency to darkness of eyes, hair, and skin." With regard to this tendency to darkness, it is well to look more searchingly at the district in which we are

[8] *Mem.* Anthrop. Soc. Lond., vol. iii., 1870, p. 384.

assembled. Dr. Beddoe, in another paper,[1] indicated the tendency by a numerical expression which he termed the *index of nigrescence*. "In the coast-districts and lowlands of Monmouthshire and Glamorgan, the ancient seats of Saxon, Norman, and Flemish colonisation, I find," says this observer, "the indices of hair and eyes so low as 33·5 and 63; while in the interior, excluding the children of English and Irish immigrants, the figures rise to 57·3 and 109·5—this last ratio indicating a prevalence of dark eyes surpassing what I have met with in any other part of Britain" (p. 43).

Many years ago Mr. Matthew Moggridge, whose scientific work is well known in this district, furnished the authors of the "Crania Britannica" with notes of the physical characteristics of the Welsh of Glamorganshire. He defined the people as having "eyes (long) bright, of dark or hazel colour, hair generally black, or a very dark brown, lank, generally late in turning grey."[2]

There can be no question then as to the prevalence of melanism in this district. Nor does it seem possible to account for this tendency, as some anthropologists have suggested, by the influence of the surrounding media. Even those who believe most firmly in the potency of the environment will hardly be inclined to accept the opinion seriously entertained some years ago by the Rev. T. Price, that the black eyes of Glamorganshire are due to the prevalence of coal fires.[3] Long before coal came into use there was the same tendency to nigrescence among the Welsh. This may be seen, as Dr. Nicholas has pointed out, in the bardic names preserved in ancient Welsh records, where the cognomen of *du*, or "black," very frequently occurs. Thus, in the "Myvyrian Archaiology of Wales," between A.D. 1280 and 1330, there are registered four "blacks" to one "red" and one "grey," namely Gwilym *Ddu*, Llywelyn *Ddu*, Goronwy *Ddu*, and Dafydd *Ddu*.[4]

The origin of this dark element in the Welsh is to be explained, as every one will have anticipated, by reference to the famous passage in Tacitus, which has been worn threadbare by ethnologists. Tacitus tells us that the ancient British tribe of Silures—a tribe inhabiting what is now Glamorganshire, Monmouthshire, Herefordshire, and parts at least of Brecknockshire and Radnor—had a swarthy complexion, mostly with curly hair, and that from their situation opposite to Spain there was reason to believe that the Iberians had passed over the sea and gained possession of the country.[5] It will be observed that although Tacitus speaks of their dark complexion, he does not definitely state that the hair was dark; but this omission has, curiously enough, been supplied by Jornandes, a Goth who, in the sixth century, wrote a work which professes to be an extract from the lost history of Cassiodorus, wherein the very words of Tacitus are reproduced with the necessary addition.[6] With these passages before us, can we reasonably doubt that the swart blood in the Welsh of the present day is a direct legacy from their Silurian ancestors?

Setting what Tacitus here says about the Silures against what he says in the next sentence about the Britons nearest to Gaul (p. 5), it is clear that we must recognise a duality of type in the population of Southern Britain in his day. This fact has been clearly pointed out by Prof. Huxley as one of the few "fixed points in British ethnology."[7] At the dawn of history in this country, eighteen centuries ago, the population was not homogeneous, but contained representatives both of Prof. Huxley's *Melanochroi* and of his *Xanthochroi*. If we have any regard whatever for the persistence of anthropological types, we should hesitate to refer both of these to one and the same elementary stock. We are led then to ask, Which of these two types, if either, is to be regarded as Keltic?

It is because both of these types, in turn, have been called

[6] "Sylorum [= Silurum] colorati vultus, torto plerique crine, *et nigro nascuntur*."—"De Rebus Geticis," c. ii.; quoted in "Mon. Hist. Brit.," Excerpta, p. lxxxiii. It is conjectured that the classical word *Silures* is derived from the British name *Essyllwyr*, the people of *Essyllwg*. See Nicholas's "History of Glamorganshire," 1874, p. 5. It is difficult to determine how far and in what respects the Silures resembled, or differed from, the other inland tribes. Of the Caledonians and of the Belgæ we know something, but of the other inhabitants we are quite ignorant.
[7] "Critiques and Addresses," p. 166.

Keltic that so much confusion has been imported into ethnological nomenclature; hence the common-sense conclusion seems to be that neither type can strictly be termed Keltic, and that such a term had better be used only in linguistic anthropology.[1] The Kelt is merely a person who speaks a Keltic language, quite regardless of his race, though it necessarily follows that all persons who speak these languages, if not actually of one blood, must have been, at some period of their history, in close social contact. In this sense, all the inhabitants of Britain, at the period of the Roman invasion, notwithstanding the distinction between Xanthochroi and Melanochroi, were probably to be styled Kelts. There can be little doubt that the xanthous Britons always spoke a Keltic tongue; but it is not so easy to decide what was the original speech of their melanochroic neighbours.

The existence of two types of population, dark and fair, side by side, is a phenomenon which was repeated in ancient Gaul. As the Silures were to Britain so were the Aquitani to Gaul—they were the dark Iberian element. Strabo states that while the natives of Keltic and Belgic Gaul resembled each other, the Aquitanians differed in their physical characters from both of these peoples, and resembled the Iberians. But Tacitus has left on record the opinion that the Silures also resembled the Iberians; hence the conclusion that the Silures and the Aquitanians were more or less alike. Now it is generally believed that the relics of the old Aquitanian population are still to be found lingering in the neighbourhood of the Pyrenees, being represented at the present day by the Basques. A popular notion has thus got abroad that the ancient Silures must have been remotely affined to the Basque populations of France and Spain. Nevertheless the modern Basques are so mixed a race that, although retaining their ancient language, their physical characters have been so modified that we can hardly expect to find in them the features of the old Silurians. Thus, according to the Rev. Wentworth Webster, the average colour of the Basque hair at the present day is not darker than chestnut.[2]

Neither does language render us any aid towards solving the Basque problem. If the Silures were in this country prior to the advent of the Cymry, and if they were cognate with the Basques, it seems only reasonable to suppose that some spoor of their Iberian speech, however scant, might still be lingering amongst us. Yet philologists have sought in vain for the traces of any Euskarian element in the Cymraeg. Prince Louis Lucien Bonaparte, perhaps the only philologist in this country who has a right to speak with authority on such a subject, has obligingly informed me that he knows of no connection whatever between the two languages. Still it must be remembered that the Iberian affinity of the Silures, suggested by the remark of Tacitus, does not necessarily mean Basque affinity. Some philologists have even denied that the Basques are Iberians.[3] All that we seek at present to establish is this—that the dark Britons, represented by the tribe of Silures, although they came to be a Keltic-speaking people, were distinct in race from the fair Britons, and therefore in all likelihood were originally distinct in speech. Nor should it be forgotten that relics of a pre-Keltic non-Aryan people have been detected in a few place-names in Wales. Thus, Prof. Rhys is inclined to refer to this category such names as Menapia, Mona, and Mynwy[4]—the last-named being a place (Monmouth) within the territory of the old Silures, where we are now assembled. We may also look for light upon this subject from a paper which will be laid before the department by Mr. Hyde Clarke. On the whole it seems to me safer to follow Prof. Rolleston in speaking of the dark pre-Keltic element as *Silurian* rather than as Basque or as Iberian.[5] ("British Barrows," p. 630.)

There is, however, quite another quarter to which the anthropologist who is engaged in this investigation may turn with fair promise of reward. I need scarcely remind any one in this department of the singularly suggestive paper which was written more than fifteen years ago by the late Dr. Thurnam, "On the Two Principal Forms of Ancient British and Gaulish Skulls."[1] The long-continued researches of this eminent archæological anatomist led him to the conclusion that the oldest sepulchres of this country—the chambered and other long barrows which he explored in Wilts and Gloucestershire—invariably contained the remains of a dolichocephalic people, who were of short stature, and apparently were unacquainted with the use of metals. The absence of metal would alone raise a suspicion that these elongated tumuli were older than the round, conoidal, or bell-shaped barrows, which contain objects of bronze, if not of iron, with or without weapons of stone, and commonly associated with the remains of a taller brachycephalic people.

Even before Dr. Thurnam forcibly pointed attention to this distinction, it had been independently observed by so experienced a barrow-opener as the late Mr. Bateman,[2] whose researches were conducted in quite another part of the country—the district of the ancient Cornavii. Moreover, Prof. Daniel Wilson's studies in Scotland had led him to conclude that the earliest population of Britain were dolichocephalic, and possessed, in fact, a form of skull which, from its boat-like shape, he termed *kumbecephalic*.[3] Nor should it be forgotten that as far back as 1844 the late Sir W. R. Wilde expressed his belief that in Ireland the most ancient type of skull is a long skull, which he held to belong to a dark-complexioned people, probably aboriginal, who were succeeded by a fair, round-headed race."[4]

But while this succession of races was recognised by several observers, it remained for Dr. Thurnam to formulate the relation between the shape of the skull and that of the barrow in a neat aphorism which has become a standing dictum in anthropology—"Long barrows, long skulls; round barrows, round skulls; dolichotaphic barrows, dolichocephalic crania; brachytaphic barrows, brachycephalic crania." No doubt exceptional cases may occur in which round skulls have been found in long barrows, but these have generally been explained as being due to secondary interments. On the other hand, the occasional presence of long skulls in round barrows presents no difficulty, since no one supposes that the early dolichocephali were exterminated by the brachycephali, and it is therefore probable that during the bronze-using period, when round tumuli were in general use, the two peoples may have dwelt side by side, the older race being, perhaps, in a state of subjugation.

It is not pretended that Thurnam's apophthegm has more than a local application. "This axiom," its author admitted, "is evidently not applicable, unless with considerable limitations, to France." Although it is here called an "axiom," it is by no means a self-evident proposition, the relation between the shape of the skull and the shape of the burial-mound being purely arbitrary. The proposition which connects the two is simply the expression of the results of accumulated observations, and it is of course open to doubt whether the number of observations was sufficiently great to warrant the generalisation. But the only test of the validity of any induction lies in its verification when applied to fresh instances, and it is remarkable that when long barrows and chambered tumuli have since been opened in this country the evidence has tended in the main to confirm Dr. Thurnam's proposition.

It is commonly believed that the brachycephali of the round barrows came in contact with the dolichocephali as an invading, and ultimately as a conquering, race. Not only were they armed with superior weapons—superior in so far as a metal axe is a better weapon than a stone axe—but they were a taller and more powerful people. Thurnam's measurements of femora led to the conclusion that the average height of the brachycephali was 5 feet 8·4 inches, while that of the long-headed men was only 5 feet 5·4 inches.[5] Not only were they taller, but they were probably a fiercer and more warlike race. In the skulls from the round barrows the superciliary ridges are more prominent, the nasals diverge at a more abrupt angle, the cheek-bones are high, and the lower jaw projects, giving the face an aspect of ferocity, which contrasts unfavourably with the mild features of the earlier stone-using people.

On the whole, then, the researches of archæological anatomists tend to prove that this country was tenanted in ante-historic or pre-Roman times by two peoples who were ethnically distinct from each other. It is difficult to resist the temptation of apply-

[1] An excellent argument against the employment of national names by anthropologists will be found in a paper by Mr. A. L. Lewis "On the Evils arising from the Use of Historical National Names as Scientific Terms."—*Journ.* Anthrop. Inst., vol. viii., 1879, p. 325.

ing this to the ethnogeny of Wales. Does it not seem probable that the early short race of long-skulled, mild-featured, stone-using people may have been the ancestors of the swarthy Silurians of Tacitus; while the later tall race of round-skulled, rugged-featured, bronze-using men may have represented the broad-headed, Keltic-speaking folk of history? At any rate, the evidence of craniology does not run counter to this hypothesis. For Dr. Beddoe's observations on head-forms in the west of England have shown that "heads which are ordinarily called brachycephalic belonged for the most part to individuals with light hair," while the short dark-haired people whom he examined were markedly dolichocephalic.[1] At the same time it must be admitted that his observations lend "no support to the view that the Keltic skull has been, or would be, narrowed by an admixture of the Iberian type." It should not, however, be forgotten that the same observer, in referring to a collection of crania from the Basque country preserved in Paris, says: "The form of M. Broca's Basque crania was very much that of some modern Silurian heads."[2]

According to the view advocated by Thurnam we have a right to anticipate that the oldest skulls found in this country would be of dolichocephalous type; and such I believe to be actually the case. Dr. Barnard Davis, it is true, has stated in the "Crania Britannica that the ancient British skull must be referred to the brachycephalic type; and such an induction was perfectly legitimate so long as the craniologist dealt only with skulls from the round barrows or from similar interments. But the long-barrow skulls examined by Prof. Rolleston,[3] and the Cissbury skulls recently studied by the same anatomist,[4] are decidedly dolichocephalic, as also are all the early prehistoric skulls which have been found of late years in France. While referring to craniology in this country, I may perhaps be allowed to remark that the eminent Italian anthropologist, Dr. Paolo Mantegazza, in a suggestive paper which has just appeared in his valuable journal, the *Archivio per l'Antropologia*, has referred to the Englishman's contempt for craniological work—work but little worthy of the practical spirit of the Anglo-Saxon race.[5] No doubt it is desirable to increase the number of our observations, but still the good-humoured remark about despising craniology can hardly be applied to a country which numbers among its living men of science such eminent craniologists as Prof. Busk, Prof. Cleland, Dr. Barnard Davis, and Professors Flower, Huxley, and Rolleston.

It may naturally be asked whether the researches of archæologists in Wales lend any support to Thurnam's hypothesis. Nothing, I conceive, would be easier than to show that very material support has come from this quarter; but I have abstained, of set purpose, from introducing into this address any remarks on the prehistoric archæology of Wales. For I have not forgotten that we are to have the privilege of hearing an evening lecture on "Primæval Man" by so distinguished an archæologist and naturalist as Prof. Boyd Dawkins. No one has done more in this country to forward Thurnam's views, whether by actual exploration or by writing, than Prof. Boyd Dawkins; and if I have not referred to his work, especially to his discoveries in Denbighshire, it has been simply because I was anxious to avoid trespassing on any subject which he is likely to bring forward.[6]

Setting aside, then, any archæological evidence derived from the bone-caves, barrows, or other sepulchres in Wales, we may finally look at the outcome of our inquiry into Welsh ethnogeny. If we admit, as it seems to me we are bound to admit, the existence of two distinct ethnical elements in the Welsh population, one of which is short, dark, and dolichocephalic—call it Silurian, Atlantean, Iberian, Basque, or what you will; and the other of which is tall, fair, and brachycephalic, such as some term Cymric and others Ligurian; then it follows that by the crossing of these two races we may obtain not only individuals of intermediate character, but occasionally more complex combinations; for example, an individual may have the short stature and long head of the one race, associated with the lighter hair of the other; or again, the tall stature of one may be found in association with the melanism and dolichocephalism of the other race. It is therefore no objection to the views herein expressed if we can point to a living Welshman who happens to be at once tall and dark, or to another who is short and fair.

At the same time I am by no means disposed to admit that when we have recognised the union of the xanthous and melanic elements in Wales, with a predominance of the latter in the south, we have approached to anything like the exhausting limit of the subject. Still earlier races may have dwelt in the land, and have contributed something to the composition of the Welsh. In fact the anthropologist may say of a Welshman, as a character in "Cymbeline" says of Posthumus when doubtful about his pedigree—

"I cannot delve him to the root."

It is possible that the roots of the Welsh may reach far down into some hidden primitive stock, older mayhap than the Neolithic ancestors of the Silurians; but of such pristine people we have no direct evidence. So far however as positive investigation has gone, we may safely conclude that the Welsh are the representatives, in large proportion, of a very ancient race or races; and that they are a composite people who may perhaps be best defined as *Siluro-Cymric*.

Many other questions relating to Welsh ethnology press for consideration—such as the hypothesis that the Kymro was preceded, in parts at least of Wales, by the Gael; but such questions must be dismissed from present discussion, for I fear that my remarks have already overrun the limits of a departmental address. Let us hope however that much light may be thrown upon a variety of questions bearing upon local anthropology in the course of the discussions which will arise in this department during the present session of the Association.

[5] The whole passage so amusingly refers to the national idiosyncracies of craniologists, that it is well worth reproduction. "In Francia, Broca, il pontefice massimo dell' *ipercraniologia* moderna, col suo ardore eternamente giovanile, non studia più i crani, ma i cervelli; in Germania si prendono ancora misure sui teschi, ma con *rationabile obsequio*, quasi si dovesse adempiere ad un dovere noioso; in Inghilterra si continua a sprezzare la craniologia, come cosa poco degna dello spirito pratico della razza anglosassone; e in Italia, paese più scettico di tutti, perchè più antico e più stanco di tutti, si continua a misurare, pur sorridendo dell' improba e pur inutile fatica."—"La Riforma Craniologica;" *Archivio*, vol. x., 1880, p. 117.
[6] For Prof. Boyd Dawkins' contributions to the subject see his interesting works on "Cave-hunting," 1874, and on "Early Man in Britain," 1880.

PALÆONTOLOGICAL AND EMBRYOLGICAL DEVELOPMENT[1]

SINCE the publication of the "Poissons Fossiles" by Agassiz and of the "Embryologie des Salmonidées" by Vogt, the similarity, traced by the former between certain stages in the growth of young fishes and the fossil representatives of extinct members of the group, has also been observed in nearly every class of the animal kingdom, and the fact has become a most convenient axiom in the study of palæontological and embryological development. This parallelism, which has been on the one side a strong argument in favour of design in the plan of creation, is now, with slight emendations, doing duty on the other as a newly-discovered article of faith in the new biology.

But while in a general way we accept the truth of the proposition that there is a remarkable parallelism between the embryonic development of a group and its palæontological history, yet no one has attempted to demonstrate this, or rather to show how far the parallelism extends. We have up to the present time been satisfied with tracing the general coincidence, or with striking individual cases.

The resemblance between the pupa stage of some Insects and of adult Crustacea, the earlier existence of the latter, and the subsequent appearance of the former in palæontological history, furnished one of the first and most natural illustrations of this parallelism; while theoretically the necessary development of the higher tracheate insects from their early branchiate aquatic ancestors seemed to form an additional link in the chain, and point to the Worms, the representatives of the larval condition of Insects, as a still earlier embryonic stage of the Articulates.

Indeed there is not a single group of the animal kingdom in which embryology has not played a most important part in demonstrating affinities little suspected before. The development of our frogs, our salamanders, has given us the key to much that was unexplained in the history of Reptiles and Batrachians. The little that has been done in the embryology of Birds has revolutionised our ideas of a class which at the beginning of the century seemed to be the most naturally circumscribed of all. Embryology and palæontology combined have led to the recognition of a a natural classification uniting Birds and Reptiles on

[1] Address by Prof. Alexander Agassiz, vice-president, Section B, at the Boston Meeting of the American Association, August, 1880.

the one side, and Batrachians and Fishes on the other. It is to embryology that we owe the explanation of the affinities of the Old Fishes in which Agassiz first recognised the similarity to the embryo of Fishes now living, and by its aid we may hope to understand the relationship of the oldest representatives of the class. It has given us the only explanation of the early appearance of the Cartilaginous Fishes, and of the probable formation of the earliest vertebrate limb from the lateral embryonic fold, still to be traced in the young of the Osseous Fishes of to-day.

Embryology has helped us to understand the changes aquatic animals must gradually undergo in order to become capable of living upon dry land. It has given us pictures of swimming-bladders existing as rudimentary lungs in Fishes with a branchial system; in Batrachians it has shown us the persistence of a branchial system side by side with a veritable lung. We find among the earliest terrestrial vertebrates types having manifest affinities with the Fishes on one side and Batrachians on the other, and we call these types Reptiles; but we should nevertheless do so with a reservation, looking to embryology for the true meaning of these half-fledged Reptiles, which lived at the period of transition between an aquatic and a terrestrial life, and must therefore always retain an unusual importance in the study of the development of animal life.

When we come to the embryology of the marine Invertebrates the history of the development of the barnacles is too familiar to be dwelt upon, and I need only allude to the well-known transformations of the Echinoderms, of the Acalephs, Polyps, in fact of every single class of Invertebrates, and perhaps in none more than in the Brachiopods, to show how far-reaching has been the influence of embryology in guiding us to a correct reading of the relations between the fossils of successive formations. There is scarcely an embryological monograph now published dealing with any of the later stages of growth which does not speak of their resemblance to some type of the group long ago extinct. It has therefore been most natural to combine with the attempts constantly made to establish the genetic sequence between the genera of successive formations an effort to establish also a correspondence between their palæontological sequence and that of the embryonic stages of development of the same, thus extending the mere similarity first observed between certain stages to a far broader generalisation.

It would carry me too far to sketch out, except in a most general way, even for a single class, the agreement known to exist in certain groups between their embryonic development and their palæontological history. It is hinted at in the succession of animal life of any period we may take up, and perhaps cannot be better expressed than by comparing the fauna of any period as a whole with that of following epochs;—a zoological system of the Jura, for instance, compared with one made up for the Cretaceous; next, one for the Tertiary, compared with the fauna of the present day. In no case could we find any class of the animal kingdom bearing the same definitions or characterised in the same manner. But apply to this comparison the data obtained from the embryological development of our present fauna, and what a flood of light is thrown upon the meaning of the succession of these apparently disconnected animal kingdoms, belonging to different geological periods, especially in connection with the study of the few ancient types which have survived to the present day from the earliest times in the history of our earth!

Although there is hardly a class of the animal kingdom in which some most interesting parallelism could not be drawn, and while the material for an examination of this parallelism is partially available for the Fishes, Molluscs, Crustacea, Corals, and Crinoids, yet for the illustration and critical examination of this parallelism I have been led to choose to-day a very limited group, that of Sea-urchins, both on account of the nature of the material and of my own familiarity with their development and with the living and extinct species of Echini. The number of living species is not very great,—less than three hundred,—and the number of fossil species thus far known is not, according to Zittel, more than about two thousand. It is therefore possible for a specialist to know of his own knowledge the greater part of the species of the group. It has been my good fortune to examine all but a few of the species now known to exist, and the collections to which I have had access contain representatives of the majority of the fossil species. Sea-urchins are found in the oldest fossiliferous rocks; they have continued to exist without interruption in all the strata up to the present time. While it is true that our knowledge of the Sea-urchins occurring before the Jurassic period is not very satisfactory, it is yet complete enough for the purposes of the present essay, as it will enable me, starting from the Jurassic period, to call your attention to the palæontological history of the group, and to compare the succession of its members with the embryological development of the types now living in our seas. Ample material for making this comparison is fortunately at hand; it is material of a peculiar kind, not easily obtained, and which thus far has not greatly attracted the attention of zoologists.

Interesting and important as are the earliest stages of embryonic development in the different classes of the animal kingdom, as bearing upon the history of the first appearance of any organ and its subsequent modifications, they throw but little light on the subject before us. What we need for our comparisons are the various stages of growth through which the young Sea-urchins of different families pass from the time they have practically become Sea-urchins until they have attained the stage which we now dignify with the name of species. Few embryologists have carried their investigations into the more extended field of the changes the embryo undergoes when it begins to be recognised as belonging to a special class, and when the knowledge of the specialist is absolutely needed to trace the bearing of the changes undergone, and to understand their full meaning. Fortunately the growth of the young Echini has been traced in a sufficient number of families to enable me to draw the parallelism between these various stages of growth and the palæontological stages in a very different manner from what is possible in other groups of the animal kingdom, where we are overwhelmed with the number of species, as in the Insects or Mollusks, or where the palæontological or the embryological terms of comparison are wanting or very imperfect.

Beginning with the palæontological history of the regular sea-urchins at the time of the Trias, when they constituted an unimportant group as compared with the Crinoids, we find the Echini of that time limited to representatives of two families. One of these, the genus Cidaris, has continued to exist, with slight modifications, up to the present time, and not less than one-tenth of all the known species of fossil Echini belong to this important genus, which in our tropical seas is still a prominent one. It is interesting here to note that in the Cidaridæ the modifications of the test are not striking, and the fossil genera appearing in the successive formations are distinguished by characters which often leave us in doubt as to the genus to which many species should be referred. In the genus Rhabdocidaris, which appears in the lower Jura, and which is mainly characterised by the extraordinary development of the radioles, we find the extreme of the variations of the spines in this family. From that time to the present day the most striking differences have existed in the shape of the spines, not only of closely allied genera, but even in specimens of the same species; differences which in some of the species of to-day are as great as in older geological periods. The oldest Cidaridæ are remarkable for their narrow poriferous zones. It is only in the Jura that they widen somewhat; subsequently the pores become conjugated, and only later, during the Cretaceous period, do we find the first traces of any ornamentation of the test (Temnocidaris) so marked at the present day in the genus Goniocidaris. As far, then, as the Cidaridæ are concerned, the modifications which take place from their earliest appearance are restricted to slight changes in the poriferous zone and in the ornamentation of the test, accompanied with great variability in the shape of the primary radioles. We must except from this statement the genera Diplocidaris and Tetracidaris, to which I shall refer again. The representatives of the other Triassic family become extinct in the lower tertiaries. The oldest genus, Hemicidaris, undoubtedly represents the earliest deviations from the true Cidaris type; modifications which affect not only the poriferous zone, but the test, the actinal and the abactinal systems, while from the extent of these minor changes we can trace out the gradual development of some of the characteristics in families of the regular Echini now living. The genus Hemicidaris may be considered as a Cidaris in which the poriferous zone is narrow and undulating, in which the granules of the ambulacral system have become minute tubercles in the upper portion of the zone and small primary tubercles in its actinal region, in which many of the inter-ambulacral granules become small secondaries, in which the plates of the actinal system have become reduced in number, and the apical system has become a narrow ring, and finally, in which the primary radioles no longer assume the fantastic shapes so common among the Cidaridæ.

We can trace in this genus the origin of the modifications of the poriferous zone, leading us, on the one side, through genera with merely undulating lines of pores to more or less distinct confluent arcs of pores, formed round the primary ambulacral tubercles, and, on the other, to the formation of open arcs of three or more pairs of pores. The first type culminates at the present day with the Arbaciadæ, the other with the Diadematidæ, Triplechinidæ, and Echinometradæ. This specialisation very early takes place, for already in the lower Jura Stomechinus has assumed the principal characteristics of the Triplechinidæ of to-day.

Although in Hemicidaris the number of the coronal plates has increased as compared with the Cidaridæ, and while we find that in many genera, even of those of the present day, the number of the coronal plates is still comparatively small, yet, as a general rule, the more recent formations contain genera in which the increase in number of the interambulacral plates is accompanied by a corresponding decrease in the number of plates of the interambulacral area so characteristic thus far of the Cidaridæ and Hemicidaridæ, a change also affecting the size of the primary ambulacral tubercles. This increase in the number of the coronal plates is likewise accompanied by the development of irregular secondary and miliary tubercles, and the disappearance in this group of the granular tuberculation, so important a character in the Cidaridæ. With the increase in the number of the interambulacral coronal plates, the Pseudodiadematidæ still retain prominent primary tubercules, recalling the earlier Hemicidaridæ and Cidaridæ, and, as in the Cidaridæ proper, the test is frequently ornamented by deep pits or by ridges formed by the junction of adjoining tubercles. The genital ring becomes narrower, and the tendency to the specialisation of one of its plates, the madreporite, more and more marked.

With the appearance of Stomechinus, the Echinidæ proper already assume in the Jura the open arcs of pores, the large number of coronal interambulacral plates, the specialisation of the secondary tubercles, and the large number of primary tubercles in each plate. With the appearance of Sphærechinus in the early Tertiary come in all the elements for the greater multiplication of the pairs of pores in the arcs of the poriferous zones, while the gigantic primary spines of some of the genera (Heterocentrotus), and the small number of primary tubercles are structural features which had completely disappeared in the group preceding the Echinometradæ, to which they appear most closely allied.

Going back again to the Hemicidaridæ, it requires but slight changes to pass from them to Acrosalenia and to the Saleniæ proper; the latter have continued to the present day, and have, like the Cidaridæ, retained almost unchanged the characters of the genera which preceded them, combined however with a few Cidaridian and Echinid features which date back to the Triassic period. We can thus trace the modifications which have taken place in the poriferous zone, the apical and actinal systems, the coronal plates, the ambulacral and interambulacral tubercles, as well as in the radioles, and in the most direct manner possible indicate the origin of the peculiar combination of structural features which we find at any geological horizon. On taking in succession the modifications undergone by the different parts of the test, we can trace each one singly, without the endless complication of combinations which any attempt to trace the whole of any special generic combination would imply.

Leaving out of the question for the moment the Palæchinidæ, we find no difficulty in tracing the history of the characters of the genera of the regular Echini which have existed from the time of the Trias and are now living, provided we take up each character independently. Nothing can be more direct than the gradual modification of the simple, barely undulating poriferous zone, made up of numerous ambulacral plates covered by granules, such as we find it among the Cidaridæ of the Trias, first into the slightly undulating poriferous zone of the Hemicidaridæ, next into the indistinct arcs of pores of the Pseudodiadematidæ, then into the arcs with a limited number of pores of the Triplechinidæ, and finally to the polyporous arcs of the Echinometradæ. What can be more direct than the gradual modification to be traced in the development of the primary ambulacral tubercles, such as are characteristic of the Echinidæ of the present day, from their first appearance at the oral extremity of the ambulacral system of the Hemicidaridæ, and the increase in the number of primary interambulacral tubercles, accompanied by the growth of secondaries and miliaries, which we can trace in Hemicidaris, Acrosalenia, and Stomechinus—the increase in number of the primary and secondary tubercles being accompanied by a reduction in the size of the radioles and a greater uniformity in their size and shape?

But while these modifications take place the original structural feature may be retained in an allied group. Thus the Cidaridæ retain unchanged from the earliest time to the present day the few primary tubercles, the secondary granules, the simple poriferous zone, the imbricating actinal system, and the few coronal plates, with the large apical system and many-shaped radioles; while in the Salenidæ the primary interambulacral tubercles, the secondary granules, the radioles, the genital ring, are recognised features of the Cidaridæ, associated, however, with an Echinid actinal and anal system, Hemicidarid primary ambulacral tubercles, and an Echinid poriferous zone. In the same way in the Diadematidæ, the large primary interambulacral tubercles are Cidaridian features, while the structure of the ambulacral tubercles is Hemicidaridian. The existence of two kinds of spines is another Cidaridian feature, while the apical and actinal systems have become modified in the same direction as that of the Echinidæ. The more recent the genus the greater is the difficulty of tracing in a direct manner the origin of any one structural feature, owing to the difficulty of disassociating structural elements characteristic of genera which may be derived from totally different sources. This is particularly the case with genera having a great geological age. Many of them, especially among the Spatangoids, show affinities with genera following them in time, to be explained at present only on the supposition that when a structural feature has once made its appearance it may reappear subsequently apparently as a new creation, while in reality it is only its peculiar combination with structural features with which it had not before been associated (a new genus), which conceals in that instance the fact of its previous existence. A careful analysis, not only of the genera of the order, but sometimes of other orders which have preceded this combination in time, may often reveal the elements from which have been produced apparently unintelligible modifications.

There is, however, not one of the simple structural features in the few types of the Triassic and Liassic Echini from which we can so easily trace the origin of the structural features of all the subsequent Echinid genera, which is not also itself continued to the present day in some generic type of the present epoch, fully as well characterised as it was in the beginning. In fact, the very existence to-day of these early structural features seems to be as positive a proof of the unbroken systematic affinity between the Echini of our seas and those of the Trias as the uninterrupted existence of the genus Pygaster or Cidaris from the Trias down to the present epoch, or of the connection of many of the genera of the Chalk with those of our epoch (Salenia, Cyphosoma, Psammechinus, &c.).

Passing to the Clypeastridæ, we find there, as among the Desmosticha, that the earliest type, Pygaster, has existed from the Trias to the present time; and that, while we can readily reconstruct, on embryological grounds, the modifications the earliest Desmosticha-like Echini should undergo in order to assume the structural features of Pygaster, yet the early periods in which the precursors of the Echinoconidæ and Clypeastridæ are found have thus far not produced the genera in which these modifications actually take place. But, starting from Pygaster, we naturally pass to Holectypus, to Discoidea, to Conoclypus, on the one side, while on the other, from Holectypus to Echinocyamus, Sismondia, Fibularia, and Mortonia, we have the natural sequence of the characters of the existing Echinanthidæ, Laganidæ, and Scutellidæ, the greater number of which are characteristic of the present epoch. If we were to take in turn the changes undergone in the arrangement of the plates of the test, as we pass from Pygaster to Holectypus, to Echinocyamus, and the Echinanthidæ, we should have in the genera which follow each other in the palæontological record an unbroken series showing exactly what these modifications have been. In the same way the modifications of the abactinal and anal systems, and those of the poriferous zone, can equally well be followed to Echinocyamus, and thence to the Clypeastridæ; while a similar sequence in the modifications of these structural features can be followed from Mortonia to the Scutellidæ of the present period.

Passing finally to the Petalosticha, we find no difficulty in tracing theoretically the modifications which our early Echinoconidæ of the Lias should primarily undergo previous to the appearance of Galeropygus. The similarity of the early Cassiduloid and Echinoneoid types points to the same systematic

affinity, and perhaps even to a direct and not very distant relationship with the Palæchinidæ. For if we analyse the Echinothuriæ of the present day, we find in genera like Phormosoma many structural features, such as the shape of the test, the character of the spines, the structure of the apical system, that of the poriferous zone, indicative of possible modifications in the direction of Pygaster or of Galeropygus, which have as yet not been taken into account.

Adopting for the Petalosticha the same method of tracing the modifications of single structural features in their palæontological succession, we trace the comparatively little modified palæontological history of the Echinoneidæ of the present day from the Pyrina of the lower Jura. This, in its turn, has been preceded by Hyboclypus and Galeropygus, while the Echinolampadæ of the present day date back, with but trifling modifications, to the Echinobrissus of the Lias, itself preceded by Clypeus: and they have been subject only to slight generic changes since that time, Echinobrissus being still extant, while such closely-allied genera as Catopygus and Cassidulus of the earlier Cretaceous are still represented at the present day; the modifications taking place in the actinal system, in the ambulacral zones of the Echinoconidæ and of the Echinolampadæ showing the closest possible systematic affinity in these families. Starting again from Hyboclypus, with its elongate apical system, we naturally pass to Collyrites and the strange Dysasteridæ forms which in their turn are closely allied to the Holasteridæ. From Holaster on the one side and from Toxaster on the other, we find an unbroken sequence of structural characters uniting the successive genera of Holasteridæ, such as Cardiaster, Offaster, Stenonia, Ananchytes, and Asterostoma, with Paleopneustes, Homolampas, and the Pourtalesiæ of the present day, while from the genera of the Toxasteridæ we naturally pass to the cretaceous Hemiaster; in this genus and the subsequent Micraster we find all the elements necessary for the modifications which appear in the Spatanginæ from the time of the Chalk to the present day. These modifications result in genera in which we trace the development of the fascioles, of the actinal, anal, and abactinal plastrons, of the beak, the formation of the petaloid ambulacra, first flush with the test, and little by little changed into marsupial pouches, the growth of the anterior groove and the manifold modifications of the ambulacral system in Spatangus, Agassizia, and Echinocardium, often recalling in some of its features structural characters of families which have preceded this in time.

Apparently in striking contrast with the Echini of the secondary period and those which have succeeded them stand the Palæozoic Echini; but when we have examined the embryology of Echini, we shall be better prepared to understand their structure and the affinities of the Palæchinidæ with the Echini of the present day, and their immediate predecessors.

Taking up now the embryological development of the several families which will form the basis of our comparisons, beginning with the Cidaridæ, we find that in the earliest stages they very soon assume the characters of the adult, the changes being limited to the development of the abactinal system, the increase in number of the coronal plates, and the modifications of the proportionally gigantic primary radioles.

In the Diadematidæ the changes undergone by the young are limited to the gradual transformation of the embryonic spines to those which characterise the family, to the changes of the vertical row of pores in the ambulacral area into arcs of three or four pairs of pores, and to the specialisation of the actinal and abactinal systems.

In the Arbaciadæ the young stages are remarkable for the prominent sculpture of the test, for the flattened spines, for their simple poriferous zone, for their actinal system, and for their genital ring. The anal plates appear before the genital ring.

In the Echinometradæ the young thus far observed are characterised by the small number of their primary tubercles, the large size of the spines, the simple vertical row of pores, the closing of the anal ring by a single plate, and the turban-shaped outline of the test. Little by little the test loses with increasing age this Cidaris-like character; it reminds us, from the increase in the number of its plates, more of Hemicidaris; then, with their still greater increase, of the Pseudodiadematidæ; and, finally, of the Echinometradæ proper. The spines, following *pari passu* the changes of the test, lose little by little their fantastic embryonic, or rather Cidaris-like appearance, and become more solid and shorter, till they finally assume the delicately fluted structure characteristic of the Echinometradæ. The vertical poriferous zone is first changed into a series of connected vertical arcs, which become disjointed, and form, with increasing age, the independent arcs of pores, of three or more pairs of pores, of the Echinometradæ.

In the Echinidæ proper we find in the young stages the same unbroken vertical line of pores, which gradually becomes changed to the characteristic generic types. We find, as in the Echinometradæ, an anal system closed with a single plate, and an abactinal system separating in somewhat more advanced stages from the coronal plates of the test. This is as yet made up of a comparatively small number of plates, carrying but few large primary tubercles, with fantastically shaped spines entirely out of proportion to the test, but which, little by little, with the increase of the number of coronal plates, the addition of primary tubercles, and their proportional decrease in size, assume more and more the structure of the genus to which the young belongs. *The original anal plate is gradually lost sight of from the increase* in number of the plates covering the anal system, and it is only among the Temnopleuridæ that this anal plate remains more or less prominent in the adult. In the Salenidæ, of which we know as yet nothing of the development, this embryonic plate remains permanently a prominent structural feature of the apical system.[1]

Among the Clypeastroids the changes of form they undergo during growth are most instructive. We have in the young Fibularinæ an ovoid test, a small number of coronal plates surmounted by few and large primary tubercles, supporting proportionally equally large primary radioles, simple rectilinear poriferous zones, no petaloid ambulacra—in fact, scarcely one of the features we are accustomed to associate with the Clypeastroids is as yet prominently developed. But rapidly, with increasing size, the number of primary tubercles increases, the spines lose their disproportionate size, the pores of the abactinal region become crowded and elongate, and a rudimentary petal is formed. The test becomes more flattened, the coronal plates increase in number, and it would be impossible to recognise in the young Echinocyamus, for instance, the adult of the Cidaris-like or Echinometra-like stages of the Sea-urchin, had we not traced them step by step. Most interesting, also, is it to follow the migrations of the anal system, which, to a certain extent, may be said to retain the embryonic features of the early stages of all Echinoderm embryos, in being placed in more or less close proximity to the actinostome. What has taken place in the growth of the young Echinocyamus is practically repeated for all the families of Clypeastroids; a young Echinarachnius, or Mellita, or Encope, or a Clypeaster proper, resembles at first more an Echinometra than a *Clypeastroid; they all have simple* poriferous zones and spines and tubercles out of all proportion to the size of the test.[2]

When we come to the development of the Spatangoids, we find their younger stages also differing greatly from the adult. Among the Nucleolidæ, for instance, the young stages have as yet no petals, but only simple rectilinear poriferous zones. They are elliptical with a high test, with a single large primary tubercle for each plate, and a simple elliptical actinostome, without any trace of the typical bourrelets and phyllodes so characteristic of this family. Very early, however, this condition of things is changed, the test soon becomes more flattened, the petals begin to form as they do in the Clypeastroids, and we can soon trace the rudiments of the peculiar bourrelets characteristic of the family, accompanied by a rapid increase in the number of tubercles and in that of the coronal plates.

Among the Spatangidæ some are remarkable in their adult condition for their labiate actinostome, for the great development of the petals, for the presence of fascioles surrounding certain definite areas, for the small size of the tubercles, the general uniformity in the spines of the test, and the specialisation of their anterior and posterior regions. On examining the young stages of this group of Spatangoids, not one of these structural features is as yet developed. The actinostome is simple, the poriferous zone has the same simple structure from the actinostome to the apex, the primary tubercles are large, *few in* number, surrounded by spines which would more readily pass as the spines of Cidaridæ than of Spatangoids. The fascioles are either very indistinctly indicated, or else the special lines have

[1] The young of the following genera have served as a basis for the preceding analysis of the embryonic stages of the Desmosticha: Cidaris, Dorocidaris, Goniocidaris, Arbacia, Porocidaris, Strongylocentrotus, Echinometra, Echinus, Toxopneustes, Hipponoë, Temnopleurus, Temnechinus, and Trigonocidaris.

[2] Among the Clypeastroids I have examined the young of Echinocyamus, Fibularia, Mellita, Laganum, Echinarachnius, Encope, Clypeaster, and Echinanthus.

not as yet made their appearance; the ambulacral suckers of the anterior zone are as large and prominent as those of the young stages of any of the regular Echini. It is only little by little, with advancing age, that we begin to see signs of the specialisation of the anterior and posterior parts of the test, that we find the characteristic anal or lateral fascioles making their appearance, only with increasing size that the spines lose their Cidaris-like appearance, that the petals begin to be formed, and that the simple actinostome develops a prominent posterior life. In the genus Hemiaster, the young stages are specially interesting, as long before the appearance of the petals, while the poriferous zone is still simple, the total separation of the bivium and of the trivium of the ambulacral system, so characteristic of the earliest Spatangoids (the Dysasterinæ), is very apparent.[1]

From this rapid sketch of the changes of growth in the principal families of the recent Echini we can now indicate the transformations of a more general character through which the groups as a whole pass.

In the first place, while still in the Pluteus all the young Echini are remarkable for the small number of coronal plates, for the absence of any separation between the actinal and abactinal systems and the test proper. They all further agree in the large size of the primary spines of the test, whether it be the young of a Cidaris, an Arbacia, an Echinus, a Clypeaster, or a Spatangoid. They all in their youngest stages have simple vertical ambulacral zones; beyond this, we find as changes characteristic of some of the Desmosticha, the specialisation of the actinal system from the coronal plates, the formation of an anal system, the rapid increase in the number of the coronal plates, with a corresponding increase in the number of the spines and a proportional reduction of their size, the formation of an abactinal ring, and the change of the simple vertical poriferous zone into one composed of independent arcs.

In the Spatangoids and Clypeastroids we find common to both groups the shifting of the anal system to its definite place, the modifications of the abactinal part of the simple ambulacral system in order to become petaloid, and the gradual change of the elliptical ovoid test of the young to the characteristic generic test, accompanied by the rapid increase in the number of the primary tubercles and spines. Finally limited to the Spatangoids are the changes they undergo in the transformation of the simple actinostome to a labiate one, the specialisation of the anterior and posterior parts of the test, and the definite formation of the fascioles.

Comparing this embryonic development with the palæontological one, we find a remarkable similarity in both, and in a general way there seems to be a parallelism in the appearance of the fossil genera and the successive stages of the development of the Echini as we have traced it.

We find that the earlier regular Echini all have more or less a Cidaris-like look—that is, they are Echini with few coronal plates, large primary tubercles, with radioles of a corresponding size; that it is only somewhat later that the Diademopsidæ make their appearance, which, in their turn, correspond within certain limits to the modifications we have traced in the growth of the young Diadematidæ and Arbaciadæ. The separation of the actinal system from the coronal plates has been effected. The poriferous zone has either become undulating, or forms somewhat indefinite open arcs; we find in all the genera of this group a larger number of coronal plates, more numerous primaries, the granules of the Cidaridæ replaced by secondaries and miliaries, and traces of a Hemicidaris-like stage in the size of the actinal ambulacral tubercles.

Comparing in the same way the palæontological development of the Echinidæ proper, we find that, on the whole, they agree well with the changes of growth we can still follow to-day in their representatives, and that, as we approach nearer the present epoch, the fossil genera more and more assume the structural features which we find developed last among the Echinidæ of the present day. Very much in the same manner as a young Echinus develops, they lose, little by little, first their Cidaridian affinities, which become more and more indefinite, next their Diadematidian affinities, if I may so call the young stages to which they are most closely allied, and finally, with the increase in the number of the coronal plates, the great numerical development of the primary tubercles and spines, and that of the secondaries and miliaries which we can trace in the fossil Echini of the Tertiaries, we pass insensibly into the generic types characteristic of the present day.

Although we know nothing of the embryology of the Salenidæ, yet, like the Cidaridæ, they have in a great measure remained a persistent type, the modifications of the group being all in the same direction as those noticed in the other Desmosticha; a greater number of coronal plates, the development of secondaries and miliaries combined with a specialisation of the actinal system not found in the Cidaridæ.

An examination of the succession of the Echinoconidæ shows but little modification from the earliest types; the changes, however, are similar to those undergone by the Clypeastroids and Petalosticha, though they do not extend to modifications of the poriferous zone, but are mainly changes in the actinostome and in the tuberculation. In fact, the group of Echinoconidæ seems to hold somewhat the same relation to the Clypeastroids which the Salenidæ hold to the Cidaridæ, and the earliest genus of the group Pygaster has remained, like Cidaris, a persistent type to the present day.

The earliest Clypeastroids are all forms which resemble the Fibularina and the genera following Echinocyamus and Fibularia; they are mainly characterised by the same changes which an Echinarachnius or a Mellita, for instance, undergoes as it passes from its Echinocyamus stage to the Laganum or Encope stage. The comparison is somewhat more complicated when we come to the Spatangoids. The comparison of the succession of genera in the different families, as traced in the Desmosticha and Clypeastroids, is made difficult from the persistency of the types preceding the Echinoneidæ and the Ananchytidæ, which have remained without important modifications from the time of the lower Cretaceous; previous to that time the modifications of the Cassidulidæ are found to agree with the changes which have been observed in the growth of Echinolampas. The early genera, like Pygurus, have many of the characteristics of the test of the young Echinolampas. The development of prominent bourrelets and of the floscelle and petals goes on side by side with that of genera in which the modification of the actinostome, of the test, and of the petals is far less rapid, one group retaining the Echinoneus features, the other culminating in the Echinolampas of the present day, and having likewise a persistent type, Echinobrissus, which has remained with its main structural features unchanged from the Jura to the present day. That is, we find genera of the Cassidulidæ which recall the early Echinoneus stage of Echinolampas, next the Caratomus stage, after which the floscelle, bourrelets, and petals of the group become more prominent features of the succeeding genera. Accompanying the persistent type Echinobrissus, genera appear in which either the bourrelets or petals have undergone modifications more extensive than those of the same parts in the genera of the Echinoneus or Caratomus type.

The earliest Spatangoids belong to the Dysasteridæ, apparently an aberrant group, but which, from the history of the young Hemiaster, we now know to be a strictly embryonic type, which, while it thus has affinities with the true Spatangoids, still retains features of the Cassidulidæ in the mode of development of the actinostome and of the petals, as well as of the anal system. The genera following this group, Holaster and Toxaster, can be well compared, the one to the young stages of Spatangus proper before the appearance of the petals, when the ambulacra are flush with the test, and when its test is more or less ovoid, the other to a somewhat more advanced stage, when the petals have made their appearance as semi-petals. In both cases the actinostome has the simple structure characteristic of all the young Spatangoids. The changes we notice in the genera which follow them lead in the one case through very slight modifications of the abactinal system, of the anterior and posterior extremities of the test, to the Ananchytid-like Spatangoids of the present day, the Pourtalesiæ, the genus Holaster itself persisting till well into the middle of the Tertiary period; while on the other side we readily recognise in the Spatanginæ which follow Toxaster (a persistent type which has continued as Palæostoma to the present day) the genera which correspond to the young stages of such Spatangoids as Spatangus and Brissopsis of the present day, genera which, on the one hand, lead from Hemiaster (itself still represented in the present epoch), through stages such as Cyclaster, Peripneustes, Brissus, and Schizaster, and, on the other, through Micraster and the like, to the Spatangoids, in which the development of the anal plastron and fasciole performs an important part, while in the former group the development of the peripetalous fasciole and of the lateral

[1] For this sketch of the embryology of the Petalosticha I have examined the young of Echinolampas, Echinoneus, Echinocardium, Brissopsis, Agassizia, Spatangus, Brissus, and Hemiaster.

fasciole can be followed. None of the genera of Petalosticha belonging to the other groups develop any fasciole in the sense of circumscribing a limited area of the test.

The comparison of the genera of Echini which have appeared since the Lias with the young stages of growth of the principal families of Echini, shows a most striking coincidence, amounting almost to identity, between the successive fossil genera and the various stages of growth. This identity can, however, not be traced exactly in the way in which it has usually been understood, while there undoubtedly exists in the genera which have appeared one after the other a gradual increase in certain families in the number of forms, and a constant approach in each succeeding formation, in the structure of the genera, to those of the present day. It is only in the accordance between some special points of structure of these genera and the young stages of the Echini of the present day that we can trace an agreement which, as we go further back in time, becomes more and more limited. We are either compelled to seek for the origin of many structural features in types of which we have no record, or else we must attempt to find them existing potentially in groups where we had as yet not succeeded in tracing them. The parallelism we have traced does not extend to the structure as a whole. What we find is the appearance among the fossil genera of certain structural features giving to the particular stages we are comparing their characteristic aspect. Thus, in the succession of the fossil genera, when a structural feature has once made its appearance, it may either remain as a persistent structure, or it may become gradually modified in the succeeding genera of the same family, or it may appear in another family, associated with other more marked structural features which completely overshadow it. Take, for instance, among the Desmosticha the modifications of the poriferous zone of the actinal and abactinal systems of the coronal plates, of the ambulacral and interambulacral systems, the changes in the relative proportion of the primary tubercles, and the development of the secondaries. These are all structural features which are modified independently one of the other; we may find simultaneous development of these features in parallel lines, but a very different degree of development of any special feature in separate families.

This is as plainly shown in the embryological as in the palæontological development. In the Cidaridæ there is the minimum of specialisation in these structural features. In the Diademopsidæ there is a greater range in the diversity of the structure of the poriferous zone and of the coronal plates, as well as of the actinal system. There is a still greater range among the Echinidæ, while among the Salenidæ the modifications, as compared to those of the Echinidæ and Diademopsidæ, are somewhat limited again, being restricted as far as relates to the poriferous zone and coronal plates, but specialised as far as the actinal system is concerned, and specially important with reference to the structure of the apical system. The special lines in which these modifications take place produce, of course, all possible combinations, yet they give us the key to the sudden appearance, as it were, of structural features of which the relationship must be sought in very distantly related groups. It is to this speciality in the palæontological development that we must trace, for instance, the Cidarid affinities of the Saleniæ, their papillæ, the existence of few large primary interambulacral tubercles, the structure of their apical system, and their large genital plates; while it is to their affinities with the Hemicidaridæ that we must refer the presence of the few larger primary ambulacral tubercles at the base of the ambulacral area, and by their Diademopsid and Echinidian affinities that we explain the indented imbricated actinal system with the presence of a few genuine miliaries. But all the structural features which characterise the earliest types of the Desmosticha can in reality be traced, only in a somewhat rudimentary form, even in the Cidaridæ. The slight undulation of the closely packed, nearly vertical poriferous zone is the forerunner of the poriferous zone first separated into vertical arcs and then into independent arcs. The limitation in the number of the rows of granules in the ambulacral zone, and their increase in size, is the first trace of the appearance of the somewhat larger primary ambulacral tubercles of the Hemicidaridæ and Saleniæ. The existence of the smooth cylindrical spines of the abactinal region of the test naturally leads to similar spines covering the whole test in the other families of the Desmosticha. The difference existing in the plates covering the actinal system from those of the coronal plates leads to the great distinction between the structure of the actinal system and of the coronal plates in some of the Echinidæ.

Passing to the Clypeastridæ and Petalosticha, we trace a parallelism of the same kind, and readily follow in the successive genera of fossil Clypeastroids, but often in widely separated genera, the precise modifications which the poriferous zone has undergone as it first becomes known to us in Echinocyamus and Fibularia, and as we find it in the most complicated petaloid stage of the Clypeastroids of the present day. We readily trace the changes the test undergoes from its comparatively ovoid and swollen shape to assume first that of the less gibbous forms, next that of the Laganidæ, and finally of the flat Scutellidæ; while we trace in the Echinanthidæ the persistent structural features of some of the earliest Clypeastroids, together with an excessive modification of the poriferous zone. Likewise for the Echinoconidæ we trace mainly the slight modifications of the poriferous zone and of the coronal plates, and finally, when we come to the Spatangidæ we find no difficulty in tracing from the most Desmostichoid of the Spatangoid genera the modifications of a test in which the ambulacral and interambulacral areas are made up of plates of nearly uniform size, in which the anterior and posterior extremities are barely specialised, to the most typical of the Ananchytidæ, in which the anterior and posterior extremities have developed the most opposite and extraordinary structural features. In a similar way we can trace among the fossil genera of different families the gradual development of the actinal plastron from its very earliest appearance as a modification of the posterior interambulacral area of the actinal side, or the growth of the posterior beak into an anal snout, the successive changes of the anal groove, the formation of the actinal labium, or the development of the bourrelets and phyllodes from a simple circular actinostome, the gradual deepening of the slight anterior groove of some early Spatangoid to form the deeply sunken actinal groove. Equally well we can trace the modifications of the ambulacral system as it passes from the simple poriferous zones of the earlier Spatangoids to genera in which the petaliferous portion makes its appearance, and finally becomes the specialised structure of our recent Spatangoid genera, such as Schizaster, Moira, and the like. Finally, we can trace to a certain extent the development of the fascioles on one side from genera like Hemiaster, in which the peripetalous fasciole is prominent, to genera like Brissopsis, Brissus, and the like, of the present day; on the other, perhaps, or both combined, the formation of a lateral and anal fasciole from genera like Micraster in Spatangus and Agassizia. Thus we must, on the same theory of the independent modifications of special structural features, trace the many and complicated affinities which so constantly strike us in making comparative studies, and which render it impossible for us to express the manifold affinities we notice, without taking up separately each special structure. Any attempt to take up a combination of characters, or a system of combinations, is sure to lead us to indefinite problems far beyond our power to grasp.

In the oldest fossil Clypeastroids and Petalosticha, as well as in the Desmosticha, we also find the potential expression of the greater number of the modifications subsequently carried out in genera of later date. The semipetaloid structure of some of the earlier genera of Spatangoids, the slight modifications of some of the plates of the actinal side near the actinostome, are the precursors, the one of the highly complicated petaloid ambulacra of the recent Spatangoids, the other of the actinal plastron, leading as it does also to the important differences subsequently developed in the anterior and posterior extremities of the test, as well as to the modifications which lead to the existence of a highly labiate actinostome. The appearance of a few miliaries near the actinostome constitutes the first rudimentary bourrelets.

Going back now to the Palæchinidæ, the earliest representatives of the Echini in palæozoic times, without any attempt to trace the descent of any special type from them, we may perhaps find some clue to the probable modifications of their principal structural features preparatory to their gradual disappearance. In the structure of the coronal plates, the specialisation of the actinal and abactinal systems, the conditions of the ambulacral system, we must compare them to stages in the embryonic development of our recent Echini with which we find no analogues in the fossil Echini of the Lias and the subsequent formations. In order to make our parallelism, we must go back to a stage in the embryonic history of the young Echini in which the distinction to be made between the ambulacral and interambulacral systems is very indefinite, in which the apical system is, it is true, specialised, but in which the actinal system remains practically a part

of the coronal system. But here the comparison ceases, and, although we can trace in the palæontological development of such types as Archæocidaris or Bothriocidaris modifications which would lead us without great difficulty, on the one side to the Cidaridæ, and on the other to the Echinothuriæ and Diadematidæ of the present day, we cannot fail to see most definite indications in some of the structural features of the Palæchinidæ of characteristics which we have been accustomed to associate with higher groups. The minute tuberculation, for instance, of the Clypeastroids and Spatangoids, already existing in the Melonitidæ, the genital ring, and anal system, are quite as much Echinid as Cidarid. The polyporus genera of the group represent to a certain extent the polypori of the regular Echini, and the lapping of the actinal plates of the Cidaridæ and of the coronal plates in some of the Diadematidæ, as well as the existence of such genera as Tetracidaris, of four interambulacral plates in Astropyga, and of a large number of ambulacral plates in some of the recent Echinometradæ, all these are Palæchinid characters which we can explain on the theory of the independent development of the structural features of which they are modifications. We should, however, remember, that the existence of a large number of coronal plates, especially interambulacral plates, in the Palæchinidæ, is a mere vegetative character, which they hold in common with all the Crinoids,—a character which is reduced to a minimum among the Holothurians, and still persists in full force among the Pentacrini of the present day, as well as the Astrophytidæ and Echinidæ.

It would lead me too far to institute the same comparison between the embryonic stages of the different orders of Echinoderms and their earliest fossil representatives. We may, however, in a very general way, state that we know the earliest embryonic stages of the order of Echinoderms of to-day, which, with the exception of the Blastoidea and Cystideans, are identical with the fossil orders, and that as far as we know they all begin at a stage where it would be impossible to distinguish a Sea-urchin from a Star-fish, or an Ophiuran, or a Crinoid, or an Holothurian,—a stage in which the test, calyx, abactinal and ambulacral systems are reduced to a minimum. From this identical origin there is developed at the present day, in a comparatively short period of time, either a Star-fish, a Sea-urchin, or a Crinoid; and if we have been able successfully to compare, in the development of typical structures, the embryonic stages of the young Echini with their development in the fossil genera, we may fairly assume that the same process is applicable when instituting the comparison within the different limits of the orders, but with the same restrictions. That is, if we wish to form some idea of the probable course of transformations which the earliest Echinoderms have undergone to lead us to those of the present day, we are justified in seeking for our earliest representatives of the orders such Echinoderms as resemble the early stages of our embryos, and in following, for them as for the Echini, the modifications of typical structures. These we shall have every reason to expect to find repeated in the fossils of later periods, and, going back a step further we may perhaps get an indefinite glimpse of that first Echinodermal stage which should combine the structural features common to all the earliest stages of our Echinoderm embryos.

And yet, among the fossil Echinoderms of the oldest periods, we have not as yet discovered this earliest type from which we could derive either the Star-fishes, Ophiurans, Sea-urchins, or Holothurians. With the exception of the latter, which we can leave out of the question at present, we find all the orders of Echinoderms appearing at the same time. But while this is the case, one of the groups attained in these earliest days a prominence which it gradually loses with the corresponding development of the Star-fishes, Ophiurans, and Sea-urchins, it has steadily declined in importance; it is a type of Crinoids, the Cystideans which culminated during Palæozoic times, and completely disappeared long before the present day. If we compare the early types of Cystideans to the typical embryonic Echinodermal type of the present day, we find they have a general resemblance, and that the Cystideans and Blastoids represent among the fossil Echinoderms the nearest approach we have yet discovered to this imaginary prototype of Echinoderms.

This may not seem a very satisfactory result to have attained. It certainly has been shown to be an impossibility to trace in the palæontological succession of the Echini anything like a sequence of genera. No direct filiation can be shown to exist, and yet the very existence of persistent types, not only among Echinoderms, but in every group of marine animals, genera which have continued to exist without interruption from the earliest epochs at which they occur to the present day, would prove conclusively that at any rate some groups among the marine animals of the present day are the direct descendants of those of the earliest geological periods. When we come to types which have not continued as long, but yet which have extended through two or three great periods, we must likewise accord to their latest representatives a direct descent from the older. The very fact that the ocean basins date back to the earliest geological periods, and have afforded to the marine animals the conditions most favourable to an unbroken continuity under slightly varying circumstances, probably accounts for the great range in time during which many genera of Echini have existed. If we examine the interlacing in the succession of the genera characteristic of later geological epochs, we find it an impossibility to deny their continuity from the time of the Lias to the present day. The Cidaris of the Lias and the Rhabdocidaris of the Jura are the ancestors of the Cidaris of to-day. The Saleniæ of the lower Chalk are those of the Saleniæ of to-day. Acrosalenia extends from the Lias to the lower Cretaceous, with a number of recent genera, which begin at the Eocene. The Pygaster of to-day dates back to the Lias; Echinocyamus and Fibularia commence with the Chalk. Pyrina extends from the lower Jura through the Eocene. The Echinobrissus of to-day dates back to the Jura. Holaster lived from the lower Chalk to the Miocene, and the Hemiaster of to-day cannot be distinguished from the Hemiaster of the lower Cretaceous.

Such descent we can trace, and trace as confidently as we trace a part of the population of North America of to-day as the descendants of some portion of the population of the beginning of this century. [But we can go no further with confidence, and bold indeed would he be who would attempt even in a single State to trace the genealogy of the inhabitants from those of ten years before. We had better acknowledge our inability to go beyond a certain point; anything beyond the general parallelism I have attempted to trace, which in no way invalidates the other proposition, we must recognise as hopeless.

But in spite of the limits which have been assigned to this general parallelism, it still remains an all-essential factor in elucidating the history of palæontological development, and its importance has but recently been fully appreciated. For, while the fossil remains may give us a strong presumptive evidence of the gradual passage of one type to another, we can only imagine this modification to take place by a process similar to that which brings about the modifications due to different stages of growth,—the former taking place in what may practically be considered as infinite time when compared to the short life history which has given us as it were a *résumé* of the palæontological development. We may well pause to reflect that in the two modes of development we find the same periods of rapid modifications occurring at certain stages of growth or of historic development, repeating in a different direction the same phases. Does it then pass the limits of analogy to assume that the changes we see taking place under our own eyes in a comparatively short space of time,—changes which extend from stages representing perhaps the original type of the group to their most complicated structures,—may, perhaps, in the larger field of palæontological development, not have required the infinite time we are in the habit of asking for them?

Palæontologists have not been slow in following out this suggestive track, and those who have been anatomists and embryologists besides have not only entered into most interesting speculations regarding the origin of certain groups, but they have carried on the process still further, and have given us genealogical trees where we may, in the twigs and branches and main limbs and trunk, trace the complete filiation of a group as we know it to-day, and as it must theoretically have existed at various times to its very beginning. While we cannot but admire the boldness and ingenuity of these speculations upon genetic connection so recklessly launched during the last fifteen years, we find that with but few exceptions there is little to recommend in reconstructions which shoot so wide of the facts as far as they are known, and seem so readily to ignore them. The moment we leave out of sight the actual succession of the fossils and the ascertainable facts of postembryonic development, to reconstruct our genealogy, we are building in the air. Ordinarily, the twigs of any genealogical tree have only a semblance of truth; they lead us to branchlets having but a slight trace of probability, to branches where the imagination plays an important part, to main

limbs where it is finally allowed full play, in order to solve with the trunk, to the satisfaction of the writer at least, the riddle of the origin of the group. It seems hardly credible that a school which boasts for its very creed a belief in nothing which is not warranted by common sense should descend to such trifling.

The time for genealogical trees is passed; its futility can, perhaps, best be shown by a simple calculation, which will point out at a glance what these scientific arboriculturists are attempting. Let us take, for instance, the ten most characteristic features of Echini. The number of possible combinations which can be produced from them is so great that it would take no less than twenty years, at the rate of one new combination a minute for ten hours a day, to pass them in review. Remembering now that each one of these points of structure is *itself* undergoing constant modifications, we may get some idea of the nature of the problem we are attempting to solve, when seeking to trace the genealogy as understood by the makers of genealogical trees. On the other hand, in spite of the millions of possible combinations which these ten characters may assume when affecting not simply a single combination, but all the combinations which might arise from their extending over several hundred species, we yet find that the combinations which actually exist—those which leave their traces as fossils—fall immensely short of the possible number. We have, as I have stated, not more than twenty-three hundred species actually representing for the Echini the results of these endless combinations. Is it astonishing, therefore, that we should fail to discover the sequence of the genera, even if the genera, as is so often the case, represent, as it were, fixed embryonic stages of some Sea-urchin of the present day? In fact, does not the very history of the fossils themselves show that we cannot expect this? Each fossil species, during its development, must have passed through stages analogous to those gone through by the Echini of the present day. Each one of these stages at every moment represents one of the possible combinations, and those which are actually preserved correspond only to the particular period and the special combination which any Sea-urchin has reached. These stages are the true missing links, which we can no more expect to find preserved than we can expect to find a record of the actual embryonic development of the species of the present day without direct observation at the time. The actual number of species in any one group must always fall far short of the possible number, and for this reason it is out of the question for us to attempt the solution of the problem of derivation, or to hope for any solution beyond one within the most indefinite limits of correctness. If, when we take one of the most limited of the groups of the animal kingdom, we find ourselves engaged in a hopeless task, what must be the prospect should we attack the problem of other classes or groups of the animal kingdom, where the species run into the thousands, while they number only tens in the case we have attempted to follow out? Shall we say "ignorabimus" or "impavidi progrediamus" valiantly to chase a phantom we can never hope to seize?

NOTES

The Second International Geological Congress will be held at Bologna in September, 1881. It is proposed to award a prize of 5,000 francs for the best international scale of colours and conventional signs for the graphic representation of formations on geological maps and sections. Each scale should be accompanied by an explanatory memoir and a sufficient number of maps and sections relative to regions of different geological characters; for the memoirs the French language is recommended. The names of the competitors should be inclosed in sealed envelopes, on which should be a motto. The scales and memoirs should be addressed, before the end of May, 1881, to the President of the Committee, Signor J. Capellini, 65, Via Zamboni, Bologna.

"The Official Guide and Handbook to Swansea and its District," prepared at the request of the Local Committee by Mr. S. C. Gamwell, is a really useful little work, which must prove of permanent value as a guide to Swansea. It contains much carefully compiled information on the History and Antiquities of Swansea, its literary and scientific, educational and other institutions, industries, places of interest in and around the town, geology of the district, palæontology, and natural history. A considerable amount of space is appropriately devoted to the scientific aspects of the district, the information given is very full, and we believe trustworthy. An excellent map is prefixed, and the work as a whole is creditable to the Local Committee and to the author.

On Sunday a statue of Denis Papin was unveiled at Blois, where he was born in 1647.

The late Mungo Ponton, W.S., Fellow of the Royal Society of Edinburgh, whose death was recently announced, was known as the discoverer of the peculiar effect of light on gelatine when treated with the bichromates, which was afterwards practically applied in the autotype process. He obtained the silver medal from the Royal Society of Edinburgh in 1838 for "model and description of improved electric telegraph." He was the first who employed the photographic method for registering automatically the fluctuations in thermometers and other instruments, and for this service he received also the silver medal of the same society in 1845. Several papers of his appeared in the new *Philosophical Journal* and in the *Quarterly Journal of Science*.

The Fifth Annual General Meeting of the Mineralogical Society of Great Britain and Ireland was held at Swansea on August 27, Mr. Jas. S. Merry, F.C.S., in the chair. A favourable report was presented by the Council and adopted by the meeting. The election of the following new members was announced:—Dr. Jas. Hector, F.R.S., of New Zealand, Mr. Thos. Stewart of Glasgow, Rev. R. Graham, LL.D., of Errol, Perthshire; Mr. Jos. Gill of Leadhills, and Rev. Geo. Gordon, LL.D., of Elgin. The following papers were read and discussed:—"On the Chemical Formula of Epidote," by M. l'Abbé Renard; "On Certain Crystallised Furnace-products," by Wm. Terrill, F.C.S.; "On the Serpentine and Hornblendic, and Schistose Rocks of Porthalla in Cornwall," by H. Collins.

On the evening of July 20, about half-past eight o'clock, a remarkable meteor, said to have resembled a comet, apparently about twenty yards in length, was observed at Vizimgaum and other places in India, traversing the sky from south to north, and remaining visible for about three-quarters of a minute, during which time the whole sky and country were brilliantly illuminated. The meteor then burst, and some time afterwards a loud sound like distant thunder, which lasted two minutes, was heard.

The rainfall in Southern China appears to have been abnormally large in the early part of this summer, for we learn from the *Daily Press* of Hongkong that the rainfall in that colony during the month of June was no less than 28·06 inches, compared with 11·32 inches in June, 1879, 15·36 inches in June, 1878, and 9·37 inches in June, 1877. It is stated that so large a rainfall as we have mentioned has never before been registered in Hongkong.

The Government printer at Brisbane has published three valuable Reports, by Mr. Robert L. Jack, the Geological Surveyor of Northern Queensland, who during the last few years has done excellent service in the cause of both geography and geology in Cape York Peninsula. The first of these Reports deals with the geology and mineral resources of the district between Charters Towers gold-fields and the coast, and is illustrated with a map and several woodcuts taken from photographs, while the second is a preliminary Report on the geological features of part of the coast range between the Dalrymple and Charters Towers roads. The third Report treats of the important Bowen River coal-field. This is accompanied by a map and some large and interesting woodcuts.

At Carácas in Venezuela on August 1 there was a heavy shock of earthquake at 7 p.m.

The United States Government proposes to hold an International Sanitary Congress at Washington in January, 1881.

The Rev. A. E. Eaton has begun a series of Notes on the Entomology of Portugal in the *Entomologist's Monthly Magazine*.

In No. 9, vol. xxxviii. of *Globus* an account of Dr. Potagos's travels in the regions of the Nile and Welle is given.

Among the articles in No. 2 of the *American Journal of Philology* (Macmillan and Co.) is one of considerable scientific interest—"Recent Investigations of Grimm's Law," by Mr. H. C. G. Brandt of Johns Hopkins University.

We are requested by Lieut. Temple to publish the following letter addressed to him by Lieut. Col. Fr. Sejersted, Director of the Royal Norwegian Geographical Survey Office:—"Christiania, August 7, 1880.—Sir,—You may possibly have noticed that I have replied in some English newspapers to remarks stated in those papers to have been made by you at a meeting on the 19th of May last of the Society of Arts, with respect to our Norwegian coast charts, and that I have especially alleged that your remarks must have been caused by ignorance of the present stage of our coast charts. I now learn from a copy of the *Journal* of the Society of Arts, containing your paper complete, that the said newspaper statements were misguiding extracts, and that your censure was not pointed against our coast charts, but against an English belabouring of those charts in no way connected with the geographical survey of Norway. As a matter of course my reply would not have been published if the said newspaper statements had been correct concerning the main point to us, and I hereby declare with great pleasure that the copy of the *Journal* of the Society of Arts, containing your paper, proves plainly that you are intimately acquainted with our coast charts and coast descriptions, which are mentioned by you in a very satisfactory manner to us. I express my wish that these lines may help to make good the injustice you have suffered from the misconceptions caused by the ambiguous newspaper statements, and I beg to leave it to you to use this letter at pleasure."

The additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. Geo. G. Turner; two American Moorhens (*Gallinula galeata*) from America, presented by Mr. G. H. Hawtayne, C.M.Z.S.; a Turnstone (*Strepsilas interpres*), captured at sea, off the Azores, presented by Capt. A. McRitchie, s.s. *Utopia*; two Koodoos (*Strepsiceros kudu*) from Africa, a Harnessed Antelope (*Tragelaphus scriptus*) from Gambia, a Syrian Fennec Fox (*Canis famelicus*) from North Africa, a King Vulture (*Gypagus papa*) from Tropical America, deposited; a Nylghaie (*Boselaphus pictus*) from India, a Michie's Tufted Deer (*Elaphodus michianus*) from China, a Cuvier's Toucan (*Ramphastos cuvieri*) from the Upper Amazons, purchased.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, August 16.—M. Wurtz in the chair.—The following papers were read:—Summary report of the cruise of *Le Travailleur* (continued), by M. Alph. Milne-Edwards. He describes the various animal species obtained.—On the establishment of hospital stations in Equatorial Africa, by M. de Lesseps. This reports the progress of Capt. Bloyet in the East (who reached Usagara on July 2) and M. de Brazza in the West (who is seeking a suitable position on one of the affluents of the Ogowé).—On the embryos accompanying cysticersi in pork, by M. Poincaré. Pork may contain microscopic germs of Tænia which may quite escape ordinary inspection. Raw meat of any kind should be avoided.—On some formulæ relative to hypergeometric functions of two variables, by M. Appell.—On various attempts at demonstration of the theorem of Fermat, by M. Pépin.—Observation on a group of lines in the solar spectrum, by M. Thollon. With the centre of the solar image, on his apparatus (on a mountain near Nice) he notes four lines, *a*, *b*, *c*, *d*, of which *a* and *b* are close to each other, and similarly *c* and *d*; *b* and *c* are of iron, *a* and *d* are telluric. On directing the apparatus to the two ends of the equatorial diameter, the iron lines are displaced relatively to the others, conformably to theory.—On the cause of variations of fixed points in thermometers, by M. Crafts. He describes experiments which reduce to *nil*, or a very small amount, the *rôle* of pressure in permanent elevation of the zero point. Glass blown at the lamp and long exposed to heat diminishes in volume through interior work.—On rapid alcoholic fermentation, by M. Boussingault. This relates to fermentation in a liquid that is boiling under a pressure so weak that the heat does not alter the organism of the ferment, while yet it is sufficient to expel the alcohol and the carbonic acid. Glycerine appears during this rapid fermentation.—Spectral examination of thulium, by M. Thalén.—On the absorption-spectra of metals forming part of the groups of yttria and of cerite, by M. Soret.—On erbine, by M. Clève. The atomic weight of the metal he finds to be 166 (ytterbium 173).—Measurement of the intensity of some dark lines of the solar spectrum, by M. Gouy. His method shows clearly the telluric nature of the group B (between 6866 and 6880), by reason of their greater intensity.—On polar electricity in hemihedric crystals with inclined faces, by MM. Jacques and Curie. They show that in all the non-conducting substances studied the direction of the electric poles is connected with the position of the hemihedric facettes. M. Thenard recalled experiments bearing on the subject made by his son fifteen years ago.—New results of utilisation of solar heat obtained at Paris, by M. Pifre. He succeeds in utilising 80 per cent. of the solar heat as against 50 (Mouchot). The reflector is made of three truncated cones, so that the generating line is a broken one. The focus is thus concentrated in much less length, and the height of the boiler may be diminished one half (without increasing its diameter). When the sky is clear the boiling of fifty litres is obtained in less than forty minutes, and the pressure rises 1 atm. every seven or eight minutes. The steam-engine is specially adapted for solar receivers.—Production of crystals of sesquichloride of chromium of persistent green colour, by M. Mengeot.—On the inconveniences presented, with regard to physiological reactions, in cases of poisoning with morphine, by the substitution of amylic alcohol for ether in the process of Stas, by MM. Bergeron and L'Hote.—On the experiment of the great cervical sympathetic, by MM. Dastre and Morat. They demonstrate the existence of vaso-dilator as well as vaso-constrictor nerves in the cervical sympathetic.—Morphological signification of the appendices serving for suspension of chrysalides, by M. Künckel. They are (in Lepidoptera) hooks of membranous anal legs modified and adapted to special biological conditions.—On a new station of the age of stone at Hanaweh, near Tyre (Syria), by M. Lortet. Myriads of flints (of very primitive form), along with numerous fragments of bone and teeth, were found in a kind of conglomerate or breccia.—On the falling stars of August 9, 10, and 11, 1880, by M. Chapelas. The mean horary number is only 53·7, making a difference of 69·3 with that last year. This seems to limit the return of the maximum of August between 1848 and 1879, giving a period of thirty-two or thirty-three years, quite like that of the phenomenon of November 12 and 13.

THURSDAY, SEPTEMBER, 9, 1880

ENGLISH AND AMERICAN BEE-KEEPING

The Bee-Keeper's Manual; or, the Honey Bee, its Management and Preservation. With a Description of the most Approved Hives and other Appliances of the Apiary. By the late Henry Taylor. Seventh Edition, modernised and very greatly enlarged by Alfred Watts. (London: Groombridge and Sons, 1880.)

British Bee-Farming, its Profits and Pleasures. By James F. Robinson. (London: Chapman and Hall, 1880.)

Manual of the Apiary. By A. J. Cook, Professor of Entomology in the Michigan State Agricultural College. Fifth Edition, revised, enlarged, mostly re-written, and beautifully illustrated. (Chicago, Illinois: Thomas G. Newman and Son, 1880.)

MR. WATTS' edition of Taylor's "Bee-Keeper's Manual" has been so copiously revised and added to that it is really a new work, embodying all the most recent discoveries and improvements in apiarian practice. For the amateur bee-keeper—as distinguished from the scientific student of bees on the one hand, and the mere honey manufacturer on the other—this volume is a most admirable guide. It is simple in arrangement, very clear in its descriptions, and copiously illustrated by really good woodcuts of every portion of the extensive apparatus used by the modern amateur. Commencing with a short account of the different kinds of honey-bee, and the main facts of its life-history, we are soon introduced to the mode of keeping bees, beginning with the old-fashioned straw hive, and successively pointing out the various improvements that have been effected. We then come to the different kinds of box, frame, and observatory hives, and the various systems of bee-management, all of which are explained and illustrated in the clearest and most intelligible manner. The latter half of the volume is devoted to a detailed account of the summer, autumn, winter, and spring management of bees; and this part is so full and so carefully written that it will prove of the greatest service to all young bee-keepers.

Mr. Watts does not seem quite so confident as most apiarians of the superior qualities of the Ligurian over the common bee. He quotes, as "worthy of the most careful consideration from those interested in the subject," a statement that the former rob the latter of their honey, and that they are also far more liable to disease. The writer—a Scotchman who has closely studied the habits of bees—says:—

"All Ligurian fanciers claim for them that they work in wet or dry earlier and later than do the blacks. Now any one can see that as soon as there is honey in the flower, so soon will the black bee go for it, and so long as there is honey so long will the black remain gathering it. Since the Ligurian can no more make honey than the black, and since it finds honey after the blacks have failed, it must obtain it from some other source than the flowers. Ligurian bee-keepers tell me—and I see no reason to doubt the statement—that the Ligurian thrives amazingly for a time where plenty of black bees are kept, and that nearly in the same proportion to the number of black hives within reach, so will be the honey-producing powers of the Ligurian. I have often seen them coming out of the black hives, and certainly they were not helping the blacks, because in nearly exact proportion as they increased in weight the blacks decreased; and this transfer of the honey is not always accompanied with fighting, the Ligurians having what all successful pilferers generally have—viz. the knack of introducing themselves unchallenged anywhere if what is wanted is to be had."

"British Bee-Farming" is a most excellent and practical work, written in the simplest style, and giving excellent directions to those who wish to keep bees for profit. We have seldom seen a book from which a beginner can obtain such exact information on all the necessary details of bee-management. Mr. Robinson strongly recommends a simple form of bar-hive, which he calls "the bee-farmer's hive," and which is figured so clearly that any village carpenter can make it; and by the use of this, and his equally simple and efficient "bee-farmer's honey extractor," he shows how a constant supply of pure honey can be obtained, week by week, without interfering with the bees' work or destroying any of the comb, the replacement of which in a small hive necessitates the consumption by the bees of twenty pounds of honey. A good deal of miscellaneous information on bees and bee-keeping is given in the second part of the work, but its chief value is that it well justifies its title, by showing in the briefest and clearest manner how bees may become a source of considerable profit as well as a continual pleasure.

Prof. Cook's volume differs considerably from the preceding, and indeed from any other English work on the subject, in its combination of science with utilitarianism, while the amateur pure and simple is hardly recognised at all. More than one-third of the book is devoted to an account of the natural history of the bee, its place in the animal kingdom, its anatomy, physiology, habits, and economy. Then follow the chapters on bee-keeping proper; and the author here addresses himself almost exclusively to those who make bee-keeping a business, and we are led to understand how much this branch of industry is advancing in America, where honey is now being manufactured on almost as large a scale as corn. An article in the *Times* last year informed us that a single bee-farm has 12,000 swarms, and keeps two steam-saws and nine men at work for five weeks in cutting up the timber for the 72,000 boxes in which the honey is packed for exportation. Prof. Cook accordingly has a chapter on "Marketing Honey," and instructs his readers in the art of "invigorating the market," "tempting the consumer," and other mercantile details; and throughout the book we find constant indications that bee-keeping is looked upon as a business rather than a hobby, and that in all its details economy of labour and materials must be studied, and all processes judged by the test of the maximum of production at a minimum of cost. A few extracts will give an idea of the style of the book.

After stating that a queen bee will often lay two or three thousand eggs a day, he remarks that this is nothing to the queen white ant, which lays 80,000 eggs a day, adding:—

"This poor helpless thing, whose abdomen is the size of a man's thumb, and composed almost wholly of eggs, while the rest of her body is not larger than the same in our common ants, has no other amusement; she cannot

walk; she cannot even feed herself or care for her eggs. What wonder then that she should attempt big things in the way of egg-laying? She has nothing else to do, or to feel proud of."

In the account of the formation of the comb the "pressure" theory is very properly rejected, but no reference is made to the complete explanation of the process given by Darwin, Waterhouse, and others. The mathematical accuracy of the cell is however disproved by the observations of Prof. Wyman, who showed by actual measurement that none of them were perfect hexagons, but that they varied in size, sometimes to the amount of one cell's width in ten, and commonly to half this amount. The rhombic bases of the cells also vary, and as this variation occurs gradually in passing from one part of the comb to another, it follows that whenever this happens the cells must diverge from the true hexagonal form. The supposed mathematical instinct of the bee has therefore no foundation to rest upon, and the beautiful explanation given by Mr. Darwin fully meets the actual facts.

An interesting chapter is devoted to "Honey Plants," the principal species from which the bees obtain their honey in America being figured. In the more northern States fruit-trees, willows, and sugar-maples, with basswood and white clover, are the most productive plants, while on the western prairies the thousands of acres of asters, solidagos, and eupatoriums afford an inexhaustible supply of honey not yet appropriated.

The illustrations of this book are often rude, and sometimes inaccurate. The honey-extractor (at p. 189) is described as acting by centrifugal force, but it is drawn square, and the comb so placed in it that it could not possibly revolve; while, at p. 128, the bottom-board described as having a bevelled notch for an opening to the hive, is shown with a triangular projection, owing to bad perspective in the drawing. These, however, are smal faults; and the English bee-keeper will no doubt obtain many useful hints from this excellent little manual of bee-culture as practised by our ingenious and energetic cousins across the Atlantic. OUR BOOK SHELF

Rainfall of the East Indian Archipelago; First Year, 1879. By Dr. P. A. Bergsma, Director of the Batavia Observatory. (Batavia: At the Government Printing Office, 1880.)

An extremely valuable system of rainfall observation has been established in the East Indian Archipelago under the superintendence of Dr. Bergsma, the well-known director of the Batavia Observatory, and the results of the first year's observations for 1879 are now before us in this octavo volume of 257 pages.

In the beginning of 1879 sixty rain-gauges were in operation, and by the end of the year the number had increased to 125. To these it is proposed to add other seventy new stations during 1880, thus raising the number of stations for the observation of the rainfall of the East Indian Archipelago to 195. Towards the securing of uniformity the same pattern of rain-gauge is used by all the observers, and the gauges are placed at the same height of $3\frac{1}{2}$ feet above the ground; but greater uniformity in the hour of observing, which is any hour from 6 to 9 a.m., is a desideratum. The stations extend from 95° 20′ to 129° 53′ E. long., and from 5° 53′ N. lat. to 10° 10′ S. lat., and as regards elevation they are at heights varying from the level of the sea to a height of 6,404 feet. Their distribution among the islands is 76 on Java, 25 on Sumatra, 7 on Borneo, 4 on Celebes, and 4 on Billiton, 3 on Madeira, and 1 on each of the islands Riouw, Bangka, Ternate, Amboina, Banda, and Timor.

The daily rainfalls at each of the 125 stations during 1879, so far as observed, are printed *in extenso*, and a table is added showing the amounts and days of rainfall for each month and for the year. The largest rainfall for one day was 11·81 inches at Amboina on July 13; and it may be remarked that at the same place on the four days ending the 15th of the same month, 29·45 inches fell. The least annual rainfall at any station was 53·27 inches at Kotta Radja, and the largest 282·33 inches at Padang Pandjang. Of the 59 stations for which there are returns for the whole year, the amount exceeded 100 inches at 33, and 200 inches at 5 of the stations. The greatest number of days on which rain fell at any station was 274 at Soekawana, and the least 136 at Onrust. It is evident that this system of observation will by and by lay before us the observational data for the determination of the distribution of the important element of the rainfall, horizontally and vertically, over the land surfaces of this portion of the globe which excites so strongly the interest of the biologist, geologist, and geographer.

Botanische Jahrbücher für Systematik, Pflanzengeschichte und Pflanzengeographie. Herausgegeben von A. Engler. Erster Band, Heft i. ii. (Leipzig: Verlag von Wilhelm Engelmann, 1880.)

It is a question whether German serials devoted in part or wholly to botanical bibliography are not becoming too numerous, but, be that as it may, this new venture is so circumscribed in its scope that it recommends itself to a large section of botanists in this country whose labours are to a great extent within its scope. Engler's "Botanische Jahrbücher" are to be exclusively devoted to systematical, historical, and geographical botany, and will contain original articles in English, French, or German, as well as a review of current literature. Under Dr. Engler's painstaking editorship we think success should attend the undertaking. The parts are not to appear at fixed intervals, nor necessarily to be uniform in size; but the limit of the interval is from three to six months, and of the size three to four sheets. The contributors to the first part are:—Oswald Heer, on the history of the ginkgo-like trees; Alphonse de Candolle, on some points of botanical nomenclature; Eug. Warming, on the results of recent investigations of the flora of Greenland; O. Beccari, on the phytogeography of the Malayan Peninsula; A. Engler, diagnoses of some new *Burseraceæ* and *Anacardiaceæ*, and a review of the more important botanical works published in 1879. It should be mentioned that the contributions of A. de Candolle and O. Beccari are abstracts of and extracts from what has appeared elsewhere, though this fact does not diminish their value. On the contrary, they are thus brought to the knowledge of many who would otherwise not have an opportunity of reading them. W. B. Hemsley

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

The Conditions Necessary for the Existence of Matter in the Liquid State—Existence of Ice at High Temperatures

Numerous experiments which I have made during the last few weeks on the boiling points of substances under low pres-

sures, the details of which will shortly be published, have led to the following conclusions in reference to the conditions necessary for the existence of any substance in the liquid state. These are two in number, viz. :—

1. In order to convert a gas into a liquid the *temperature* must be *below* a certain point (termed by Andrews the *critical temperature* of the substance), otherwise no amount of pressure is capable of liquefying the gas.

2. In order to convert a solid into a liquid the *pressure* must be *above* a certain point, which I propose to call the *critical pressure* of the substance, otherwise no amount of heat will melt the substance.

If the second of the above conditions be true, it follows that if the necessary temperature be attained, the liquefaction of the substance depends solely on the superincumbent pressure; so that if by any means we can keep the pressure on the substance below its critical pressure, no amount of heat will liquefy it, for in this case the solid substance passes directly into the state of gas, or in other words it sublimes without previous melting.

Having come to this conclusion, it was easily foreseen that if these ideas were correct it would be possible to have *solid ice at temperatures far above the ordinary melting-point.* After several unsuccessful attempts, I was so fortunate as to attain the most perfect success, and have obtained solid ice at temperatures so high that it was impossible to touch it without burning one's self. This result has been obtained many times and with the greatest ease, and not only so, but on one occasion a small quantity of water has frozen in a glass vessel which was so hot that it could not be touched by the hand without burning it. I have had ice a considerable length of time at temperatures far above the ordinary boiling-point, and even then it only sublimed away without any previous melting. These results were obtained by *maintaining* the superincumbent pressure below 4·6 mm. of mercury; *i.e.*, the tension of aqueous vapour at the freezing-point of water. Other substances also exhibit these same phenomena, the most notable of which is mercuric chloride, for which latter the pressure need only be reduced to about 420 mm. On letting in the pressure the substance at once liquefies.

For the success of these experiments in the case of water one or two details of manipulation are necessary, but these will be subsequently described. THOS. CARNELLEY

Firth College, Sheffield, September 6

A Doubtful British Mollusk

I HAVE just observed that I am quoted in Dr. Gwyn Jeffreys' "British Conchology" (vol. v. p. 161) as an authority for the discovery of *Clausilia parvula* (a Continental snail) in Staffordshire. Many years ago, when I was a schoolboy, I found six or seven specimens at Kinver, near Stourbridge. I took them at first for a smooth variety of *C. rugosa*, but noting other differences sent them to Dr. Jeffreys, who identified them as above. I never had another opportunity of visiting the spot, but brother conchologists, who went on my recommendation, failed to find any specimens. The sheep-walk on which I picked them up was close to the grounds of Enville, where there are many foreign shrubs, and I have now little doubt that they were introduced. At the same time the large size of the specimens seemed to indicate that they had been long acclimatised, as northern individuals are larger than southern. GRANT ALLEN

Broad Street, Lyme Regis, Dorset

A Halo

MAY I mention a strange appearance which I saw in the heavens on August 29, and ask for an explanation of it? It was a rainbow without rain, and in the same quarter of the heavens as the sun.

At 5.45 p.m. I observed in a little nearly circular opening in the clouds, at the same height above the horizon as the sun, and about 23° to the north of it, all the colours of the rainbow. They were very vivid, and lasted for several minutes. Two persons who were with me also saw this strange sight, which I cannot account for in any way. Was it seen by any of your readers? And what could be the cause of it? L. SOAMES

Brighton, September 2

[This was probably a portion of the ordinary halo of 22°. If so, it indicates the presence of ice-crystals (not of drops of water) in the upper atmosphere. Such things are common enough in autumn, especially when there is a sudden lowering of temperature by an anticyclone.—ED.]

Tone of Violins

I SAW a little time back, but omitted to note it at the time, a brief notice of some German experiments showing that the strings of good old instruments of fine tone tended far more than in the case of inferior violins to vibrate in closed curves or simple curves. I have searched NATURE in vain for some weeks, but cannot find it, though I thought it was in these columns. I am particularly anxious to recover it for purposes of my own connected with another branch of physics, and shall be obliged if any reader can refer me to the notice, or to the paper, or any translation of it. LEWIS WRIGHT

August 30

ADOLPH EDOUARD GRUBE

BY the sudden death of Prof. Grube of Breslau on June 23, zoological science has been deprived of one of its enthusiastic and veteran cultivators. Born in Königsberg on May 12, 1812, he entered the university of that city in 1831, and graduated in medicine in 1837. Thereafter he became a private lecturer on zoology in Königsberg. In 1844 he was appointed to the Professorship of Zoology in the University of Dorpat, and lastly was transferred, in 1857, to a similar post in the University of Breslau, where he laboured till his death.

He chose for the subject of his inaugural dissertation (in 1837) the structure of *Pleione carunculata*, Pallas, and it is interesting that at this early age he selected one of the group in which his chief work in after-life was accomplished; for though he published various valuable researches in other departments (*e.g.*, those on the Branchiopod Crustaceans), still the Annelida most benefited by his labours during the subsequent forty-three years. Moreover, he observed so carefully, as well as laboured so industriously, that he was *facile princeps* in the department at his death. The bare enumeration indeed of his zoological works and papers is formidable; and their perusal bears imperishable witness to the well-directed energy and great ability of their author. He himself, with great modesty, used to state that his work fell far short of that of the late M. Claparède, who, with a delicate physique, nevertheless accomplished a marvellous amount of valuable work, both with pen and pencil. But though perhaps less of an artist than the talented Swiss, the greater tenacity of constitution in the stalwart German, combined with his indomitable energy and perseverance throughout a longer life, enabled him to overtake a much greater amount of work, especially in descriptive zoology.

The conscientious manner in which he carried on his scientific labours is well shown in his "Familien der Anneliden" (1851), a work which even now is of great value, and indispensable to workers in the department. The same may be said of his "Entwicklung der Anneliden" (1844) and his "Annulata Œrstediana" (1857). In his original papers in the *Archiv für Naturgeschichte* and in the recent admirable series in the *Sitzung der Schlesischen Gesellschaft*, on the families of the Annelida, he demonstrated the encyclopædian and critical knowledge which he had of the whole group in a remarkable manner, just as his "Bemerkungen über Anneliden der Pariser Museums" showed his great experience in discriminating the species described by others. His last large publication (a work of 300 pp., 4to, and fifteen fine plates by his tried assistant Assman) is devoted to the numerous Philippine annelids collected by Prof. Semper, and is a lasting memorial of his accuracy and patient industry.

Nor was he a zoologist who confined his researches to a single group. He was an accomplished carcinologist, and his faunistic treatises, *e.g.*, his "Actinien, Echinodermen u. Würmer des Adriatischen u. Mittelmeers," his "Ausflug nach Triest u. dem Quarnero," as well as his special papers on the Echinodermata, on *Peripatus* and other Arthropods, testify abundantly to the breadth

of his information and his unwearied efforts to advance zoological science. He was no less a thoughtful student of the labours of others than a discover of new forms and an accurate original inquirer.

To one who had worked at the fauna of Siberia, at the collections made during the Novara expedition and those of the German exploring ship *Gazelle*, at the varied stores in the "Museum Godeffroy" of Hamburg, who had made himself familiar with the shores of the Adriatic and the Mediterranean, as well as those of France and Britain, the splendid zoological series made by H.M.S. *Challenger*, under the direction of Sir Wyville Thomson and his colleagues, could not but prove an irresistible attraction; and it was this which tempted him more than anything else to make his last visit to this country in 1876, when he attended the Meeting of the British Association in Glasgow.

Privately Prof. Grube was one of the most amiable and accomplished of men. Of commanding presence (he was a cuirassier in his youth), and frank and manly bearing, his fund of general information, his musical tastes, and great geniality, endeared him to all his friends. Nor was he less beloved as a teacher by his students. Full of life and work, and with an industry that never seemed to flag, he was suddenly cut off in the midst of his labours, and just as he was organising fresh researches.

A full biography of Prof. Grube will appear in the *Leopoldina* in Halle, but, meanwhile, it is well to indicate in this country the sense of the great loss which zoological science has sustained by the death of this eminent investigator and teacher. W. C. M.

THUNDERSTORMS[1]

IV.

ALMOST all the facts to which I have now adverted point to water-substance, in some of its many forms, as at least one of the chief agents in thunderstorms. And when we think of other tremendous phenomena which are undoubtedly due to water, we shall have the less difficulty in believing it to be capable of producing thunderstorms also.

First of all let us think of some of the more obvious physical consequences of a fall of a mere tenth of an inch of rain. Suppose it to fall from the lowest mile of the atmosphere. An inch of rain is 5 lb. of water per square foot, and gives out on being condensed from vapour approximately 3,000 units of heat on the centigrade scale. The mass of the mile-high column of air a square foot in section is about 360 lb., and its specific heat about a quarter. Thus its temperature throughout would be raised by about 33° C., or 60° F. For one-tenth inch of rain, therefore, we should have a rise of temperature of the lowest mile of the atmosphere amounting to 3·3° C., quite enough to produce a very powerful ascending current. As the air ascends and expands it cools, and more vapour is precipitated, so that the ascending current is farther accelerated. The heat developed over one square foot of the earth's surface under these conditions is equivalent to work at the rate of a horse-power for twelve minutes. Over a square mile this would be ten million horse-power for half an hour. A fall of one-tenth of an inch of rain over the whole of Britain gives heat equivalent to the work of a million millions of horses for half an hour! Numbers like these are altogether beyond the limits of our understanding. They enable us, however, to see the full explanation of the energy of the most violent hurricanes in the simplest physical concomitants of the mere condensation of aqueous vapour.

I have already told you that the source of atmospheric electricity is as yet very uncertain. Yet it is so common and so prominent a phenomenon in many of its manifestations that there can be little doubt that innumerable attempts have been made to account for it. But when we consult the best treatises on meteorology we find it either evaded altogether or passed over with exceedingly scant references to evaporation or to vegetation. Not finding anything satisfactory in books, I have consulted able physicists, and some of the ablest of meteorologists, in all cases but one with the same negative result. I had, in fact, the feeling which every one must experience who attempts to lecture on a somewhat unfamiliar subject, that there *might* be much known about it which I had not been fortunate enough to meet with. Some years ago I was experimentally led to infer that mere *contact* of the particles of aqueous vapour with those of air, as they fly about and impinge according to the modern kinetic theory of gases, produced a separation of the two electricities, just as when zinc and copper are brought into contact the zinc becomes positively electrified and the copper negatively. Thus the electrification was supposed to be the result of chemical affinity. Let us suppose, then, that a particle of vapour, after impact on a particle of air, becomes electrified positively (I shall presently mention experiments in support of this supposition), and see what farther consequences will ensue when the vapour condenses. We do not know the mechanism of the precipitation of vapour as cloud, and we know only partially that of the agglomeration of cloud-particles into rain-drops; but of this we can be sure that, if the vapour-particles were originally electrified to any finite potential, the cloud-particles would be each at a potential enormously higher, and the rain-drops considerably higher still. For, as I have already told you, the potential of a free charged sphere is proportional directly to the quantity of electricity on it and inversely to its radius; so when eight equal and equally charged spheres unite into one sphere of double the radius, its potential is four times that of each of the separate spheres. The potential in a large sphere, so built up, is in fact directly proportional to its surface as compared with that of any one of the smaller equal spheres of which it is built.

Now, the number of particles of vapour which go to the formation of a single average rain-drop is expressed in billions of billions; so that the potential of the drop would be many thousands of billion times as great as that of a particle of vapour. On the very lowest estimate this would be incomparably greater than any potential we can hope to produce by means of electrical machines.

But this attempt at explanation of atmospheric electricity presents two formidable difficulties at the very outset.

1. How should the smaller cloud-particles ever unite if they be charged to such high potentials, which of course must produce intense repulsions between them?

2. Granting that, in spite of this, they do so unite, how are they separated from the mass of negatively electrified air in which they took their origin?

I think it is probable that the second objection is more imaginary than real, since there is no doubt that the diffusion of gases would speedily lead to a great spreading about of the negatively electrified particles of air from among the precipitated cloud-particles into the less highly electrified air surrounding the cloud. And if the surrounding air were equally electrified with that mixed with the cloud, there would be no electric force preventing gravity from doing its usual work. This objection, in fact, holds only for the *final* separation of the whole moisture from the oppositely electrified air; and gravity may be trusted to accomplish this. That gravity is an efficient agent in this separation is the opinion of Prof. Stokes. It must be observed that as soon as the charge on each of the drops in a cloud rises sufficiently, the electricity will pass by discharge to those which form the bounding layer of the cloud.

The first objection is at least partially met by the

[1] Abstract of a lecture, delivered in the City Hall, Glasgow, by Prof. Tait. Continued from p. 410.

remark that in a cloud-mass when just formed, if it be at all uniform, the electric attractions and repulsions would approximately balance one another at every point, so that the mutual repulsion of any two water-drops would be almost compensated, except when they came very close to one another.

But there is nothing in this explanation inconsistent with the possibility that the particles of water may be caused to fly about repeatedly from cloud to cloud, or from cloud to an electrified mass of air; and in many of these regions the air, already in great part deprived of its moisture, may have become much cooled by expansion as it ascends, so that the usual explanation of the production of hail is not, at least to any great extent, interfered with.

I may here refer to some phenomena which seem to offer, if closely investigated, the opportunity for the large scale investigations which, as I shall presently show, will probably be required to settle the source or sources of atmospheric electricity.

First, the important fact, well known nearly 2,000 years ago, that the column of smoke and vapour discharged by an active volcano gives out flashes of veritable lightning. In more modern times this has been repeatedly observed in the eruptions of Vesuvius and other volcanos.

Sabine, while at anchor near Skye, remarked that the cloud-cap on one of the higher hills was permanently luminous at night, and occasionally gave out flashes resembling those of the aurora. I have not been able to obtain farther information as to this very important fact; but I have recently received a description of a very similar one from another easily accessible locality.

My correspondent writes from Galway, to the following effect, on the 2nd of the present month:—

"At the commencement of the present unprecedentedly long and severe storm the wind blew from south-west and was very warm. After blowing for about two days it became, *without change of direction*, exceedingly bitter and cold; and the rain was, from time to time, mixed with sleet and hail, and lightning was occasional. This special weather is common for weeks together in March or early April. The air is (like what an east wind brings in Edinburgh) cold, raw, dry, and in every way uncomfortable, especially to people accustomed to the moist Atlantic winds. During these weeks a series of small clouds, whose shadows would only cover a field of a few acres, seem to start at regular intervals from the peaks of hills in Connemara and Mayo. They are all more or less charged with electricity. From high ground, behind the city, I have at one time seen such a cloud break into lightning over the spire of the Jesuits' church. At another, I have seen such a cloud pour down in a thin line of fire, and fall into the bay in the shape of a small incandescent ball. On one occasion I was walking with a friend, when I remarked, 'Let us turn and make a run for it. We have walked unwittingly right underneath a little thundercloud.' I had scarcely spoken when a something *flashed on the stony ground at our very feet*, a tremendous crash pealed over our heads, and the smell of sulphur was unmistakable. I fancy that I have been struck with these phenomena more than others, from the circumstance that they have always interfered with my daily habits. My walks often extended to considerable distances and to very lonely districts. Now these small local spurts of thunderstorms would hardly excite attention in the middle of a town, all the less as the intervening weather is bright, though raw—these spurts coming on every three or four quarters of an hour. Neither would they excite much attention in the country, as, while such a little storm was going on in one's immediate neighbourhood, you would see at no great distance every sign of fine weather. In fact they always seem to me like the small change of a big storm."

My correspondent, though a good observer and eloquent in description, is not a scientific man. But it is quite clear from what he says that a residence of a few weeks in Galway, at the proper season, would enable a trained physicist to obtain, with little trouble, the means of solving this extremely interesting question. He would require to be furnished with an electrometer, a hygrometer, and a few other simple pieces of apparatus, as well as with a light suit of plate armour, not of steel but of the best conducting copper, to insure his personal safety. Thus armed he might fearlessly invade the very nest or hatching-place of the phenomenon, on the top of one of the Connemara hills. It is to be hoped that some of the rising generation of physicists may speedily make the attempt, in the *spirit* of the ancient chivalry, but with the offensive and defensive weapons of *modern* science.

Another possible source of the electricity of thunderstorms has been pointed out by Sir W. Thomson. It is based on the experimental fact that the lower air is usually charged with negative electricity. If ascending currents carry up this lower air the electricity formerly spread in a thin stratum over a large surface may, by convection, be brought into a very much less diffused state, and thus be raised to a potential sufficient to enable it to give a spark.

However the electrification of the precipitated vapour may ultimately be accounted for, there can be no doubt of the fact that at least as soon as *cloud* is formed the particles are electrified; and what I have said as to the immense rise of potential as the drops gradually increase in size remains unaffected. I have tried various forms of experiment, with the view of discovering the electric state of vapour mixed with air. For instance, I have tested the vapour which is suddenly condensed when a receiver is partially exhausted; the electrification of cooled bodies exposed to moist air from a gasholder; and the deposition of hoar-frost from a current of moist air upon two polished metal plates placed parallel to one another, artificially cooled, and connected with the outer and inner coatings of a charged jar. All have given results, but as yet too minute and uncertain to settle such a question. These experiments are still in progress. It appears probable, so far, that the problem will not be finally solved until experiments are made on a scale much larger than is usual in laboratories.

A great thunderstorm in summer is in the majority of cases preceded by very calm sultry weather. The atmosphere is in a state of unstable equilibrium, the lower strata are at an abnormally high temperature, and highly charged with aqueous vapour. It is not easy, in a popular lecture like this, to give a full account of what constitutes a state of stable equilibrium, or of unstable, especially when the effects of precipitation of vapour are to be largely taken into account. It is sufficient for my present purpose to say that in all cases of thoroughly stable equilibrium, a slight displacement *tends to right itself;* while, in general, in unstable equilibrium, a slight displacement tends to increase. Now, if two cubic feet of air at different levels could be suddenly made to change places, without at first any other alteration, and if, on being left to themselves, each would, under the change of pressure which it would suddenly experience, and the consequent heating or cooling, with its associated evaporation or precipitation of moisture, tend to regain its former level, the equilibrium would be stable. This is not the case when the lower strata are very hot, and fully charged with vapour. Any portion accidentally raised to a higher level tends to rise higher, thus allowing others to descend. These, in consequence of their descent, tend still farther to descend, and thus to force new portions up. Thus, when the trigger is once pulled, as it were, we soon have powerful ascending currents of hot moist air, precipitating their moisture as cloud as they ascend, cooling by expansion, but warmed by the latent heat of the vapour condensed. This phenomenon of ascending

currents is strongly marked in almost every great thunderstorm, and is precisely analogous to that observed in the centre of a West Indian tornado and of a Chinese typhoon.

When any portion of the atmosphere is ascending it must be because a denser portion is descending, and whenever such motions occur *with acceleration* the pressure must necessarily be diminished, since the lower strata are not then supporting the whole weight of the superincumbent strata. If their whole weight were supported they would not descend. Thus even a smart shower of rain must directly tend to lower the barometer. [A long glass tube, filled with water, was suspended in a vertical position by a light spiral spring, reaching to the roof of the hall. A number of bullets hung at the top of the water column, attached to the tube by a thread. When the thread was burned, by applying a lamp, the bullets descended in the water, and *during their descent* the spring contracted so as to raise the whole tube several inches.]

In what I have said to-night I have confined myself mainly to *great* thunderstorms, and to what is seen and heard by those who are within their sphere of operation. I have said nothing of what is commonly called *summer-lightning*, which is probably, at least in a great many cases, merely the faint effect of a distant thunderstorm, but which has also been observed when the sky appeared tolerably clear, and when it was certain that no thunderstorm of the ordinary kind had occurred within a hundred miles. In such cases it is probable that we see the lightning of a storm which is taking place in the upper strata of the atmosphere, at such a height that the thunder is inaudible, partly on account of the distance, partly on account of the fact that it takes its origin in air of small density.

Nor have I spoken of the aurora, which is obviously connected with atmospheric electricity, but in what precise way remains to be discovered. Various theories have been suggested, but decisive data are wanting. Dr. Balfour Stewart inclines to the belief that great auroras, visible over nearly a whole terrestrial hemisphere, are due to inductive effects of changes in the earth's magnetism. This is not necessarily inconsistent with the opinion that, as ordinary auroras generally occur at times when a considerable change of temperature takes place, they are phenomena due to the condensation of aqueous vapour in far less quantity, but through far greater spaces, than the quantities and spaces involved in ordinary thunderstorms.

In taking leave of you and of my subject I have two remarks to make. First, to call your attention to the fact that the most obscure branches of physics often present matter of interesting reflection for all, and, in consequence, ought not to be left wholly in the hands of professedly scientific men. Secondly, that if the precautions which science points out as, at least in general, sufficient, were recognised by the public as *necessary*, the element of danger, which in old days encouraged the most debasing of superstitions, would be all but removed from a thunderstorm. Thus the most timid would be able to join their more robust fellow-creatures in watching fearlessly, but still of course with wonder and admiration, one of the most exquisite of the magnificent spectacles which Nature from time to time so lavishly provides.

PHYSICS WITHOUT APPARATUS

IV.

THE science of heat constitutes one of those departments of physics in which both the uninitiated beginner and the advanced student can find food for thought. To follow out the theoretical teachings of the science of heat requires a knowledge of abstruse mathematical formulæ; but, on the other hand, a very large proportion of the fundamental facts of experiment upon which the science depends can be illustrated with the simplest means.

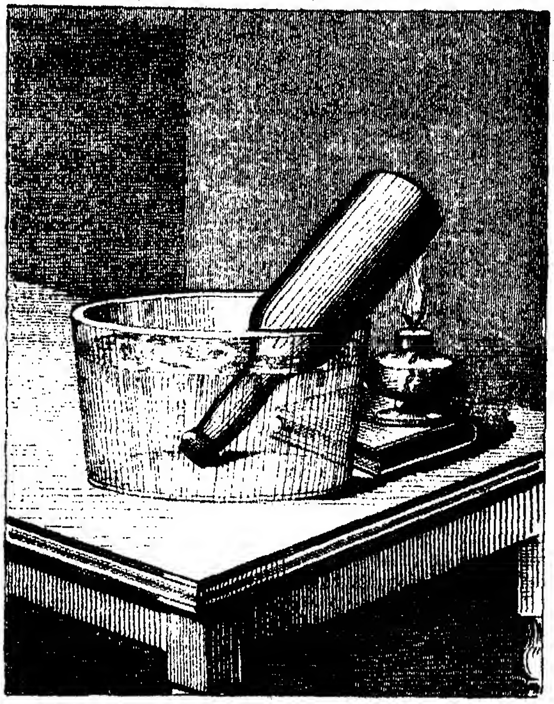

Fig. 11.

The property possessed by almost all material bodies of *expanding* when they are warmed affords us the means

Fig. 12.

of ascertaining the *degree* to which they are warmed. Thus the expansion of the quicksilver in the bulbs of our

[1] Continued from p. 368.

thermometers shows us the degree of temperature of the surrounding air. Again, the heat imparted to the air within a paper fire-balloon makes it expand and become specifically lighter than the surrounding atmosphere through which it rises. In general it may be asserted that matter, in whichever state it may be—solid, liquid, or gaseous—expands when heat is imparted to it, and contracts when heat is taken from it. Fig. 11 illustrates a very simple manner of showing the expansion of air when heated. An empty wine-bottle is placed with its mouth downwards in a deep dish or jar containing water, the bottom of the bottle projecting over the side of the jar. Heat is then applied by means of a spirit-lamp; or, if this is not available, by burning under it a piece of cotton wool soaked in spirits and held on the end of a fork. The glass of the bottle becomes hot—if too hot it may crack—and the air inside shares its warmth and begins to expand. There being only a limited space inside the bottle, some of the air will be forced out, and will rise in bubbles through the water. If now the flame be removed, the reverse operation of contraction by cooling may be witnessed, for as the air inside the bottle cools it will occupy a smaller and smaller amount of space, and the water will gradually rise up in the bottle-neck. Of course this is seen better with a bottle of clear glass than with one of a dark or opaque tint.

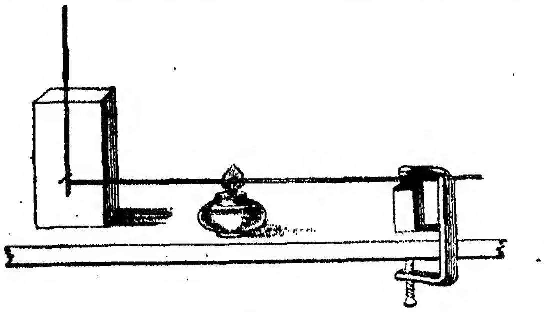

FIG. 13.

FIG. 14.

The contraction of a liquid on cooling can be even more simply shown. Take a common medicine bottle. Warm it gently (by rinsing it out with a little hot water) so that it shall not crack by the sudden heating, and then fill it *brimful* of boiling water. Leave it to cool; and in less than half an hour you will find that the water which you poured in to overflowing has shrunk down into the neck of the bottle, having contracted as it cools.

It was mentioned above that the hot air in a fire-balloon raises it, being lighter than the cold air. In the same way hot water will rise through cold, and float on the top of it, being specifically lighter. You may prove this in several ways. Fill a deep jar with water, and then, taking a red-hot poker, plunge about an inch of the tip of it into the surface of the water. Presently the whole of the water at the top will be boiling furiously; but the water at the bottom will be just as cool as before, for the hotter water will not have gone down, but will have floated at the top, being lighter in consequence of expansion. The same thing can be shown very prettily by the following simple experiment. Fill a wide and deep glass jar—the glass of a parlour-aquarium will do excellently—to about half its depth with cold water. Provide yourself also with a kettle full of boiling water, a funnel, a bit of wood about three inches square, and with some ink—red ink if possible. Pour into the kettle enough of the ink to colour it with a perceptible tint; this is simply that you may be able to distinguish between the colourless cold water and the coloured hot water which you are going to cause to float at the top. The only difficulty of the experiment is how to pour out the hot water without letting it *mix* with the cold water. Fig. 12 shows how you may do this with the help of the things you have got together. The bit of wood (or cardboard) is laid on the water as a float, and you must pour the hot water on to this to break the force of its fall. The funnel will also help to break the fall of the hot water, and will aid you to guide the stream on to the middle of the float. With

FIG. 15.

these precautions you need not fear failure, and you will enjoy the spectacle so seldom seen, though so often actually occurring, of *hot water floating on the top of cold water*.

It is almost as easy to demonstrate the fact that solid bodies, such as wood, iron, and glass, expand when heated. A steel knitting-needle, for example, is both longer and thicker when hot than it is when cold. To prove so minute a quantity as the increase in thickness would require very delicate apparatus indeed, but the increase of *length* may be rendered visible by the following simple arrangement given by Miss C. Martineau in her capital "Easy Lessons in Heat." The knitting-needle must be fixed firmly to the table by a table-clamp (Fig. 13). Against the other extremity rests the end of a straw to serve as an index or pointer. This straw, which should be at least eight or nine inches long, is transfixed by a pin at about a quarter of an inch above the point where it touches the knitting-needle, the pin being stuck into a block of wood or other substantial support. The slightest movement of the end of the steel needle will be rendered apparent by the movement of the straw index.

Another pretty experiment which is easily performed is that of boiling water in a sheet of paper. Take a piece of paper and fold it up, as schoolboys do, into a square box without a lid, as shown in Fig. 14. Hang this up to a walking-stick by four threads, and support the stick upon books or other convenient props. Then a lamp or taper must be placed under this dainty cauldron. In a few minutes the water will boil. The only fear is lest the threads should catch fire and let the water spill into the lamp and over the table. The flame must therefore not be too large. A small taper will give a flame quite large enough. The paper does not burn, because it is wet; and even if it resisted the wet it still would not burn through, because the heat imparted to it on one side by the flame would be very rapidly conducted away by the water on the other. Another experiment of a similar nature, but perhaps even more striking, is as follows:—Twist up the edges of a common playing-card or other bit of cardboard, so as to fashion it into a light tray. On this tray place a layer of small shot or bits of lead, and heat it over the flame of a lamp. The lead will melt, but the card will not burn (Fig. 15). It may be charred a little round the edges, but immediately below the lead it will not be burned, for here again the lead conducts off the heat on one side as fast as it is supplied on the other. Lastly, we give an experiment which, like the two preceding, proves that a good conducting substance may protect a delicate fabric from burning by conducting away the heat rapidly from it. Lay a piece of muslin quite flat upon a piece of metal. A live coal placed on the muslin will not burn it, for the metal takes away the heat too fast. If the muslin is however laid on a bad conductor, such as a piece of wood, it will not be protected, and the live coal will kindle the muslin.

(*To be continued.*)

NOTES

The International Congress of Anthropology and Prehistoric Archæology, which opens at Lisbon on the 19th inst., promises to be an interesting one. On the mornings of the 21st, 23rd, 25th, and 27th, questions relative to Portugal will be discussed—Cut Flints of the Tertiary, Characteristics of the Palæolithic or Quaternary Age, the Neolithic Period, Kitchen-middens, Sepulchral Caves, Age of Metals, &c. Among the papers to be read on the afternoons of these days are the following:—M. Arcelin, Antiquity of Man in the Valley of the Saone; M. E. Cataillhac, Recent Prehistoric Discoveries in the South of France; M. Ernest Chantre, an Exploring Journey in the Caucasus; M. Hildebrand, the State of Prehistoric Studies in Sweden; M. Schaffhausen, Prehistoric Man, &c. Several interesting excursions have been arranged for. Perhaps the most important question to be brought before the Congress will be that of the worked stones said to have been found by M. C. Ribeiro in the Tertiary. The Local Committee have opened numerous cuttings between Carregado and Cereal, and in that distance of twenty kilometres it is stated that worked stones will be met with at every step in the Miocene deposits. The railway companies of Spain and Portugal will issue tickets at a reduction of one-half to members of the Congress.

At the approaching Congress at Edinburgh on October 6 to 13, the discussion on the first special question in the Educational Department, "What may be the dangers of educational overwork for both sexes, with special reference to the higher class of girls' schools, and the effects of competitive examinations?" will be opened with papers by Dr. Keiller, M.D., of Edinburgh, and Miss Edith Peachey, M.D., of Leeds. Papers on the second special question, "How far, and under what conditions, ought the teaching of higher subjects in elementary schools to form part of a system of national education?" will be contributed by Sir George Campbell, K.C.S.I., and Dr. Robertson, LL.D. Prof. Laurie will read a paper on the third special question, "Is it desirable that public secondary schools should be placed under local authorities and be subject to the supervision of the Committee of Council on Education?"

We are glad to learn that Mr. Mundella intends, during his sojourn on the Continent, to visit some of the principal foreign technical schools. We have no doubt he will thus get some enlightenment as to what real technical education means.

The Geological Society of France have issued circulars announcing that an extraordinary session will be held at Boulogne, from September 9 to 19, under the presidency of Prof. Gosselet of Lille, with an ample programme of papers and excursions.

At a meeting of delegates from local scientific societies, held at Swansea on August 31, Mr. J. Hopkinson in the chair, various suggestions, principally with the view of securing a better representation of scientific societies at the meetings of the British Association and a more intimate relationship between provincial societies, were made, and the following resolutions were passed:—1. That this Conference recommends that at future meetings of the British Association it is desirable that the delegates from the various scientific societies should meet, with the view of promoting the best interests of the Association and of the several societies represented. 2. That Mr. Hopkinson and Mr. Fordham be a committee to carry out the views expressed at this conference, and report to the conference of delegates to be held at York in 1881, in accordance with the foregoing resolution.

To judge from the three volumes of its *Bulletin* which have been sent us, the Philosophical Society of Washington seems to produce some good work. The Society was founded ten years ago, and the volumes embrace the period from 1871 to 1880. The late Prof. Joseph Henry was the first president of the Society, the object of which is stated to be the free exchange of views on scientific subjects and the promotion of scientific inquiry among its members. The following are a few of the papers contained in the volumes before us:—"On the Adopted Value of the Sun's Apparent Diameter," by Prof. E. S. Holden; "On the Delta of the Mississippi," by Prof. Forshey; "On the Zodiacal Light," by Prof. S. Alexander; a detailed report on the unusually brilliant meteor of December 24, 1873; a long and elaborate memoir of Prof. Joseph Henry, with detailed notices of his varied scientific work; also the addresses he delivered during his presidency; "On the 'Prodromus Methodi Mammalium' of Storr," by Mr. Theodore Gill; a curious inquiry on the

Number of Words used in Speaking and Writing, by Prof. E. S. Holden; "New Species of Fossil Plants from Alleghany Co., Virginia," by Mr. F. B. Meek; "The Gentile System of the Omahas," by Rev. J. O. Dorsey. Most of the papers, however, appear in very brief abstracts.

ENGINEERS are engaged daily in making surveys for the purpose of determining the site of the projected tunnel under the St. Lawrence between Hochelaga and Longueil.

THE War Office authorities have detailed a whole company of the Royal Engineers for instruction in the art of military ballooning, in lieu of the small detachment hitherto employed in the experiments. The company selected is the 24th (Field Company) at Aldershot, and it will be placed under the command of Capt. Elsdall, R.E.

ON the anniversary of the Russian Emperor's coronation, the foundation-stone of the Siberian University at Tomsk was laid. The building was projected in the reign of the Emperor Alexander I.

THE *Panama Star and Herald* of the 12th ult. says that the reports received concerning the eruption of the Fuego, the largest volcano in the republic of Guatemala, show that it was preceded by earthquakes of considerable violence, the theatre of whose operations was confined to the country surrounding the volcano, within a radius of some twenty or thirty miles. In Antigua, Amatitlan, Palin, Petapa, and several other points the shocks were of such violence as to occasion serious alarm among the inhabitants and cause them to abandon their houses for several hours. With the commencement of the eruption, however, the earthquake period ended, and the people in the streets of the various pueblos were able to witness in tranquillity the splendid appearance of the burning mountain. During the morning of the day succeeding the eruption the pueblos on the Costa Grande, to the northward of the volcano, were shrouded in gloom, and for some time after sunrise people in offices were compelled to employ artificial light in order to carry on their labours. Ashes and dust fell in great quantities at many miles distance, and people who were at too great a distance from the volcano to witness the eruption were for some time in doubt as to their origin. Happily the disturbance has passed with no more serious matter to record than the alarm which it momentarily occasioned.

AT the last meeting of the Balloon Society of Great Britain the recent balloon voyage out to sea at Cherbourg was referred to. Mr. Simmons stated that when he some years ago made a similar trip at Hull he went twenty miles out to sea and then got into an anticipated return current which he found a few feet above the outward current, and which safely landed him at the desired spot on *terra firmâ*. The president read a letter from a member of the Society who had made one of his ascents in a thunderstorm and found the atmosphere at an altitude of about 200 feet and for a height of 100 feet to be of a dull leaden hue, but as soon as he had risen above this stratum he found the sky quite unclouded, and witnessed perfectly clearly the storm raging below in all its grandeur. On Saturday afternoon a balloon contest took place from various points in the neighbourhood of London, under the auspices of the Balloon Society. Eight balloons were to have started, but only five succeeded in getting away. A silver medal was to be awarded to the balloon that traversed the greatest distance in one hour and a half. The competition seems to have had some connection with Commander Cheyne's proposed Arctic Expedition; but so far as we have ascertained no new scientific results seems to have been obtained. One balloon seems to have attained a height of 14,000 feet.

DURING the Session of the City and Guilds of London Institute, commencing October 4, Prof. Armstrong, F.R.S., and Prof. Ayrton, Inst.C.E., will continue their tutorial and laboratory courses of instruction in Chemistry and Physics as applied to the Arts and Manufactures, at the Cowper Street Schools, Finsbury, in rooms rented from the Middle Class Schools Corporation, pending the erection of the City and Guilds Technical College, Finsbury. Dr. Armstrong will deliver a course of about thirty lectures on "Organic Chemistry, with special Reference to its Industrial Applications," on Mondays, at 8.30 to 9.30 p.m., commencing October 4. He will also deliver a course of about twenty-four lectures on Tuesday and Friday afternoons at 4 to 5 o'clock, commencing October 5. Although the chief object of these lectures is to afford such preliminary training as is necessary for those who may desire later on to study particular branches of Applied Chemistry, more than usual attention will be given to matters of technical importance. There will also be daily Laboratory Classes. Prof. Ayrton will deliver a course of evening lectures on "Electrical Instrument Making," on Tuesdays at 8.30 to 9.30 o'clock, commencing October 5, the first twelve of the lectures being given before Christmas. On Friday evenings, at 8.30 to 9.30 o'clock, commencing October 8, Prof. Ayrton will also deliver a course of lectures, the first twelve being given before Christmas, on "Weighing Appliances and Motor Machinery," adapted to the wants of makers and users of machinery. He will also deliver a course of about twenty-four lectures on Monday and Wednesday afternoons, at 4 to 5 o'clock, commencing October 4, on the "Electric Light."

BY a decree of the French Minister of Public Instruction the Ethnographical Museum at the Trocadéro has been organised. Dr. Hamy and M. Landrin have been appointed conservators.

A LARGE number of rooms have been added to the French Museum of National Antiquities at St. Germains, and are awaiting a formal opening by the President of the Republic. In one of them have been collected a series of relics of Roman age relating to religious ceremonies and inscriptions; in a second room has been disposed a large number of bas-reliefs and statues exhibiting arms and scenes of military life; and in the third room we found many sepulchral monuments showing the arts and trades as practised during the Roman rule in Gaul. Some rooms have been already opened to the public, and in one of them is the celebrated Autun mosaic representing Bellerophon triumphing over Chimæra; execution and preservation are both wonderful.

MR. ROWSELL of King William Street, Strand, has just published a catalogue which includes a large and valuable collection of scientific works, principally biological.

MESSRS. LONGMANS AND CO. announce the forthcoming publication of a new series of "Popular Lectures on Scientific Subjects," by Prof. Helmholtz, translated by Dr. E. Atkinson.

AT a concert given every night in the garden of the Palais Royale, Paris, the orchestra is placed in the vicinity of the fountains, which are illuminated by eight splendid Siemens lamps, which work admirably. Two other Siemens lamps have been placed in the shop of a jeweller in the Galleries, and the experiment may eventually lead to the lighting of the whole palace by the electric light.

THE heat was so intense at Clermont on September 4 last that the ceremony of the inauguration of Pascal's statue, which was to have taken place that day, was postponed to the following morning at 8 o'clock. The principal speech was delivered by M. Bardoux, formerly Minister of Public Instruction, the representative of Clermont in the Lower French House.

THE French Central Society of Agriculture and Insectology has opened in the *Orangerie* of the Tuileries its biennial exhibition of insects. The exhibition is an instructive one, embracing

insects useful and noxious, and the various industries which depend on insects.

We take the following from the *Electrician* :—"When a little girl is found 'playing at telephone,' and reproducing to the life the 'ways' of those who ordinarily profit by the new means of communication, the circumstance may be taken as an indication that telephony is in some localities becoming really popular. The following sketch of a baby telephonist, 'pretending' to communicate with her papa, is from the *Concord Monitor* :—She was a pretty child, happy-hearted, full of fun, and a great mimic. Only two summers had sent sunshine across her curls and waked to sensuous delight the infantile beauty and form. She dwelt in a pleasant home filled with creature comforts, among them the new innovation, the telephone. She had often watched this wonderful mechanism, and while she neither knew nor cared for the secrets of its operation, she had learned by heart the peculiar and one-sided formula of a telephone conversation. Unheeding that some one was watching her, the other day she put a little hand to the wall and imitated the pushing of the button on the telephone. Up went the other hand to the ear, as if holding the ebony cylinder, and the little miss went on in mimicry of her elders, in the following fashion :—'Hello.' She then paused for an answer from the central office. 'Hello. Please hitch on Mr. —— house to Mr. —— office.' Pause. 'Is 'at you, papa?' Pause. 'When is you coming home?' Pause. (Turning to her dolls, the little one here spoke impatiently, 'Do you keep still; I can't hear a word.') 'Yes.' (Rising inflection.) Pause. 'I don't know.' (In doubt.) Pause. 'Yes.' (Gleefully.) Pause. 'Why papa.' (In surprise.) Pause. And so the little one went on, maintaining perfectly an imaginary conversation, till at last she dropped her hand with a motion indicative of weariness from holding the telephone, and pronounced the conversational 'That's all; good bye,' with all the nonchalance of a veteran."

The Proceedings of the American Antiquarian Society, No. 74, we learn from the *American Naturalist*, contains a paper by Mr. Philipp J. J. Valentini, on the Katunes of Maya history. The Katunes were a series of notable events that transpired from the time of the departure of the Mayas from their original home until their destruction. Don Juan Pio Perez, a learned Yucatecan, had found an old Maya manuscript containing this account, but failed to discover the author's name. From this precious document Mr. Valentini attempts to reconstruct the Maya chronology in the same manner that he deciphered the Mexican calendar stone. The results at which he arrives are as follows :—1. That the conquerors and settlers of the Yucatecan peninsula, as well as those of the Anahuac lakes, were joint participants in a correction of their national calendar about the year 290 B.C. 2. That about the year 137 A.D., when a total eclipse of the sun took place, the ancestors of both nations set out from their common fatherland, Tula, or Tulapan. 3. That about the year 231 A.D. both nations made their appearance on the coast of Central America, and succeeded in conquering a large portion of the peninsula.

Dr. Forel has issued in a separate form his paper from the *Archives des Sciences* on the Temperature of the Lake of Geneva and other Freshwater Lakes.

The additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus radiatus*) from India, presented by Mr. C. Kerry Nicholls; a Common Fox (*Canis vulpes*), European, presented by Mr. E. Schweder; a Gold Pheasant (*Thaumalea picta*) from China, presented by Mr. James McGregor; a Weka Rail (*Ocydromus australis*) from New Zealand, presented by Mr. H. Frank Rose; a Brazilian Cariama (*Cariama cristata*) from Bolivia, presented by Mr. Charles Stanley Barnes; Six Mocking Birds (*Mimus polyglottus*) from North America, presented by Mr. W. Cross; a Gannet (*Sula bassana*), British, presented by Mr. George Edson; a Sloth Bear (*Melursus labiatus*) from India, a Common Squirrel (*Sciurus vulgaris*), European, four Mississippi Alligators (*Alligator mississippiensis*) from the Mississippi, deposited; a White-lipped Peccary (*Dicotyles labiatus*), two Boatbills (*Cancroma cochlearia*) from South America, purchased.

THE BRITISH ASSOCIATION

In addition to the grants in the list which we gave last week, the following were voted at the final general meeting :—Mr. James Glaisher, Luminous Meteors, 15*l.*; Prof. Sylvester, Fundamental Invariants, 40*l.*; Prof. W. C. Williamson, Tertiary Flora, 20*l.*; Prof. Rolleston, Prehistoric Remains in Dorsetshire, 25*l.*

The total sum voted was 1,010*l.*, considerably more than the receipts of the Swansea meeting.

It is expected that the public lectures at the York meeting next year will be given by Prof. Huxley, Prof. Tyndall, and Mr. Spottiswoode.

REPORTS

Report on the best means for the Development of Light from Coal-gas of different qualities, by a Committee consisting of Dr. Wm. Wallace (secretary), Prof. Dittmar, and Mr. John Pattinson, F.C.S., F.I.C. Drawn up by Mr. Pattinson.—If gas be allowed to burn under little or no pressure it gives a smoky flame of little luminosity; when forced out under great pressure it yields a non-luminous blue flame like that of a Bunsen's burner. The aim in constructing a good gas-burner is so to regulate the supply of air and so to control pressure that the maximum amount of light may be obtained. This is best accomplished by an Argand burner.

From series of tables showing the result of experiments, the following conclusions are drawn :—The illuminating power is increased as the gas, issuing with less velocity, is mixed or brought in contact with less air. No increase in illuminating power is produced by heating the gas before its combustion. This confirms the results obtained by the London Gas Referees in 1871. By heating the air admitted to the centre of a standard Argand burner to 520° F., an increase of light amounting to 9 per cent. was produced for a rise of 450° in temperature. The trouble and expense of heating the air would probably prevent the adoption of this means of increasing the luminosity. With ordinary flat-flame burners the greatest amount of light is evolved under a pressure of one inch of water.

After giving measurements of the intensity of light evolved by gas burned in various varieties of burners (Bray's, Silber's, and Sugg's), the author concludes that the luminosity depends, so far as the burner is concerned, on the amount of gas burnt and on the pressure. The only burner presenting undoubted advantages over others, and that owing to more perfect regulation of air-supply, is the Argand burner; but on account of its expense, the trouble of keeping it clean, and the necessity of employing a governor for each burner, it is improbable that it will come into general use. Governors are now constructed for single burners by Sugg, Peebles, Wright, Borradaile, and others. Such governors are of great service, not only in saving gas, but also in regulating supply and giving constancy in luminosity.

Thirteenth Report of the Committee, consisting of Prof. Everett, Prof. Sir William Thomson, Mr. G. J. Symons, Prof. Ramsay, Prof. Geikie, Mr. J. Glaisher, Mr. Pengelly, Prof. Edward Hull, Dr. Clement Le Neve Foster, Prof. A. S. Herschel, Mr. G. A. Lebour, Mr. A. B. Wynne, Mr. Galloway, Mr. Joseph Dickinson, Mr. G. F. Deacon, and Mr. E. Wethered, appointed for the Purpose of investigating the Rate of Increase of Underground Temperature downwards in various Localities of Dry Land and under Water. Drawn up by Prof. Everett (secretary).—Observations have been taken in the Talargoch Lead Mine, Flintshire (between Rhyl and Prestatyn), under the direction of Mr. A. Strahan, of the Geological Survey, and Mr. Walker, Chairman of the Board of Directors of the mine.

The top of the shaft is 190 feet above the level of the sea. The lowest workings are 900 feet below sea-level. The veins run across an angle of Carboniferous Limestone, bounded on both sides by

faults which throw down coal-measure shale; and as the faults have a considerable inclination, the lowest workings run beneath the shale for a considerable distance. The limestone dips at angles varying from 45° to 55°, and is of two kinds, one white and massive, the other thin bedded black with thin shale partings.

There are levels at intervals of about twenty yards vertically, in the vein, most of which have been driven for some years; but all the observations have been taken in newly-opened ground.

They have been taken by boring a hole 24 inches deep at a distance of from 1½ to 5 yards from the fore breast, and either on the same day or on the next day inserting one of the Committee's slow-action thermometers, with a foot of plugging consisting of dry rag and clay behind it. After an interval generally of four days the thermometer was taken out and read, then reinserted, and read again about a week later, the difference between the two readings never amounting to so much as half a degree.

The observations were taken at six different places in the mine, which are designated by the observers Stations I. to VI.; but in one instance, that of Station II., owing to the swelling of newly-exposed shale, the hole became distorted, so that after extracting the dry rag and clay, an hour was expended in working out the thermometer, the reading of which has therefore been rejected. The following is a list of the five remaining stations, arranged in order of depth:—

No. of Station.	Depth from Surface in Feet.	Temperature, Fahr. °	Distance and Direction from Mostyn Shaft.
IV.	465	53·4	190 yds. S.W.
V.	555	52·9	170 yds. S.E.
VI.	636	58·8	840 yds. S.W.
III.	660	54·0	120 yds. S.
I.	1041	60·8	190 yds. N.E.

It will be observed that the order of the temperatures is not the same as the order of the depths; it therefore becomes important to describe the positions with some particularity.

Stations IV., V., and III. are near together in ground plan, IV. and V. being about 250 yards apart, and III. nearly midway between them, and they have all the same rock overhead between them and the surface, namely, black and white limestone.

At Station I. the rock overhead consists almost entirely of sandstones and shales, with thin coal-seams. At Station VI. it consists of white limestone and shale.

It may be mentioned that the temperature at VI. was observed on three several occasions, namely, January 14, January 21, and February 19, and was in each case found to be the same. Mr. Strahan further states that this station is near a large fault, which contains iron pyrites and gives off water charged with sulphuretted hydrogen; the temperature of the water as pumped up Walker's shaft from a depth of 770 feet, being 63° at the top of the lift. It seems probable that the decomposition of this pyrites may be the cause of the exceptionally high temperature at this station.

The comparison of the temperatures will be most clearly brought out by tabulating the rate of increase from the surface down to each station, as calculated from an assumed surface temperature, which may be fairly taken as 48°. As all the depths are considerable, an error of a degree in the surface temperature will not have much influence on the comparison, which stands thus:—

Station.	Depth in feet.	Excess above surface. °	Feet per Degree.
IV.	465	5·4	86
V.	555	4·9	113
VI.	636	10·8	59
III.	660	6·0	110
I.	1,041	12·8	81

Stations V. and III., which give the slowest rate of increase, are both of them in a vein called the "South Joint;" and Stations IV. and I., which agree well with each other, though differing from the rest, are both of them in another vein called the "Talargoch vein;" while Station VI. is in the "Country rock." The horizontal distance between IV. and III. is only 120 yards; but if we attempt to deduce the rate of increase from comparing these two, we have an increase of only 0°·6 in 195 feet. It thus appears that, notwithstanding the proximity of the two veins, their conditions as to temperature are very different.

Widely as the results differ among themselves, they agree upon the whole in showing that the average rate of increase is slow; and this general result is in harmony with what has been found at the nearest localities mentioned in our previous reports, namely, Dukinfield and Liverpool. Here, as at Dukinfield, all the strata are highly inclined.

Some additional observations at Dukinfield have recently been made for the Committee by Mr. Edward Garside, student of engineering in Queen's College, Belfast. The Astley Pit, in which they were taken, has now been carried to a much greater depth than it had extended at the time of Sir Wm. Fairbairn's observations, to which allusion was made in our Report for 1870. The two deepest seams of coal in it are called the "Cannel Mine" and the "Black Mine," the former being the deeper of the two; they both slope downwards at about 15°, the deepest point being the far end of the Cannel Mine. The following is Mr. Garside's summary of the observations; the "surface-depth" being distinguished from the "shaft-depth," because the surface is not level, but slopes slightly in the same general direction as the seams. The shaft-depth gives the difference of levels, but the surface-depth, which is practically the same as the distance of the nearest point of the surface, is what we must use in computing the rate of increase of temperature.

Date in 1880.	Seam Coal.	Surface Depth. Feet.	Shaft Depth. Feet.	Temperature of Strata. Fahr.	Temperature in Air Road. Fahr.	Distance from Main Air Column. Yards.
June 17	Cannel	2,700	2,754	86½	75½	160
,, 19	Black	2,407½	2,631	80	78¾	630
,, 21	Cannel	2,416½	2,482½	81	79	600
July 2	Black	1,987½	2,047½	74	71½	460

The pit is described as being entirely free from water.

Report of the Committee for making Secular Experiments on the Elasticity of Wires, by Mr. J. J. Bottomley.—The wires prepared by the Committee in Glasgow are still under experiment.

Report of the Committee on the Specific Inductive Capacity of a good Sprengel Vacuum, by Mr. W. E. Ayrton.—Boltzmann had estimated the specific inductive capacity at ·9994; while Professors Ayrton and Perry had estimated it at ·9985. In the experiments of the committee much higher vacua had been obtained, and had found some rather remarkable and not readily intelligible results. With *very* high vacua the inductive capacity of the compound aluminium condenser employed appeared to be less than at slightly lower degrees of exhaustion. The method adopted consisted in applying the aluminium condenser to a modification of a Hughes' induction balance in connection with a sliding condenser, a telephone, and a small induction coil.

Sir W. Thomson criticised the method as not being purely electrostatic in its nature. The discussion was continued by Mr. Gordon and Mr. Fitzgerald, who alluded to a possible connection between the fluctuations of the phenomena observed and those observed in the phenomena of Crookes' radiometer-force.

All the observations were taken with one of the committee's slow-acting thermometers, in holes drilled in the floors at the far ends of newly-opened horse-road levels; the holes being four feet deep and two inches in diameter. All the holes were free from cracks, and were in the same kind of rock—an argillaceous earth called "warren earth." They were allowed to stand for a short time, to allow the heat caused by drilling to escape. The thermometer was then inserted, and the portion of the hole between it and the mouth plugged with cotton waste and the dust which came out of the hole in drilling. After being left for forty-eight hours it was taken out and read.

The data for calculating the rate of increase are given in the first two columns below.

Depth in Feet.	Temperature Fahr.	Feet per Degree from Surface.
1,987½	74	79·5
2,416½	81	75·5
2,407½	80	77·7
2,700	86½	72

The third column shows the number of feet per degree of difference from the surface, assuming the surface-temperature to be 49°.

Comparing the observations at 1,987½ and 2,416½ feet, we have an increase of 7° in 429 feet, which is at the rate of 1° in 61·3 feet; and comparing the two deepest observations, we have an increase of 6½° in 292½ feet, which is at the rate of 1° in

45 feet. It thus appears that the rate of increase in this pit is more rapid as we go deeper. The greatest depth in Sir Wm. Fairbairn's observations was 685 yards, or 2,055 feet, and the temperature which he found for this depth was 75½°, which agrees to half a degree with the observations now reported.

The committee have to express their regret at the loss of two of their colleagues—Prof. Clerk Maxwell and Prof. Ansted—by death, during the past year.

Report on the Ultra-Violet Spectra, by Prof. A. K. Huntington.—The physical portion of the report was read in Section A. Before the Chemical Section Prof. Huntington drew attention to the following points:—The work of former experimenters on this subject is of great interest. The late Dr. Miller, in his experiments, was obliged to conclude that no connection could be drawn between the chemical composition of a substance and its power of absorbing ultra-violet rays. His method of experimentation, however, was deficient, inasmuch as he used layers of varying thickness, and in every case employed saturated solutions. His substances were not so pure as is necessary in such an investigation.

Dr. Miller also investigated the absorption of the ultra-violet rays by reflection from polished metallic surfaces. The results obtained were that gold shows almost total reflection; next best is burnished lead. Other metals present a greater or less absorption. Prof. Stokes' results confirm Dr. Miller's. His process differed from that of Dr. Miller, inasmuch as he passed the light through a layer of the solution of the substance under experiment on to a fluorescent screen, while Dr. Miller photographed the spectrum. His results were of great value, and from a chemical point of view it is of interest to note that glucosides and alkaloids have great absorptive power, and that on addition of acids absorption begins somewhat later than in presence of an alkali.

In 1874 Mr. Sorby constructed a spectroscope with a fluorescent eyepiece, and was thus able to observe the spectra directly. His results, though valuable, are vitiated by the impurity of the material he used.

Mention must also be made of experiments by Prof. Cordieu, who experimented on the influence of the atmosphere in cutting off rays on the ultra-violet end of the spectrum.

Prof. Hartley, one of the members of the Committee, has recently experimented on this subject, and some of the results of his research have been communicated to the Royal Society. His experiments, made with an improved form of Dr. Miller's apparatus, have led to interesting conclusions. He has found that monatomic alcohols of the methyl series exhibit little or no absorption. The first of the series, methyl alcohol, is, when pure, quite as "diaphanous" as water to invisible rays. Fatty acids, containing the same number of atoms of carbon as the alcohols to which they are related, have a higher absorptive power. Increased complexity of the molecule causes increased absorption. All members of the benzene series, in fact all bodies whose constitution is best expressed by the "ring-formula," give absorption-bands of great intensity; the hydrocarbons themselves, however, occupying the lowest position in this respect. Isomeric bodies of this group differ widely in their spectrum, which thus affords a convenient means of identification. Doubly-linked bodies, such as ethene, propene, anylene, give no absorption-spectrum; and in fact the ring-form appears to be a *sine-quâ-non*, for the terpenes and camphor do not absorb ultra-violet rays.

The intensity of the absorption-bands of naphthalene and anthracene is remarkable; a solution of 1 part of the latter body in 50 million times its weight of acetic acid may still be recognised.

On the Spectra of Metalloids, by Dr. A. Schuster, F.R.S.—The author stated that he had considerable difficulty in distinguishing the spectrum of an element from that of a compound. For example, the familiar spectrum of a Bunsen's flame is ascribed by some to carbon, and by others to a hydrocarbon, the argument in favour of the latter view being that the temperature of the flame is not sufficiently high to volatilise carbon as such. The reply to this argument is that during its passage from its compound with hydrogen to CO or CO_2, the element carbon is actually liberated, and then exhibits the band-spectrum; and in confirmation of this theory it has been noticed that gas impregnated with a salt of a metal such as copper or iron, gives in the Bunsen's burner the true metallic spectrum and not the spectrum of a compound. The same argument applies here, for the metal is actually liberated during its passage from (say) the chloride to the oxide. Besides, the band spectrum is seen still more effectively when cyanogen is burned, even when dried as perfectly as possible. This band-spectrum is seen in the sun's rays, and it is highly improbable that cyanogen should be able to resist such an enormously high temperature.

The author then considered the question:—Why should an element give different spectra at different temperatures? Bands are characteristic of compounds, and at low temperatures elements show a banded spectrum. At higher temperatures such spectra become simpler, and the evident conclusion is that complex molecules of the elements are dissociated into those of a simpler order. This view is rendered highly probable by the fact that the spectrum of mercury is a constant one, and that no known increase of temperature alters its character; now, assuming the molecule of hydrogen to consist of two atoms, that of mercury consists of a single atom, and it is evident that no simplification is possible.

The change of the spectra of chlorine, bromine, and iodine, as the temperature is increased would seem to corroborate Prof. Victor Meyer's recent conclusions with regard to the molecular complexity of these elements.

It was also suggested that the spectrum of an element might vary according to the compound from which it is liberated. Were it possible to decompose carbon monoxide and dioxide, and to obtain the spectrum of the single carbon atoms which they contain, it would probably differ from the well-known banded spectrum of carbon which there is reason to suppose is that of at least a two-atom molecule.

Mr. W. Chandler Roberts pointed out that Prof. Wiedemann has undertaken measurements to ascertain whether a change of temperature takes place during alteration of the spectrum, and hoped that interesting results would be obtained.

Report of the Committee on Erratic Blocks, presented by the Rev. H. W. Crosskey. (Abstract.)—Although the destruction of erratic blocks is proceeding with considerable rapidity, the Committee were able to report the discovery and preservation of some important specimens.

One of the most remarkable blocks of Shap granite yet observed is described by Mr. J. R. Dakyns at Seamer Station, near Scarborough. It measures roughly 5 ft. 8 in. × 4 ft. 10 in. × 4 ft. 3 in., and was fairly imbedded in gravel, forming the summit of a well-marked terrace 225 feet above the sea-level. This boulder is specially interesting in that it is the only boulder of Shap granite in the neighbourhood whose position in the beds is known; and this position shows that at the age assigned to the gravels (which is a comparatively recent one) icebergs must have been floating about. It has been preserved in the garden of the Station House.

The report records particulars of boulders discovered in the neighbourhood of Urmston, near Manchester, and also of a large number both of isolated boulders and groups of boulders observed in Leicestershire by Mr. J. Plant.

Mr. Pengelly furnishes a very interesting part of the report in an account he gives of some transported blocks and accumulations of blocks which he has observed in South Devon, the transposition of which it does not seem altogether possible that the action of water alone could have effected. A block of greenstone occurs in the village of Kingston, South Devon, measuring 4 × 2 × 2 feet, and weighing upwards of a ton. There is a mass of greenstone figured on the map of the Survey, extending to about a mile west-north-west of Kingston, where it makes its nearest approach to the village. Blocks of quartzite have been found in great abundance in the parishes of Diptford and Morleigh. They can be traced to their source on the higher levels of the neighbourhood; a bed of quartzite identical in character with the travelled blocks being interbedded conformably with the ordinary slaty Devonian rocks of the district. There can be no doubt that the blocks have been transported from south to north, and from higher to lower ground. The gradient, however, is very slight, and as almost all the blocks are very angular as well as large, it is difficult to suppose that their transportation was the result of nothing more than running water.

A block of greenstone occurs near Diptford Court, weighing fully 1·75 ton. A mass of igneous rock apparently of the same kind is found at a distance of five miles due south of the boulder, and another about the same distance north.

The blocks locally termed in South-Western Devon "Whits-

kers", are described in the report. They are composed of white opaque quartz, having in some cases a laminated structure, and traversed occasionally with veins and crystals of the same material. That the blocks have travelled a considerable distance cannot be doubted; and that their transportation was not effected by the action of water only appears proved. The blocks are all more or less rugged and sub-angular, although without any decided traces of glacial polish or scratches. They occur most plentifully on the higher ground.

They have been so largely utilised by the farmers and for artificial rockeries that it is to be feared, unless care is taken to prevent it, those now remaining on the spots they have so long occupied undisturbed may altogether disappear.

The report concluded with an appeal to local observers to report upon the erratics still unrecorded before the work of destruction is completed, and evidence throwing light on difficult problems of glacial geology is destroyed.

Report on the Exploration of Caves in the South of Ireland, by Prof. A. Leith Adams. Includes a Report by Mr. R. J. Ussher.—Describes caves at Carnigea Gower, four miles south of Middleton. Stalagmite floor on sandy clay; beneath the stalagmite was much charcoal, the roof had an opening to the surface, down which much kitchen rubbish had been thrown, associated with hammer stones, flint flakes, iron implements, and remains of recent animals. A report was read on the implements, by Mr. R. Day, which are of no great antiquity; one piece of pottery was believed to have a Roman (capital) letter inscription.

Report on the Carboniferous Polyzoa, by W. G. R. Vine.—Discusses the character of the genus and species and the views held on them by the earlier workers, and after a comparison of the specific forms he relegates to each of these the precise genera to which they belong.

Report on the "Geological Record," by Mr. W. Whitaker.—Four volumes have been published, each of which gives an abstract of all geological work done throughout the world, for one year; they contain an average number of 20,200 entries in each volume.

Sixteenth Report of the Committee appointed to Explore Kent's Cavern, by Mr. Pengelly.—The deposits passed through in the cavern were:—

Iron and Bronze.		BLACK MOULD. Roman Remains (Ovine).
Palæolithic	Newer Type.	GRANULAR STALAGMITE, 5 feet. Extinct Animals.
		CAVE EARTH. Extinct Animals. (Hyæna).
	Rougher Type.	CRYSTALLINE STALAGMITE, 12 feet. (Bears).
		BRECCIA.

Work commenced in March, 1865, by excavating down to 4 feet throughout the whole cavern; finished in November, 1879, the floor had at that time been so excavated, at a cost of 1,850*l*. to the Association. A further grant was then given to lay bare the limestone floor; and subscriptions from private sources amounted to 51*l*. received, which enabled the base of the cave deposit to be excavated for a length of 132 feet. Occasionally stalagmitic fragments occurred on the base of the breccia, resting on the rock. On June 19, 1880, the work was suspended, it having only yielded seventeen finds—amongst them a flint nodule, which had not been touched by the implement maker—which are of greater rarity. Archæological finds were more numerous than remains of animals; the implements correspond to those of the oldest river gravels in type. Referred to the good work done by Mr. George Smerdon, the foreman of the workmen during sixteen years, who has become crippled with rheumatism, brought on by execution of the work, and suggested the desirability of raising subscriptions to purchase for him an annuity of 10*l*. a year.

Report of the Committee, consisting of Mr. James Heywood, Mr. Shaen, Mr. Stephen Bourne, Mr. Wilkinson, the Rev. W. Delaney, and Dr. J. H. Gladstone (Secretary), appointed for the purpose of reporting whether it is important that H.M. Inspectors of Elementary Schools should be appointed with reference to their ability for examining the scientific specific subjects of the Code in addition to other matters.—The Committee nominated at Sheffield for the purpose of considering "whether it is important that H.M. Inspectors of Elementary Schools should be appointed with reference to their ability for examining the scientific specific subjects of the Code in addition to other matters," have received a considerable amount of evidence upon the subject, and beg to report as follows:—

1. It has come to their knowledge that the teaching of the scientific specific subjects is practically discouraged by the incapacity of many of H.M. Inspectors to examine in them.

2. This incapacity is explained by the fact that the Inspectors are not generally chosen so much for their fitness to judge of such educational work, as on account of their high scholarship, or through political patronage.

3. In the opinion of this Committee there might be an examining body for H.M. Inspectors, composed of three of the most experienced of the present senior Inspectors, associated with a similar number of the Science Examiners of the Science and Art Department. The examination should be thrown open to elementary teachers, and the candidates might be tested in the practical work of examination in one of the Central Elementary Schools in London.

4. The Committee believe that the opening of the Inspectorship to fully qualified elementary teachers would tend to raise the *esprit de corps* of the profession, and improve the character of both inspector and teacher.

5. The Committee are further of opinion that while a university degree may be fitly regarded as a test of scholarship, it is not a test of the particular qualifications for an examiner, and therefore is not sufficient in itself to guarantee the holder thereof as worthy the position of Inspector. There appears to be no reason why academical honours should be made an indispensable condition of appointment.

6. The Committee recommend that a memorial be presented to the Lords of the Committee of Privy Council on Education embodying the above conclusions.

Report of the Committee, consisting of Dr. Pye-Smith, Prof. M. Foster, and Prof. Burdon Sanderson (Secretary), appointed for the purpose of investigating the Influence of Bodily Exercise on the Elimination of Nitrogen (the Experiments to be conducted by Mr. North).—During the past year four series of preliminary experiments, each of several weeks' duration, have been made by the Committee on the subject, the expenses of which have been met from other funds. In the course of these experiments unexpected difficulties have been encountered relating to method. The most serious of these difficulties having now been for the most part overcome, we are in a position to proceed with our inquiries next winter, and have therefore to request that the sum of 50*l*., previously granted to us, may again be placed at our disposal.

SECTION A—MATHEMATICAL AND PHYSICAL

On some Laws which regulate the Succession of Temperature and Rainfall in the Climate of London, by H. Courtenay Fox, M.R.C.S.—The following paper is an attempt to answer the question: Is there to be found any definite relation between extremes of rainfall or temperature in any month or season, and the weather of the month or season next following?

The data used by me are the same as those upon which the foregoing paper on "Synchronisms" is based, viz., the monthly temperature and rainfall for the Royal Observatory for sixty-six years—1815 to 1880. In accordance with the principles explained by me at p. 277 of the Report of the British Association for 1879, each month is distributed under the five heads of temperature—according as it was very cold, cold, average, warm, or very warm; and under the five heads of rainfall—according as it was very dry, dry, average, wet, or very wet.

I have presented three tables, which show, for each month or season which is classed under one or other of the extremes of rainfall or temperature, the character, in these respects, of the month or season next following.

A careful study of these tables enables us (whilst omitting all those results which are of an ambiguous character) to state the following definite propositions:—

1. A *cold* spring is very prone to be followed by a cold summer, a cold summer tends to be followed by a cold autumn, and a cold autumn has a slight tendency to be succeeded by a winter of low temperature.

2. *Warm* summers are generally followed by warm autumns.

3. In no fewer than eight out of the twelve months (that is in every one except February, March, May, and October), very *low* temperature tends to be prolonged into the succeeding month.

4. If June, July, August, or December be *warm*, the next month will probably be a warm one also.

5. Two months, June and July, tend, when very *dry*, to be followed by dry ones. On the other hand, a dry August indicates the probability of a *wet* September.

6. A *wet* December is apt to be succeeded by a wet January.

In addition to the foregoing, there are also a few instances in which the rainfall of certain months appears to be definitely related to antecedent extremes of temperature, and *vice versâ*. Thus

7. If August or September be *warm*, the ensuing September or October inclines to be wet. If, on the other hand, September or November be *cold*, the succeeding October or December is likely to be a dry month.

8. If February, June, or July be very *dry*, the next month has a strong tendency to be warm.

9. If January, March, or April be *wet*, we may also expect the next month to be a warm one. But a wet May or July gives a strong probability of cold weather in June or August respectively.

Mr. W. H. Preece read a paper *On the Best Form to give to Lightning Conductors*. The question was whether the lightning conductor should be a solid rod, or tubular, or flat. Snow Harris, Prof. Henry, M. de Melsens, and M. Guillemin advocated straps of great surface. Faraday strongly maintained that there was no advantage in strap or tube forms, as the surface does nothing in conducting the current. Mr. Preece had obtained the use of Dr. De La Rue's magnificent batteries, and had procured conductors of equal material, length, and weight, but differing in form. A condenser charged from 3,400 cells afforded a very powerful source of electricity, more than forty-two microfarads being thus available to produce an enormous spark. Experiments made by heating and deflagrating wires through the different conductors left no doubt that these discharges do obey the law of Ohm, and therefore that the additional surface of flat and tubular conductors is of no advantage in their conductivity.

Prof. Osborne Reynolds rather doubted the conclusions of Mr. Preece, on account of our not knowing the conditions under which the electricity passes from the air into the surface of the conductor. Prof. Ayrton thought the experiments should be tried with much greater difference of potential. The 3,000 cells would not produce a free spark of more than $\frac{1}{16}$ of an inch long, whereas flashes of lightning might extend over miles.

Mr. Preece, in replying, pointed out that increased surface, though increasing its inductive capacity, did not add to its efficiency, which depended only on its conductivity.

Mr. Preece also communicated an observation on the peculiar behaviour of copper wires. Very powerful discharges of electricity were found to increase the conductivity of newly-drawn copper wires by an appreciable percentage. Leaden wires showed no such changes. In the subsequent debate it appeared that the opinion was that the effect of the first current was to anneal the wire.

On the Necessity for a regular Inspection of Lightning Conductors, by Richard Anderson, F.C.S., A. Inst. C.E.—The author referred to a paper by M. W. de Fonvielle, "On the Advantage of keeping Records of Physical Phenomena connected with Thunderstorms," read before this Association in 1872. M. de Fonvielle recommended to the attention of the members the steps which had been taken by the French Government for obtaining information regarding thunderstorms, and suggested that the Association should institute some organisation for the collection of such data; arguing that it would be of much value to science, as well as to the public. Nothing, however, has been done by the Association since 1872; and the author not only confirmed the conclusions at which M. de Fonvielle arrived as to the desirability of collecting such data, but was of opinion that the organisation should go further, and arrange for a regular inspection of all public buildings which had lightning-conductors applied.

The necessity for this he demonstrated by adducing a number of striking cases where damage, more or less severe, had occurred to buildings, even though having lightning-conductors attached to them. The cases now cited, he explained, were supplementary to those communicated in his paper on a similar subject to the Association in 1878. A few of the cases were as follows:—

In October, 1878, an elevated building situated at the back of Victoria Station, occupied as a furniture repository, was struck by lightning and sustained damage, although furnished with a $\frac{5}{8}$-inch by $\frac{1}{8}$-inch copper band lightning-conductor and a tube of $\frac{5}{8}$-inch diameter rising above the iron crestings on the tower. The lightning shattered the cresting and bent the point of the lightning-rod, besides doing other damage to the building. On testing, the author found the resistance very great, and on opening out the earth-terminal found it imbedded in concrete.

On June 26 last, lightning struck All Saints Church, Lambeth, doing considerable damage, although there was a $\frac{5}{8}$-inch diameter copper-rope conductor on the west gable, with a copper tube rising 18 inches above. A stone cross about 50 feet from the conductor was thrown down, injuring the roof of the north aisle. On testing the conductor, the author found that it had no "earth" whatever, the rope being simply placed in 2 inches of loose rubbish. The copper was of very inferior quality; conductivity being 32·10 per cent., or about double that of iron.

The author quoted also a few cases from his recent work on "Lightning-Conductors, their History," &c:—

In August, 1878, the Powder Magazine at Victoria Colliery, Burntcliffe, Yorkshire, was struck by lightning, though furnished with a conductor, 13 feet above the building, and terminating in 13 feet of clayey soil. The building was blown to pieces. On testing the conductivity of the copper, it was found to be 39·2, instead of 92 to 94 per cent. The conductor was insulated from the building and from a large iron door, which it ought not to have been.

The author concludes from this evidence that it is not sufficient merely that rods of copper should be attached to a building, but it is necessary that after being fixed they should be regularly inspected, to see if they are in good order, so as to be really efficacious.

Sir Wm. Thomson gave a communication *On a Method of Measuring Contact Electricity*. Sir W. Thompson had devised this method at the time when Hankel published his results in 1861. A method identical with it had lately been described by M. Pellat, and consisted in employing a small electromotive force in connection with a dividing resistance slide, to give a counterbalancing electromotive force to that produced by contact.

Sir W. Thomson next described *A Method of Determining without Mechanism the limiting Steam-Liquid Temperature of a Fluid*. This was a simple apparatus, consisting of a closed glass tube containing liquid sulphurous acid filled to a sufficient height to insure that the liquid in the lower half will expand to the top. Prof. W. Ramsay criticised the proposal, and stated that he had found an apparatus in which a screw was employed to produce increase of pressure instead of using the expansion of the liquid itself. With this apparatus he had repeated Andrews' research on a large number of substances.

Mr. G. F. Fitzgerald read a paper *On the Possibility of originating Wave-disturbances in the Ether*. This was a mathematical paper, in which, by comparing the equations of Maxwell's theory of the propagation of electric action through a medium with those of direct action at a distance, he deduced the conclusion that electric currents and systems cannot originate in the ether such disturbances as those of light.

Mr. R. M. Shida gave an account of *A New Determination of the number of Electrostatic Units in the Electromagnetic Unit*. The value V of this ratio he deduced was $294{\cdot}4 \times 10^8$.

M. Wilfrid de Fonvielle exhibited his magnetro-electric gyroscope, which has been already described in our pages.

M. Janssen sent a communication to the Section, which was read by the Secretary, upon his recent researches *On the obtaining Positive Photographs by Prolonged Exposure*.

Mr. Wiesendanger showed a new electromotor, which will be described hereafter in our pages.

Mr. Philip Braham exhibited an ingenious adaptation of lime-light for microscopic illumination, and also described a simple instrument for detecting polarised light.

On the Best Form of Magnet for Magneto Machines, by W. Ladd.—At the British Association meeting at Dundee in 1867, I made some remarks upon different forms of magnets, and exhibited these diagrams, showing, by the "lines of force" naturally arranged, the great superiority of the circular magnet where an armature is to be employed.

Since that time some thousands of that form of magnet have been made for medical, mining, and other purposes.

Some months ago, in conversation with M. Breguet of Paris, I showed him these same diagrams, and he was very much impressed with their importance; he has since then constructed a machine, using the Gramme armature, and with a smaller quantity of steel in the magnets he has made a far more powerful

machine than hitherto constructed with either the Jamin or the ordinary horse-shoe form. It is also more symmetrical in appearance, and occupies less space.

With this machine I can heat to incandescence nineteen inches of platinum wire by four turns of the handle, while to heat fourteen inches of the same size wire by a machine having a Jamin magnet it took ten turns of the handle.

Mr. Bottomley followed up his report with a paper *On the Elasticity of Wires*. This paper related the effect of adding loads gradually to a wire which carried a load, and which was found to increase in the limit of breaking strain when longer times were allowed to elapse between the successive increments of the load. A charcoal iron wire which bore a load of 41 lbs. when suddenly loaded would support 52 lbs. after having borne the load of 41 lbs. for 790 hours. Some remarks were made by Sir W. Thomson and by Dr. Siemens, who referred to some recent experiments made in Germany of the stretching of wires and rods of steel, which tended to show that protracted tensile strain affected the chemical condition in which the carbon of the steel was combined with the iron in it. Mr. J. E. H. Gordon referred to the connection between the mechanical and magnetic properties of steel under different conditions.

On the Comparison of Declination Magnetographs at various Places, by Prof. W. G. Adams.—This paper was accompanied by diagrams of simultaneous magnetic disturbances at St. Petersburg, Kew, and Vienna, showing that many of the sudden magnetic disturbances occur simultaneously over very great areas, but that in some cases the variations were in opposite directions. In the debate which followed Sir Wm. Thomson spoke of these observations as beginning to open out a glimpse of the true cause of the magnetic storms. He observed that if similar records of the other magnetic elements, inclination and intensity, could be procured, we should know definitely whether these disturbances were due to any changes of the magnetism of the earth itself, or whether they were due to an external magnetic action. Magnetic observations had been going on for forty years, and it was a reproach that more had not hitherto been done. He also referred to the alleged connection between auroræ and magnetic storms. Mr. J. Glaisher and Staff-Commander Creak mentioned cases of sudden magnetic disturbances. Capt. Creak recalled the observations of the Arctic expeditions of 1875-6, when a deflection of 5° was observed within forty minutes, the Kew records showing synchronously a smaller fluctuation. He argued that an observing station in a more northerly latitude was necessary. Mr. W. H. Preece recounted a magnetic and electrical storm which affected Ireland and the west of England on August 12. Magnetic disturbances always were accompanied by earth currents which affect the telegraph-wires. The same storm affected even the Atlantic cables and the Cape cable. He believed they would be found to have affected the whole earth. The electromotive force on this occasion, through the Atlantic cable, was about as great as that of 300 Daniell's cell, or more exactly one volt per 6·6 miles. Capt. Creak also exhibited the new Admiralty charts of the magnetic variation for 1880.

Prof. G. H. Minchin read a communication *On Photoelectricity*. He had obtained feeble currents from two silver plates coated with sensitive films of iodide, chloride, or bromide of silver, dipping into a common fluid, and then one of them exposed to the light. He had also observed that preparations of fluorescent and phosphorescent bodies upon silver plates acted similarly.

Prof. Silvanus P. Thompson gave a paper *On Electric Convection Currents*, pointing out their analogies with true conduction currents, and of currents of electrolytic conductivity in respect of electro-magnetic phenomena. The application to ring-figures produced by disruptive convection and by electrolytic conduction was considered, and their deformation in the magnetic field. It was pointed out that considerations of a similar nature had been advanced by Prof. Ayrton at an earlier date.

Experiments on Thin Films of Water, with regard to the Absorption of Radiant Heat, by the Hon. F. A. R. Russell.—The experiments, the general results of which are given below, were made with the object of ascertaining the diathermancy of water in very thin films, and these experiments afforded incidentally an opportunity of observing the behaviour of films subject to varying conditions.

The arrangement of instruments was similar to that illustrated at p. 383 of Prof. Tyndall's "Heat as a Mode of Motion." The instruments used were: a dead-beat mirror galvanometer and scale, a thermopile, and a screen. The soap film was carried by a piece of a cork sole perforated by a hole slightly larger than the hole in the screen, about 1¼ inch in diameter. The sources of heat were (1) a copper or iron ball heated from behind by a small gas flame; (2) a gas flame from a Bunsen burner and (3) a hydrogen flame in air.

The film was mostly made from a solution of about half a drachm of shavings of Castile soap, dissolved five to fifteen minutes in about five cubic inches of water, at 60° F.

The film, soon after being placed perpendicularly at the orifice in the screen, exhibited coloured bands, which descended in regular succession until the last band appeared, which contained a bright blue line. The descentof the bands continued at a slackened rate till the grey, and finally the black, occupied a portion of the upper half of the film, which half was alone subject to experiment. A condition more or less of equilibrium then prevailed, the tension of the black portion counteracting the force of gravity. A light yellow or bronze was always the last colour to appear, and preceded the white or grey, which again was succeeded by black. When there was any black in the film, the bursting of the film was marked by a slight click or snapping sound. The best films lasted frequently between ten and thirty minutes, and sometimes the black portion alone was under observation fifteen or twenty minutes.

The following table shows the absorption per cent. for each of the three sources of heat, and the thickness of the film, as derived from a table in Watt's "Dictionary of Chemistry," giving Newton's thicknesses of thin films of air, water, and glass. A table in Cooke's "New Chemistry" gives the thicknesses of soap-films as considerably greater than those stated in Newton's table. The "light film" of Cooke corresponds to my "grey," and his "grey" to my "fine grey." Newton's "white" corresponds to my "grey." The refractive index of the solution used by me was 1·34 and 1·35, a little higher than that of pure water.

State of Film.	Metal.	Gas.	Hydrogen.	Thickness of Film in millionths of an inch.
Last band alone	9 ?	8 ?	—	8·3
Bronze	6	5·7	—	5·2
All grey (white)	4·7	—	4·5	3·9
Fine grey	—	3·4	—	1·8
Half grey, half black...	—	2·9	—	2·3
Two-thirds black, one-third grey	—	1·6	1·6	1·8
Half fine grey, half black	0·7	—	—	1·34
Black and slight fine grey	—	—	1·2	
Fine grey and black, or all black	0·29	—	—	0·75
All black	0·29	1·5	0·6	

SECTION B—Chemical Science

On the Influence of Water on the Union of Carbonic Oxide with Oxygen at a High Temperature, by Harold B. Dixon, M.A.—The author obtained the curious result that a mixture of carbonic oxide and oxygen in such proportions as to form carbon dioxide, when free, or nearly free, from water, does not explode, either by a direct discharge from a Leyden jar or when sparks are passed through it from a Ruhmkorff coil. By allowing a minute portion of aqueous vapour to mix with the gases, explosion immediately takes place on the passage of the spark. In presence of a very small trace of water, combustion takes place, but slowly, not with explosive energy. The author suggests as an explanation the following equations:—

$$CO + H_2O = CO_2 + H_2$$
$$H_2 + O = H_2O.$$

Prof. Williamson suggested that it would be interesting to determine the inferior limit to the power of water vapour in causing an explosion, and that Mr. Dixon would probably extend his research in this direction.

Prof. Harcourt pointed out that various other similar instances are known, among others the impossibility of causing union of calcium oxide and carbonic anhydride, in absence of water, and the refusal of dry chlorine to act on hot sodium.

Mr. Thomas noticed that in mixtures containing large amounts of marsh-gas the presence of water vapour also influenced the rapidity of explosion.

Prof. Silva remarked that the influence of diluents may have a contrary effect from that of water-vapour, and that the question is worth investigation.

Metallic Compounds containing Organic Radicals, Part I., by J. Sakurai.—The author has succeeded in obtaining a compound of methylene iodide, CH_2I_2, with mercurous iodide, Hg_2I_2, of the formula CH_2IHgI. It is a white crystalline substance, insoluble in water, cold alcohol, ether, chloroform, and ethylic iodide. It is soluble in boiling alcohol and in methylene iodide. It melts at 108°-109° C.

Besides this substance, another, insoluble in all ordinary solvents, is produced, which possesses the formula $CH_2(HgI)_2$. Chlorine and bromine act on these substances, forming methylene chlorides or bromides, and halogen salts of mercury. The author proposes to attempt to produce the zinc and sodium analogues of this body.

On some Relations between the Atomic Volumes of Certain Elements and the Heat of Formation of some of their Compounds, by Walter Weldon, F.R.S.E.—It has been observed that the heat evolved by the union of chlorine with a metal is greater than that of bromine, and that the heat given off by bromine is greater than that by iodine. In a similar manner oxygen gives off more heat than sulphur. Berthelot has observed that positive elements obey the same rule, but that there are some exceptions caused *par diverses circonstances mal connues*. That the heat of combination is inversely proportional to the atomic weights of the reacting elements is sometimes the case, but is not a general law; but on comparing the heat evolved by combination of positive elements with their volumes, a direct numerical proportion is observable. To this law there are two exceptions, viz. cadmium and manganese. Cadmium is usually classed along with zinc and magnesium, although it closely resembles indium. It compares with magnesium, but not with zinc. The atomic volume of cadmium is greater than that of zinc, yet the heats of formation of its chloride, oxide, &c., are less than those of zinc. The heat of formation of indium compounds, which have not yet been observed, should be greater than those of zinc. In the same way the heats evolved during formation of compounds of manganese are greater than those of iron, yet the atomic volume is less. Either this case is exceptional, or manganese does not belong to the iron group.

In over 100 instances it has been observed that molecular heats of formation of elements of the same group divided by the atomic volumes of the electro-negative elements give numbers either identical with, or bearing some simple relation to, each other.

After some complimentary remarks from Prof. Williamson, Prof. W. Ramsay pointed out that the heats evolved by the combustion of allotropic modifications of carbon and phosphorus bore the same relation to each other as their specific volumes, and hinted that the heat evolved by the combination of elements of the same group with other elements bore some remarkably simple proportion to the relation of the number of atoms in the complex molecules of the solid elements.

On the Specific Rotatory Power of Cane and Invert Sugar, by Alfred H. Allen.—The author points out that on inverting sugar its weight is increased by absorption of water, and that allowance is not usually made for this fact. He has therefore calculated the following corrected table for S_j:—

	S_j.
Cane-sugar	+ 73·8
Invert sugar	− 25·6 at 15° C.
Dextrose	+ 57·6
Lævulose	− 108·8 at 15° C.

The deviation for a plate of quartz 1 mm. thick is under similar conditions 24° for its transition tint, and 21·66° for the sodium ray. Hence the corresponding values for S_D may be calculated by multiplication by $\frac{21·66}{24} = 0·9025$.

On the Identification of the Coal-Tar Colours, by John Spiller, F.C.S.—The process recommended is the action of sulphuric acid on the dyeing material, taken in conjunction with the shades produced on, and the tendency to dye silk, wool, or cotton. The most remarkable reactions are the following:—Magdala-red with sulphuric acid gives a blue-black; Saffranin, a grass-green, becoming indigo-blue on strongly heating; Chrysoïdin, deep orange, turning almost to scarlet on heating; Alizarin, ruby red, or maroon; Eosine, golden yellow; Primrose (naphthalene-yellow), first yellow, then colour discharged; Chrysaniline, brown fluorescence; Aurine, yellowish brown; Atlas-orange, rose-colour, changing to scarlet on heating; Atlas-scarlet, no alteration; Biebrich-scarlet, R, blue-black; ditto, B, blue-green; Aniline-scarlet, permanent golden yellow; Indulin, slaty blue to indigo; all violets give a yellow, or brownish yellow; Phenyl and diphenylamine blues, dark-brown solutions; Iodine and malachite greens, bright yellow solutions, the former giving off iodine on heating; lastly, Citronine, a pale cinnamon or neutral tint.

On the Density of Fluid Bismuth, by W. Chandler Roberts, F.R.S., and Thomas Wrightson, C.E.—The density of bismuth, just molten, was determined by a modification of the usual process for determining the specific gravity of liquids devised by Mr. R. Mallet, and was found to be 10·039, as a mean of three experiments. By an apparatus termed the oncosimeter, which admits of the weight of a ball of metallic bismuth being taken in molten bismuth by means of a delicate spring balance, its mean specific gravity deduced from six experiments was found to be 10·055; that of solid bismuth is 9·82.

On Crystals of $HgHSO_4$, by P. Braham.—Mercury, when left in contact with sulphuric acid for two years, deposits extremely deliquescent crystals of the above formula.

On the Treatment of Complex Ores containing Zinc, by E. D. Parnell.—The presence of zinc renders the extraction of lead and copper from their ores so difficult that manufacturers reject them; nor are zinc ores containing less than 25 per cent. of zinc adapted for the extraction of that metal.

Further Notes on Petroleum Spirit and Analogous Liquids, by A. H. Allen.—To distinguish petroleum spirit from shale naphtha and from benzene, mix one volume of boiled carbolic acid with three volumes of these liquids. The carbolic acid refuses to mix with the former, but mixes with the two latter. On similar treatment with coal-tar, pitch, petroleum spirit and shale naphtha do not mix, whereas benzene does. With carbolic acid, burning oil from shale can be distinguished from kerosene, the burning oil from petroleum, for the former is not miscible, whereas the latter turns violet, and partially mixes; and if warmed, crystals of carbolic acid separate on cooling. By treatment with nitric acid and with bromine, it was shown that naphtha from petroleum contains 80 per cent. of paraffins and 20 per cent. of olefines; photogene, 55 to 80 per cent. of paraffins, and that wax consists entirely of paraffins; whereas shale naphtha contains 75 to 90 per cent. of olefines; photogene from the same source, 60 to 65 per cent. of olefines, and that the lubricating oil consists entirely of olefines.

On the so-called Normal Solutions for Volumetric Analysis, by A. H. Allen.—This communication was a recommendation that the various different meanings of the term "normal" be done away with, and that a *normal solution* be understood to be one containing in 1,000 cub. cents. such an amount of reacting body as will combine with, replace, or oxidise one gram of hydrogen.

On the Determination of the Loss of Heat in Steam-boilers, arising from Incrustation, by William Thomson.—This plan consists of evaporating the various waters in vessels exposing an equal surface of each, care being taken to keep the total amount constant by means of a constant supply. After a given time the remainder is measured and the ratio calculated. Deposit of incrustation greatly impedes evaporation.

On the Identification of the Ink used in writing Letters and Documents as Evidence in Cases of Libel, Forgery, &c., by W. Thomson, F.R.S.E.—The author has observed that different specimens of writing give different coloured reactions with various reagents, such as sulphuric, hydrochloric, nitric, or oxalic acid, or by caustic soda, solutions of bleaching-powder, and chlorides of tin. Such differences may be of use in detecting forgery, for the change of colour affords evidence as to whether all the writing has been performed with the same ink.

The Effects of Magnesia on Vegetation, by Major-General Scott, C.B., F.R.S.—The author's conclusion, drawn from numerous experiments, is that there is overwhelming evidence against the notion that soil naturally contains so much magnesia that an extra supply will be of little or no benefit. There are strong grounds for supposing that magnesia, like phosphoric acid, is not only an essential ingredient of plants, and aids in their nutriment, but also that it determines the beneficial action of other ingredients.

On the Action of Oils on Metals, by William H. Watson.—Most oils attack copper and iron, but not to the same extent. Some act much more on copper than on iron, and *vice versâ*.

On Bleaching-Powder Residues, by J. F. W. Hodges.—To extract active chlorine from 10 grains of bleaching powder, so

that it does not react with starch paper, 5,000 cub. cents. of water are required. Even then it reacts with iodine and starch. The amount of residue varied between 22 and 30 per cent. of the total quantity of bleaching powder. This residue, on treatment with acid, evolved a minute amount of active chlorine; the residue, applied to cotton and treated with acid, has no bleaching or injurious action.

On the Coal-seams of the Eastern portion of the South Wales Basin, and their Chemical Composition, by J. W. Thomas.

On the Refraction Equivalent of Diamond and the Carbon Compounds, by J. H. Gladstone, Ph.D., F.R.S.—The specific refractive energy (that is, the refractive index – 1 divided by the density) of numerous compounds of carbon was determined by Gladstone and Dale in 1863. From their experiments it was found that carbon uncombined, as in the diamond, and also in combination with hydrogen and oxygen, has a specific refractive energy of 5·0. Yet in compounds of the aromatic series, where several atoms of carbon are united by more than one bond, the refraction equivalent is raised about 2·0. This does not embrace the facts that the terpenes have a refraction equivalent lying between 2 and 4 over the calculated numbers; that the cinnamyl compounds also show abnormality; and that hydrocarbons containing a greater number of atoms of carbon than of hydrogen increase in refractive energy at a rate more rapid than theory demands. Thus naphthalene shows a surplus of 16·4, anthracene of 31·7, and pyrene of 43·6 over the calculated numbers.

Dr. Bedson, who has been recently investigating the subject in conjunction with Mr. W. Carleton Williams, remarked that sufficient allowance had not been made for dispersion in the last-mentioned instances; that from their experiments they have found the degree of concentration of the solution to exercise a marked influence; and he suggested that in naphthalene, anthracene, and pyrene, the molecules are much more complex than in benzene, for several groupings of carbon atoms are noticeable, among them two groups in which an atom of carbon is united to other atoms of carbon by all four bonds.

On a New Process for the Production from Aluminous Minerals of Sulphate of Alumina from Iron, by J. W. Kynaston.—After a preliminary sketch of the various methods of preparing sulphate of alumina in a state of greater or less purity from various minerals containing it, the author describes his own process for preparing it free from iron from bauxite, a silicate and titanate of alumina and iron. This he does by treating it with a mixture of oxalic and hydrochloric acids, allowing it to stand for a week or ten days. The insoluble portion is freed from oxalic acid by repeated washing, and the residue converted into sulphate of alumina by treatment with sulphuric acid. This product is almost free from iron. The oxalic acid is recovered by precipitation with lime, and subsequent decomposition of the salt with sulphuric acid. The expense of this process has prevented its adoption. The author has now devised a process whereby the iron is precipitated as arsenite, and then by means of carbonate of lime neutralising any free acid, and at the same time producing some tetrabasic sulphate of alumina. The remaining ferrous iron is then removed by addition of ferrocyanide of lime. The blue precipitate is induced to settle by addition of a little sulphate of iron or zinc. Excess of arsenic is precipitated with sulphide of lime. This process is at present in operation at St. Helen's.

On a New Process for separating Silver from Copper Ores and Reguluses, by William Henderson.—This process is applicable to calcined Spanish pyrites containing a large proportion of arsenic before calcination. The "raw regulus," when fused with 20 per cent. of its weight of sodium bisulphate, yields metallic silver in large amount. The iron and copper are converted into oxides, while the silver remains as sulphate, and may be extracted from the residue with water. The process has as yet been worked only on a small scale.

SECTION C.—GEOLOGY

Notes on the Submarine Geology of the English Channel off the Coast of South Devon, by Mr. A. R. Hunt, F.G.S.—Attention was called to the presence of large detached blocks of stone over an area extending from S.S.W. of the Start to S. of the Eddystone. One of these blocks in Torquay was stated to weigh 9¼ cwt., another not landed measured 3 feet 6 inches. They consisted of granite, conglomeritic grit, serpentine, and abbrogubbon.

A paper *On the Site of a Palæolithic Implement Manufactory at Crayford, Kent*, by Mr. F. C. Spurrell, was read by Prof. Dawkins. This occurred in brick-earths containing a large number of extinct mammalia, and on the same horizon with them. They were probably manufactured on the spot, by the old dwellers, and belong to the same type as the implements of St. Acheul. Many of the specimens when found were completely shattered, and the fragments were united by Mr. Spurrell.

On the Island of Torghatten, Norway, and on the Influence of Joints on Denudation, by Prof. W. J. Sollas. Describes a conical or hat-shaped mountain, traversed by a tunnel 600 feet in length, through which the light can be seen. The rock is compact gneiss, *roche moutonées* occur up to the level of the platform, which terminates slightly below the entrances to the tunnel, which are somewhat lower than the centre. Attributes its origin to mechanical disintegration, aided by joints.

On the Contortion of a Quartz Vein in Mica Schist from Bodö, Norway, by Prof. W. J. Sollas. Describes excessively contorted band of quartz between foliation planes.

On the Geological Age and Relations of the Sewalik and Pikermi Vertebrate and Invertebrate Faunas, by W. T. Blanford.—The deposits from these two areas have both been referred to the Miocene, and contain an analogous fauna. The Sewalik beds are a portion of a great Tertiary area crossing India from Assam to Sind. The lower beds are nummulitic and marine, the upper series entirely freshwater. Of 48 genera in the Sewalik fauna, with 93 species in the Siwalik area, 12 are peculiar, 4 genera do not occur higher than the European miocene, 25 genera are recent, including cats, dogs, bears, true elephants, antelopes, and sheep. The lower Manchhar mammalian fossils were shown to be older than the Sewalik series, but are newer than the Upper Miocene, and therefore the Sewalik series is referable to the Pliocene. The Sewalik fauna contains six reptiles, of which three are still living. Ruminants are numerous in both the Sewalik and the Pikermi deposits; the latter rest on a bed with Pliocene marine mollusca. Suggests as the climate grew colder in Pliocene times the Miocene mammals migrated southwards.

On the Relations to be established between Coast-line Direction represented by Great Circles on the Globe and the Localities marked by Earthquakes in Europe, by Prof. J. P. O'Reilly.—Refers to the rectilinear direction of coast-lines as that between Carnsore and Wicklow heads, this if produced and regarded as part of a great circle which passes through the Dykes of Southern Scotland and corresponds to the east coast-line of Scotland north of the Firth of Tay, the Carnsore coast-line direction being strictly parallel to the strike of the rocks west of it, and of the termination of the great masses of granite of Kilkenny. Refers to the linear direction of the limit of earthquake-movement in Southern Sweden, and he suggests the similarity of direction in coast-lines and the boundaries of earthquake-movement have the relation to each other of cause and effect, the coast-line being the result of slips along the lines of weakness produced by earthquakes.

On the Sandstones and Grits of the Lower and Middle Series of the Bristol Coal-fields, by E. Wethered.—These carboniferous sandstones are composed of angular grains, those of the Millstone Grit being the least so. He describes an intermediate stage between grit and soft clay as "hard duns," of a hardness of 7, being a rock that scratches glass. The Brandon Hill grit yielded on analysis 98·5 per cent. of silica; it is used for mining purposes and for brickmaking. The thickness of the Pennant grit is 970 feet, associated with coal-measures of 2,000 feet thickness. He regards the "Pennant grits" as a local deposit, and as occurring on more than one horizon. The "Duns" contain more alumina, and he considers the silicates (except the silicates of alumina) by the action of carbonic acid gas.

A paper *On the Hiatus said to have been found in the Rocks of West Cork*, by Mr. G. H. Kinahan, was read by Mr. Ussher.—The following classification was given:—

Griffiths	Prof. Jukes	Prof. Hull
Carboniferous slate.	Carboniferous slate.	Carboniferous slate and Coomhoola grit.
Yellow Sandstone.	Upper Old Red.	Kiltorcan beds.
Old Red Sandstone.	Lower Old Red.	Glengariff beds (Silurian).
Silurian.	Glengariff grit.	

The author rejects Prof. Hull's view, that an important hiatus and unconformability occurs above the Glengariff beds, and he considers that a complete sequence of formations occurs from the Silurians up to the Carboniferous.

Note on the Range of the Lower Tertiaries of East Suffolk, by Mr. W. H. Dalton, was read by Mr. Whitaker.—Describes sections obtained in deep wells and borings through the drift. One at Yarmouth proved the chalk to be 500 feet from the surface; between the drift and the chalk there being no less than 300 feet of Lower Tertiaries. These wells also prove the surface of the chalk to be an inclined plane beneath the Tertiaries, and the surface of the Tertiaries beneath the drift also obeys the same law. At Brandfield the chalk was found at 48 feet below the mean sea-level.

Proof of the Organic Nature of Eozoon Canadense, by Mr. Charles Moore.—Refers to the opinion of Prof. Moebius, of Kiel, of specimens supplied him by Dr. Carpenter, that the eozoonal structure is referable to the mineral kingdom, which view is also taken by Dr. Otto Hann of Ruthlengen, and describes his own examination of a specimen of Laurentian rock from Canada, supplied him by Dr. Carpenter, and of others by Mr. J. Hind. A specimen weighing twenty grains was decalcified and placed in stoppered bottles in water filtered through asbestos; this when magnified was found to reveal a clear siliceous-looking fibroid growth of organic structure of black gum and olive colours. These curled fibres can only be compared to a bit of polished golden wire. They are formed of three round golden close-set columns. It is not a parasitic shell, for when dry it is rigid; but when moist, curved and curled specimens are flexible. They are not unlike the pedicle to which the capsule of some Rhizopoda are attached; but in such a case they must have been devoured by the eozoon, which is not probable. In addition there is another organic structure, not thicker than a spider's web, like mycelium growth of the present day, and also anomalous bodies, possibly the ova, or gemmules of forams. Refers to a similar mycelium growth, as in Eozoon found on nummalites; also similar structures in the Globigerina of the *Challenger* dredgings from the bottom of the Atlantic.

On the Post-Tertiary and Glacial Deposits of Kashmir, by Lieut.-Col. Godwin-Austen.—Refers to the work done by Mr. F. Drew. The author is of opinion that certain deposits containing human remains were deposed by a lake, still existing, but formerly of larger dimensions. Refers the older beds to the age of the upper conglomerates of the Upper Sewaliks. He referred to the deposits at different heights on the banks of the Indus, extending up to eighty feet above the river, forming cliffs or bluffs with angular, probably glacial, deposits. The next terraces occurred at 120 feet, and these again had still higher beds above them, and the author believes the whole of the series reach not less than 1,000 feet in thickness.

On the Fault-Systems of Central and West Cornwall, by J. H. Collins.—Fifteen distinct fault-systems, and possibly far more; the older system is newer than the Carboniferous; when the earliest was produced, the country was much the same as it is now. The granite juction-faults are always filled up with schist; these oldest faults are succeeded by the elvan veins; these cut a fissure in the slate rock, which has been bent and distorted, and often faulted; these are nearly all of precisely the same age. The tin-lodes are the next, followed by a second system, crossing the older in an oblique direction. Of still newer date are the east and west copper veins. The eighth system is also copper, known as the Caunta copper lodes. Then followed the ninth system, or cross-courses, running north and south, generally only containing oxide of copper and quartz. The later lodes never contained tin; in the last only quartz. The fifteenth set are the "alluvial faults;" the ancient alluvial tin gravels are traversed by them.

On the Geology of the Balearic Islands, by Dr. Phené.—Refers to the cave deposits in the grottos of Antiparos and of the almost mountainous dimensions of the external deposits called Pambuk Kalesi at Hierapolis, in Anatolia. He describes the superb caverns near Artâ, la Cueva de la Hermita, in Majorca. The southern portion of the island is Miocene, the more northern begins on the east with a sea-coast of Devonian, followed by Triassic and Jurassic deposits, again succeeded by Devonian. The cave occurs in a fragment of Miocene cliffs. In its vast size and its magnificent columns of uniform thickness it may be compared with the proportions of Westminster Abbey; its dimensions are exceedingly vast, and its lines resemble Gothic and Moorish architecture in their delicate traceries.

On some Pre-Cambrian Rocks in the Harlech Mountains, by Dr. Hicks.—Describes the Cambrian area of the Harlech Mountains, where he considers rocks occur equivalent to the felsitic group of Banger of pre-Cambrian age, and he believes the Harlech rocks of Prof. Sedgwick rest on these ancient rocks, which form a part of a very ancient anticlinal, the conglomerates at the base of the Harlech group being derived from the felsitic pre-Cambrian rocks beneath.

On the Action of Carbonic Acid on the Limestone, by Prof. Boyd Dawkins, F.R.S.—Caves in the limestone are to be looked upon as subterranean watercourses, which are produced partly by the dissolving action of the carbonic acid in the rainwater, and partly by the mechanical action of the streams flowing through them. The insoluble carbonate of lime in the rock is changed into the soluble bi-carbonate and carried away in solution. The additional atom of carbonic acid, however, is in a condition of unstable chemical combination, and if it be removed either by evaporation or by the action of the free current of air, the insoluble carbonate of lime is at once deposited. Hence it is that some caverns have their walls covered with a drapery of stalagtite and the little straw-like pendants from the roof formed round the edges of each drop gradually become developed into columns of various sizes. The stalagmitic pedestals also rise from the floor where a line of drops falls from the roof and ultimately unite with the column let down from above. On the surface, too, of the pools an ice-like sheet of stalagmite gradually shoots across from the sides, and sometimes where the water is still covers the whole surface. Admirable illustrations of all these processes are to be seen in the caves of Pembrokeshire, and especially in the Fairy Cave on Caldy Island.

The rate of the accumulation of carbonate of lime depending primarily upon the access of water and the free access of air, both being variable, varies in different places. Sometimes it is very swift, as for example in the Ingleborough Cave, where a series of observations by Prof. Phillips, Mr. Farrar, and the author extending over the years from 1845 to 1873 give the annual rate at ·2946 inch. It is obvious therefore that all speculation as to the antiquity of deposits in cases which are based on the view that the accumulation is very slow is without value.

The mountain limestone ravines and passes are to be viewed in the main as caverns formed in the manner above stated, which have lost their roofs by the various sub-aërial agents which are ever at work attacking the surface of the limestone. If any of these be examined, it will be seen that the tributary caves open on their sides, and in some cases the ravine itself is abruptly terminated by a cavern.

On a Raised Beach with Diluvial Drift in Rhos Sili Bay, Gower, by Prof. Prestwich.—This beach is coextensive with a cliff 1½ mile in length, at the south-west corner of the peninsula of Gower. The cliff is 50 to 80 feet in height, sloping from the top to the parallel range of Old Red Sandstone, consisting of red sandstones and quartz conglomerate. The cliff consist of lenticular, rudely stratified, re-arranged material 40 to 50 feet in thickness; contains neither shells nor bones, and rests on a well-rolled raised beach, with pebble from the Carboniferous limestone, coal-measures, and other measures, its average thickness 8 to 10 feet, but occasionally it is piled up much higher; it contains shell of *Littorinus*, *Purpura lapillus*, *Turritela terebra*.

Prof. Prestwich also read a paper *On the Geological Evidence of the Submergence of the South-West of Europe during the Early Human Period*.—Refers to the residual deposits, consisting of gravel, fragments of rock, exhibiting little or no bedding; of this group is the "Warp" of the Rev. Mr. Trimmer, the "Trail" of Rev. O. Fisher, the result of great cold and weathering; "Head," by Mr. Godwin-Austen, derived from cliffs during severe climate; others have referred it to the denudating action of ice and snow, rain action, and to "waves of translation." All these groups the author correlates; in early days all superficial deposits were referred to the "diluvial theory" of Dr. Buckland. Refers to old river terraces proving the gradual wearing away of the valleys; but the author would revive a portion of the old "diluvial theory" for certain other deposits. He groups the Loess, warp, head, trail, and alluvial deposits occupying the centres of broad valleys, into one group, produced by a flood caused by a great temporary submergence of the land and its subsequent re-elevation, which spread material without rounding the fragments. Coarse *débris* always to be traced from higher to lower levels; shells are rare, *débris* is local, and these beds cover all others, at all levels. Refers to the "warp" of the Thames, as difficult to distinguish from London clay, gradually becoming more gravelly on the lower slopes, and merging into the ordinary valley gravels. The trail lying on the gault of Maidstone was then described, capping the hill, and following down the slope of the hill with an increasing thickness on the lower slopes.

The "trail" of the Severn derived from the northern hills is spread over the central flat regions, and forms the Cotswolds to the east. "Head" is stated to cover all the old beaches of the south of England and of Wales, as at Rottingdean, and Berling Gap, near Worthing, the low cliff behind the South-Eastern station at Dover, both sides of the Bristol Channel, between Calais and Blanc Nez, reaching a thickness of 80 to 100 feet, the height being limited only by the heights of the ground between. The beach often contains erratic boulders, and he refers the raised beach to a period during the glacial episode, but at a time when the present coast-line had obtained. Sangatte Cliff contains delicate land shells and the remains of the mammoth; ground palæolithic implements. Others occur at Cherbourg and in the Isle of Ré; between there and Gibraltar none are known to occur, though they possibly may be present.

Refers to the clay-gravel or head overlying the raised beach of Portslade, between Brighton and Chichester as containing land shells, palæolithic implements, and bones of land animals; raised beach and head of Guernsey; these deposits and others on the French chalk, Belgium, and the Rhine country he considers to be due to causes other than the deposition of fluviatile material, marine deposits, ice or snow slopes or ice-cap. The *débris* is not a talus, for it slopes as a small angle and increases in thickness in retreating from the hill and slope. The submergence destroyed the palæolithic man and many of the older animals, and amounted to more than 1,000 feet.

Prof. W. J. Sollas read papers *On a Striated Stone from the Trias of Portishead; On the Action of a Lichen on Limestone*, and *On Sponge Spicules from the Chalk of Trimmingham, Norfolk*.

On the Geological Literature of Wales, by Mr. W. Whitaker, who gave a list of all the publications that have referred to Welsh geology from the seventeenth century to 1873, containing more than 500 entries.

Sketch of the Geology of British Columbia, by Dr. G. M. Dawson, jun., describes littoral deposits of Miocene age, capped by volcanic rocks in the Queen Charlotte Islands. Cretaceous rocks from the Upper Neocomian to the Upper Chalk, equivalent to the Chico group of California, yield the bituminous cols of Manaimo; anthracite occurs at a somewhat lower horizon. The pre-Cretaceous rocks are contorted and disturbed, and those of Vancouver Island are probably of Carboniferous age, and are associated with volcanic deposits; rocks probably Huronian occur in Queen Charlotte Islands. In the Rocky Mountains are Carboniferous and Devonian limestones and Triassic sandstones.

Notes on the Occurrence of Stone Implements in the Coast Laterite, South of Madras, and in High-level Gravel and other Formations in the South Mahratta Country, by Mr. R. Bruce Foote.—The author describes high-level (partly laterite) gravels of fluviated and lacustrine origin in the basin of the Gatpratha, and Malprabha tributaries of the Kistna in the South Mahratta country yielded large numbers of several types. He then alluded to the occurrence of well-shaped implements, chiefly of the pointed oval type, and made of hard siliceous limestone, in a great talus of limestone and Deccan trap block cemented by calcareous tufa into a great breccia-conglomerate. This occurs along the foot of the hills north of Kistna and west of Soorapoor, in the Nijam's territory. The implements were found worked out in gullies.

On the Pre-Glacial Contour and Post-Glacial Denudation of the North-West of England, by Mr. De Rance, F.G.S., Assoc. Inst. C.E.—The country described is that lying between the Silurian mountains of North Wales and the Lake District, and bounded east by the Carboniferous hills of the Pennine chain. The plains of Lancashire and Cheshire lying at their feet are deeply covered with glacial drift, reaching in one instance, near Ormskirk, a thickness of no less than 230 feet. The deep valleys of the Lake District had attained their present proportions before the Glacial epoch, during which the lakes were excavated, in the case of Windermere, to a depth of 230 feet, or deeper than the English Channel between Boulogne and Folkestone, the bottom of the lake being 100 feet beneath the sea-level. In the valleys of the mountain country the marine glacial deposits are not present, having been re-excavated out by later glaciation, where originally present. In Lancashire, Cheshire, and Flintshire the marine drift occupies an extensive area, and valleys like those of the Ribble and the Irwell, nearly 200 feet in depth, have been excavated in and through them; occasionally the bottom of the valley is beneath the sea-level, pointing to the land being higher in pre-glacial times. A terrace of post-glacial deposits fringes the glacial area at, and often below, the sea-level, consisting of peat with a forest at the base, resting on a marine post-glacial deposit; the peat-beads are found beneath the sea-level to an extent, in one case, of about 70 feet, and it was pointed out that an elevation of this amount would connect Lancashire, Cheshire, and much of North Wales with the Isle of Man.

SECTION D—BIOLOGY

Mr. Gwyn Jeffreys moved and Prof. Rolleston seconded a vote of thanks to Dr. Günther for his address, which was supported by Dr. Sclater. Prof. Rolleston suggested that in every large town a small rate should be levied in favour of a local museum, which is actually done in Liverpool. He also insisted on the importance of a lecture-room in connection with the national natural history collections.

On the Classification of Cryptogams, by Alfred W. Bennett.—In the most recent classification of cryptogams, that by Sachs, in the fourth edition of his "Lehrbuch," he divides Thallophytes (including characeæ) into four classes of equal rank, Protophyta, Zygosporeæ, Oosporeæ, and Carposporeæ. It is proposed in the present paper to retain Sachs' class of Protophyta for the lowest forms of vegetable life; but to restore the primary division of the remainder of thallophytes into Fungi and Algæ, as being more convenient to the student, and at least as much in accordance with probable genetic affinities.

Asre gards minor points the characeæ are removed altogether from thallophytes, and again constituted into a separate group of the first rank; the myxomycetes are regarded as presenting a low type of structure, scarcely raised above the protophyta, and not exhibiting true sexual conjugation; volvox and its allies are removed from the zygosporeæ to the oosporeæ; and the phæosporeæ are separated off as a distinct order from the fucaceæ.

The thallophytes are therefore first of all divided into three primary classes:—PROTOPHYTA, FUNGI, and ALGÆ. The protophyta are divisible into two sub-classes, *Protomycetes* and *Protophyceæ*. The protomycetes consist of a single order, the schizomycetes, of which saccharomyces is regarded as an aberrant form. The protophyceæ are composed of the protococcaceæ (including palmellaceæ and scytonemeæ), nostocaceæ, oscillatorieæ, and rivularieæ. The *Myxomycetes* are treated as a supplement to the protophyta. The fungi are made up of three sub-classes, employing in the main the same characters as Sachs, but, in their terminology, using the syllable "sperm" instead of "spore." The first division, the *Zygomycetes* (or zygospermeæ achlorophyllaceæ), is composed of the mucorini only (including the piptocephalidæ). The second, the *Oomycetes* (or oospermeæ achlorophyllaceæ), comprises the peronosporeæ and saprolegnieæ (including the chytridiaceæ). The third, the *Carpomycetes* (or carpospermeæ achlorophyllaceæ), is made up of the uredineæ, ustilagineæ, basidiomycetes, and ascomycetes, the lichenes being included in the last as a sub-order. The algæ are arranged under three corresponding sub-classes. The *Zygophyceæ* (or zygospermeæ chlorophyllaceæ) is made up of the following orders:—Pandorineæ, hydrodictyeæ, confervaceæ (under which the pithophoraceæ may possibly come), ulotrichaceæ, ulvaceæ, botrydieæ, and conjugatæ (the last comprising the desmidieæ, diatomaceæ, zygnemaceæ, and mesocarpeæ). The *Oophyceæ* (or oospermeæ chlorophyllaceæ) includes the volvocineæ, siphoneæ (with the nearly allied dasycladeæ), sphæropleaceæ, œdogoniaceæ, fucaceæ, and phæosporeæ. The *Carpophyceæ* (or carpospermeæ chlorophyllaceæ) is made up of the coleochæteæ and florideæ.

The CHARACEÆ constitute by themselves a group of primary importance. The MUSCINEÆ are unchanged, comprising the *Hepaticæ* and *Musci* (including sphagnaceæ). In VASCULAR CRYPTOGAMS it is proposed to revert to the primary distinction into *Isosporia* and *Heterosporia* as most in accordance with probable genetic affinities. The isosporia consist of the filices (including ophioglossaceæ), lycopodiaceæ, and equisetaceæ. The heterosporia comprise the rhizocarpeæ and selaginellaceæ. In the terminology of the heterosporia the inconvenience and incorrectness are pointed out of the use of the terms "macrospore" and "macrosporangium;" and it is proposed to call the two kinds of spores and their receptacles respectively *microspore*, *megaspore*, *microsporangium*, and *megasporangium*; or better, in reference to their sexual differentiation, *androspore*, *gynospore*, *androsporangium*, and *gynosporangium*.

A Reformed System of Terminology of the Reproductive Organs of the Cryptogamia, by Alfred W. Bennett and George Murray.

—After giving illustrations of the present chaotic state of cryptogamic terminology, the authors proceed to state that the object they have kept in view is to arrive at a system which shall be symmetrical and in accordance with the state of knowledge, and which shall at the same time interfere as little as possible with existing terms. A few new terms are introduced, but the total number is greatly reduced.

In the fourth edition of his "Lehrbuch" Sachs defines a "spore" as "a reproductive cell produced directly or indirectly by an act of fertilisation," reserving the term "gonidium" for those reproductive cells which are produced without any previous act of impregnation. The practical objections to this limitation of terms are pointed out, and it is proposed to restore the term *spore* to what has been in the main hitherto its ordinary signification, viz., *any cell produced by ordinary processes of vegetation, and not by a union of sexual elements, which becomes detached for the purpose of direct vegetative reproduction.* The spore may be the result of ordinary cell-division or of free cell-formation. In certain cases (*zoospores*) its first stage is that of a naked mass of protoplasm; in rare instances it is multicellular, breaking up into a number of cells (*polyspores*, composed of *merispores*, or breaking up into *sporidia*). Throughout thallophytes the term is used in the form of one of numerous compounds expressive of the special character of the organ in the class in question. Thus, in the protophyta and mucorini we have *chlamydospores;* in the myxomycetes, *sporangiospores;* in the peronosporeæ, *conidiospores;* in the saprolegnieæ, oophyceæ, and some zygophyceæ, *zoospores;* in the uredineæ, *teleutospores, æcidiospores, uredospores,* and *sporidia;* in the basidiomycetes, *basidiospores;* in the ascomycetes (including lichenes), *conidiospores, stylospores, ascospores, polyspores,* and *merispores;* in the hydrodictyeæ, *megaspores;* in the desmidieæ, *auxospores;* in the volvocineæ and mesocarpeæ, *parthenospores;* in the siphoneæ and botrydieæ, *hypnospores;* in the œdogoniaceæ, *androspores;* in the florideæ, *tetraspores* and *octospores*. The cell in which the spores are formed is in all cases a *sporangium*.

In the terminology of the male fecundating organs very little change is necessary. The cell or more complicated structure in which the male element is formed is uniformly termed an *antheridium*, the ciliated fecundating bodies *antherozoids* (in preference to "spermatozoids"). In the florideæ and lichenes, the fecundating bodies are destitute of vibratile cilia; in the former case they are still usually termed "antherozoids," in the latter "spermatia," and their receptacles "spermogonia." In order to mark the difference in structure from true antherozoids, it is proposed to designate these motionless bodies in both cases *pollinoids;* the term "spermogonium" is altogether unnecessary, the organ being a true antheridium.

A satisfactory terminology of the female reproductive organs presents greater difficulties. The limits placed to the use of the term spore and its compounds require the abandonment of "oospore" for the fertilised oosphere in its encysted stage anterior to its segmentation into the embryo. The authors propose the syllable *sperm* as the basis of the various terms applied to all those bodies which are the immediate result of impregnation. It is believed that it will be found to supply the basis of a symmetrical system of terminology which will go far to redeem the confusion that at present meets the student at the outset of his researches. For the unfertilised female protoplasmic mass, it is proposed to retain the term *oosphere*, and to establish from it a corresponding series of terms ending in *sphere*. The entire female organ before fertilisation, whether unicellular or multicellular, is designated by a set of terms ending in *gonium*.

In the zygomycetes and zygophyceæ, the conjugated *zygospheres*, or contents of the *zygogonia*, constitute a *zygosperm;* in the oomycetes and oophyceæ the fertilised *oosphere*, or contents of the *oogonium*, is an *oosperm;* in the carpophyceæ the fertilised *carposphere*, or contents of the *carpogonium*, constitutes a *carposperm*. In this last class the process is complicated, being effected by means of a special female organ which may be called the *trichogonium* (in preference to "trichogyne"). The ultimate result of impregnation is the production of a mass of tissue known as the *cystocarp* (or "sporocarp"), within which are produced the germinating bodies which must be designated *carpospores*, since they are not the direct results of fertilisation. In the carpomycetes no similar process is at present known. Any one of these bodies which remains in a dormant condition for a time before germinating is a *hypnosperm*. In the cormophytes (characeæ, muscineæ, and vascular cryptogams) the fertilised *archesphere*, or contents of the *archegonium*, is an *archesperm*.

In the basidiomycetes, ascomycetes, and some other classes, it is proposed to substitute the term *fructification* for "receptacle," for the entire non-sexual generation which bears the spores.

In the discussion which followed, Prof. Rolleston and Prof. I. B. Balfour took part, the latter objecting to the proposed alterations in classification and terminology in several points. He believes all the schizomycetes to be degraded ascomycetes, and prefers Sachs' classification of the vascular cryptogams. He also objected to the use of the term "sperm" in the sense proposed.

Further Remarks on the Mollusca of the Mediterranean, by J. Gwyn Jeffreys, LL.D., F.R.S.—At the Bradford Meeting of the Association in 1873 I made some remarks on the Mollusca of the Mediterranean, and gave a list of those species which had not yet been noticed as Atlantic, being then 222 in number. Since that time many of the species have been discovered in the Atlantic, or been ascertained to be varieties of other well-known Atlantic species. This list will be found in pages 113 to 115 of the Report. I will now give a list of those Mediterranean species which are also Atlantic, or varieties of other species, on the authority of the Marquis de Monterosato, the Marquis de Folin, Dr. Fischer, the Rev. Mr. Watson, and myself.

BRACHIOPODA.—*Argiope cordata*, Risso; *Thecidium mediterraneum*, Risso. CONCHIFERA.—*Pleuronectia lævis*, Jeffreys, a monstrosity of *Pecten similis; Mytilus minimus*, Poli; *Nucula convexa*, J. = *L. ægensis*, Forbes, young; *Leda oblonga*, J. = *L. micrometrica*, Seguenza; *L. subrotundâ*, J. = *L. minima*, Seg.; *Solenella cuneata*, J. (*Malletia*); *Venus cygnus*, Lamarck = *V. nux*, Gmelin; *Pecchiolia insculpta*, J. (*Verticordia*). GASTROPODA.—*Emarginula adriatica*, O. G. Costa; *Trochus scabrosus*, J. = *T. gemmulatus*, Philippi; *Fossarus costatus*, Brocchi; *Rissoa caribæa*, D'Orbigny; *R. rudis*, Ph.; *R. maderensis*, J.; *Cæcum chiereghinianum*, Brusina = *C. glabrum*, Montagu, variety; *Vermetus triquetra*, Bivona; *Scalaria cantrainei*, Weinkauff; *Odostomia polita*, Biv.; *O. tricincta*, J.; *O. fasciata*, Forb.; *Eulima microstoma*, Brus.; *E. jeffreysiana*, Brus.; *Natica dillwynii*, Payraudeau; *N. marmorata*, H. Adams; *Solarium pseudoperspectivum*, Brc.; *Xenophora mediterranea*, Tiberi; *Cerithium costatum*, Da Costa; *C. elegans*, De Blainville; *Triton seguenzæ*, Aradas and Benoit = *T. nodifer*, Lam., var.; *Lachesis folineæ* (*Delle Chiaje*) Ph.; *Cassidaria echinophora*, Linné; probably *C. tyrrhena*, Chemnitz, is a variety; *Defrancia hystrix*, De Cristofori and Jan.; *Pleurotoma pusilla*, Scacchi = *P. multilineolata*, Deshayes, var.; *Cypræa physis*, Brc.? *Utriculus striatulus*, J.; *Akera fragilis*, J.; *Diphyllidia lineata*, Otto; *D. pustulosa*, Sc. Total 41 species.

This reduces the number of supposed exclusively Mediterranean species from 222 to 181; and it must be borne in mind that the Atlantic Nudibranchs and Cephalopods have never been completely worked out. Philippi's list of Mediterranean Nudibranchs and Verany's list of Mediterranean Cephalopods amount to 58 out of the above residue of 181. When further researches by dredging have been made in the North Atlantic, I believe the difference between the Mollusca in that extensive ocean and in the Mediterranean will be still more diminished, if it do not in time altogether disappear.

THE MEETING OF THE IRON AND STEEL INSTITUTE AT DÜSSELDORF

THE recent meeting of the Iron and Steel Institute at Düsseldorf was peculiarly interesting, as illustrating the international character of the Society, and also because of the opportunity which it afforded to English members of studying German workshops and methods of manufacture. The papers which were read were mostly by German authors, and dealt with many subjects of importance to those interested in the manufacture of iron and steel. Many of them were of too technical a character to be noticed at length in these pages, but as an exception we may mention the paper on "The Dephosphorisation of Iron in the Converter," by Herr J. Massenez of Hoerde in Westphalia.

This subject has received great attention at the recent meetings of the Institute, but not more so than its importance deserves. We referred at length to the basic process of dephosphorising pig iron, when reviewing the proceedings at the spring meeting, and the paper now before us contains a most satisfactory record of results since attained, together with much valuable information as to the chemical changes which take place during the conversion. The method is best known by the names of the

inventors, Messrs. Thomas and Gilchrist, and its great importance lies in the fact that it enables Bessemer steel and a very pure homogeneous iron to be produced from the poor class of phosphoric iron ore which abounds in the Cleveland district and also in the basin of the Saar, and in Lorraine and Luxembourg, which ores have not hitherto been available for the production of steel, on account of the difficulty of eliminating the phosphorus, the presence of which element is well known to be highly detrimental to the quality of the steel. To the Germans this invention is possibly of greater value than to ourselves, on account of the prevalence with them of the poorer class of ore, and the comparative scarcity of hematite.

At the present moment five German companies are working the Thomas-Gilchrist process, and in the course of a few months many others will be in a position to follow suit.

Herr Massenez gives in his paper a series of chemical analyses, showing the composition of the metal at different stages during the blow. The information contained in these tables is also exhibited graphically by diagrams, in which the quantities of the various elements at the different stages are represented by the ordinates of curves. These "show that so long as the silicon is in combustion the phosphorus not only is not attacked, it actually increases. First of all, as is well known, the silicon is attacked, and is reduced to a mere trace at the expiration of two minutes. A portion of the carbon burns off at the same time with the silicon; however, only after the silicon is reduced does the carbon curve descend rapidly. The manganese curve is from the commencement to the end of the blow regularly decensional, showing that this body oxidises but slowly. The small quantity of copper disappears after the end of the first minute's blow. Surprising is the fact that the sulphur-curve slowly rises till the commencement of the after-blow, and then only decreases partially, or very slowly, at the latter end of the same. The phosphorus is energetically consumed in large quantities *after* decarbonisation has taken place, and its combustion is the cause of the high temperature at the end of the process. At the commencement of the blow, and during the time the silicon is oxidising, the phosphorus increases in the metal in the proportion as caused by the lessening of the volume of pig iron through the combustion of silicon, manganese, and carbon. After the reduction of the silicon, and during the period the carbon is reduced from 2·72 per cent. to 0·16 per cent., only a fraction of the carbon disappears (from 1·32 per cent. to 1·18 per cent.); afterwards the very rapid combustion of this body takes place, leaving only a trace of the same, a reaction which characterises the whole process."

It is satisfactory to learn from this paper that the chemistry of the process is now thoroughly understood, and that the only difficulties which remain to be overcome are of a purely mechanical nature, and are principally due to the shortness of life of the converter bottoms. The discussion which followed was fully equal in interest to the paper itself, and was taken part in by most of the leading members of the Institute. It bore principally upon the commercial side of the invention, which has hitherto been its weak point. We learn, however, that well-founded hopes are entertained that this last difficulty in the way of a general introduction of the process is in a fair way of being removed.

In our last review of the proceedings of this Institute we noticed a paper by Prof. Akerman, on "The Hardening of Iron and Steel." This paper, which was taken as read at the spring meeting, was discussed at Düsseldorf. Most of the opinions expressed were necessarily of a rather speculative character, for very little is really known as to the *rationale* of hardening and tempering. Many eminent authorities seemed, however, to be agreed that carbon exists in iron and steel in three separate forms, and not in two only, as has hitherto been supposed, and that the hardening is due only to one of these forms. A point of great practical importance was referred to by Mr. Adamson, viz., the prevalent practice of endeavouring to strengthen steel by tempering in oil. This practice was strongly condemned by Mr. Adamson. He maintains that the dipping in oil, though it may increase the tensile strength of the metal, impairs its elasticity and ductility. We commend this opinion to the attention of the authorities at Woolwich Arsenal. It is well known that the steel barrels of all our guns are tempered by immersion in oil, and if Mr. Adamson's statements be correct, it is not to be wondered at that so many disappointing failures have taken place.

The last paper to which we shall refer dealt with the subject of iron permanent way. It contained an account of the experience obtained on the German state railways of the use of iron instead of timber for sleepers. There are few subjects of greater importance to ironmasters than this substitution of iron for woodwork in the permanent ways of railways, for the amount of metal which would thus be consumed is almost incalculable. The paper, which was read by Privy-Councillor Grüthefein, embodies much valuable information as to the different systems of iron permanent way at present in use. From it we learn that there are at the present moment 1,542 kilometres of line in Germany laid with the new description of sleeper, and that the results obtained are so satisfactory that the system is being continually extended. It is interesting to notice that in Germany the new sleepers are mostly laid on the longitudinal plan, a system which has not given satisfaction in this country. In the discussion which followed, the opinion was strongly stated by English engineers that longitudinal sleepers would be absolutely incapable of withstanding the effects of the very heavy and fast traffic of the main lines in this country.

In conclusion we must congratulate the Iron and Steel Institute on the extended sphere of usefulness and the cosmopolitan character which it has gained by going out of the beaten track, and holding an autumn meeting on the Continent.

ANNUAL CONGRESS OF THE GERMAN ANTHROPOLOGICAL SOCIETY

THE Eleventh General Meeting of the German Anthropological Society was held at Berlin during the past month, Prof. Virchow taking the chair and acting as president at each of the six sittings. At the opening sitting, after speeches by Herr von Gossler and the President, in which they reviewed the past and the present condition of the Society, and notably drew attention to its aims and its achievements, Herr Friedel gave a short exposition of his paper "On Prehistoric Discoveries made in Berlin and its Neighbourhood." This was followed by an interesting address from Dr. Schliemann respecting the site of Troy. He re-stated his now well-known convictions, and gave considerable evidence in support of the belief that Homer's Troy was not merely a mythical town, but that it had once actually filled a place in the world's history. "I wish," said the Doctor, "I wish that I were able to prove Homer to have been an eye-witness of the Trojan war. But unfortunately this is impossible. In his day swords were in general use as a weapon, and iron well known as a metal; in Troy, again, swords were unheard of, while of iron the inhabitants knew nothing whatever. So, too, the manners, the customs and the general civilisation which he describes are of an epoch that is centuries later than the one to which the results of my excavations belong. Homer presents to us the legend of Ilium's tragic fate in the form which it had been handed down to him by the bards who had gone before; and, as we have already seen, he invests the traditional account of the war and of the fall of Troy with the colouring of the time in which he lived. Yet he was not without personal knowledge of the actual localities, for his descriptions (both the general one of Troy itself, as also of the plains of Troy in particular) are, if taken as a whole, quite accurate and truthful." At the close of his address, Dr. Schliemann announced his intention of commencing a series of excavations on the site of Orchomenos in Bœotia, the prehistoric capital of the Minyans, on his return to Athens, the Greek Government having accorded him full permission to do this.

At the second sitting, on August 6, after a short address by the President, Prof. Ranke spoke at some length upon the subject of German ethnology and anthropology, pointing out the distinct advance that these sciences had made, and citing, as helps to study, the several important works which had appeared in the country by Lindenschmit, Arnold, Bracht, Poppe, Genthe, v. Sadowski, and other distinguished anthropologists. He specially called attention to the progress that had been made in the science of craniology, it being now nearly always possible to distinguish between a male and a female skull. Prof. Virchow then briefly put forward the proposition that the next (the twelfth) session of the Society should be held at Ratisbon, a town which, for many reasons, he thought was well fitted to serve such purpose. This proposal was carried unanimously; and after an address by Herr Friedel the meeting was adjourned.

Herr Handelmann, at the third sitting, read a valuable paper upon the prehistoric fortresses and earthworks of which traces remain in the Schleswig-Holstein district. This was followed by an address from Dr. Koehl respecting the excavations and prehistoric discoveries that had been made at Meckenheim, near Bonn. Dr. Mehlis, Herr von Jazdzewski, and others also addressed the meeting.

On the following day, August 9, Dr. Kollmann laid before the Society numerous important statistics with reference to the ethnology of Switzerland, and in connection with the division of blond and brunette types, showing where such division may be found to occur. Dr. Tischler's paper upon recent prehistoric discoveries made at Dolkeim, in East Prussia, was also listened to with very great interest.

At the fifth sitting, Herr Fraas, speaking on behalf of the Cartographical Commission, proceeded to show in how far this institution had been of service to the cause of anthropology; he also dwelt upon the need for drawing up accurate maps of the different districts and localities in which prehistoric discoveries had been or would be made.

Pfarrer Dahlem of Ratisbon afterwards addressed the assembly, his subject being, Ratisbon in its relation to archæology past and present. Speaking of the antiquity of the town, he rejected as fabulous the belief of chroniclers that it had been built before the foundation of Rome, or even of Troy, although its early existence is proved by two old Roman finds, the one a military diploma of the time of Marcus Aurelius, dating from A.D. 166, and the other a large block of stone three metres in length and one metre in height, being a fragment of the *porta principalis* of the city. The inscription on this latter clearly sets forth that Marcus Aurelius and his son Commodus had erected the *vallum cum portis et turribus*. As this inscription, from the titles given to the Emperor, was engraved upon the gate either immediately before or closely following the death of Marcus Aurelius, it is indisputable that in the years preceding that time, between about A.D. 170 and 180, the town was built by one of the three legions that the Roman Emperor had recruited from Italy in order to quell an invasion in that part of Germany now termed Bavaria. That this was the probable date may be inferred from the belief that the inscription would surely not have been added until the whole were completed. The lecturer clearly showed that Ratisbon was a town of very great historic interest; the choice of it as a meeting-ground for the next annual conference of the German Anthropological Society is thus in every way a most desirable one.

At the sixth sitting, Prof. Bastian, who was warmly welcomed by his colleagues upon his return from a two years' period of travel, delivered a very eloquent address, in which he pointed out the many difficulties in connection with the study of ethnology and anthropology, and warned his hearers against drawing *à priori* conclusions in dealing with a science that needed such minute and careful research, where the field was so vast, so limitless a one, and where no clue, however slight, could ever afford to be lightly set aside. "We are occupied to-day," said he, in conclusion, "with a science that as yet is in its cradle, one over which the shadow of many centuries must sweep ere it can reach manhood, but which will then clearly and completely set forth that which has been termed 'the knowledge of man about man,' a science which, though it does not solve the deepest problems of our existence, will yet throw a partial light upon them. And in its construction we are merely builders and masons, content if we may but do our humble part towards this one object, the completion of so great and wonderful a work."

After speeches by Dr. Henning, Dr. Montelius, and others, Prof. Undset of Christiania gave an interesting account of the recently-discovered Viking ship that has been excavated from a large burying-mound at Sandefjörd, in the vicinity of Christiania. The mound in question has always been termed "The King's Mound" (*Königshügel*), and until last winter no excavations had ever been attempted there. Under the superintendence of Prof. Nicolaysen, however, operations were then commenced, which resulted in a most interesting and extraordinary discovery. Beneath the hill was found a large ship, seventy-five feet in length, sixteen feet in breadth, and about seven or eight feet in depth. In it a kind of vault had been built, wherein were deposited the remains of some valiant sea-king who, may be, had won his people's love and reverence. The ship had been buried fully rigged, with masts, cordage, sails and rudder all complete, the entire timbers being in a wonderful state of preservation, owing to the fortunate circumstance that the mound had been constructed of a moist clay. In all its details the vessel appears to have been most beautifully finished, and there is no lack of ornamentation. In the hold, together with the human remains, were found the bones of several horses and dogs that had evidently been buried with their master. Prof. Undset considered that the burial must have taken place some time during the tenth century. The ship was conveyed to Christiania, where it was at once placed in the University Museum for Prehistoric Antiquities in that city. Several photographs have been taken of it, and the results of further investigation and research respecting it will shortly be published in a longer and more detailed form.

Herr Ranke then delivered an address upon the prehistoric discoveries that had been made in the caves of Upper Franconia; and Prof. Schaaffhausen of Bonn also spoke with reference to important researches made in the caves at Gerolstein, at Letmathe, and Eiserfey. The interest of this sitting—the final one—centred in the speech of Herr Brugsch Bey, the distinguished Egyptologist, who, in the course of it, pointed to Egypt as a rich and valuable field for prehistoric research.

OUR ASTRONOMICAL COLUMN

SOUTHERN VARIABLE STARS.—In the *Uranometria Argentina* amongst the large number of stars indicated as variable, we find twelve to which Dr. Gould has applied the letters of Argelander's nomenclature, their fluctuations having been determined with greater certainty than some others. The following is a list of these objects arranged in order of right ascension:—

No.	Name.	R.A. 1875. h.	m.	s.	N.P.D. 1875. °	′	Limits of Variation.
1	R Sculptoris	1	21	13	123	11·5	5·8–7·7
2	R Eridani	4	49	42	106	37 2	5·4–6·0
3	S Eridani	4	54	7	102	43·4	4¾–5¾
4	R Puppis	7	36	2	121	22·3	6½–7½
5	R Carinæ	9	29	6	152	14·2	4¾–10
6	R Velorum	10	1	27	141	34·8	6½–7¼
7	R Antliæ	10	4	22	127	7·1	6¼–8
8	S Carinæ	10	5	23	150	56·3	6¼–9
9	T Carinæ	10	50	18	149	51·2	6¼–6¾
10	R Muscæ	12	34	28	158	43·3	6·6–7·4
11	R Centauri	14	7	35	149	19·8	6–10
12	R Triang. Aust.	15	8	37	156	2·1	6·6–7·5

1. Gould describes this as "one of the most brilliantly coloured stars in the heavens"—an intense scarlet, which remains unchanged through all the stages of its light. Maxima occurred early in December, 1872, and in January, 1874. Period about 207 days with symmetric light-curve.

2. Variation independently shown by the estimates of three observers, to the extent of more than half a magnitude; red.

3. 64 Eridani—"certainly variable;" Bessel calls it 8m. in his zones, which Gould conjectures may be owing to clouds, or ? a misprint.

4. Though appearing to the naked eye and even with the opera glass as a single star is in fact a cluster of faint stars = 3094 of Herschel's Cape Catalogue. There is only one star in it brighter than 8¼, and Gould assumes that the variations of brilliancy are due to this star alone. The object is Lacaille 2916.

5. Lacaille 3932, noted by him 7m. on March 3, 1752. The intervals between the maxima determined at Cordoba, are respectively 329, 306, and 323 days; the minimum appears to take place considerably more than half a period later than the maximum; red in all stages even while at the tenth magnitude. No epoch of maximum is given.

6. R Velorum. The variable character is beyond question. It is Lacaille 4156.

7. R Antliæ. Estimated near the brighter limit March 19, 1871, and in May, 1872; near the fainter one April 28, 1873, and June 14, 1874.

8. S Carinæ. A reddish star, Lacaille 4189. On May 21, 1874, it was 6·3, and in May, 1877, 8¾, but sufficient observations have not yet been made to determine the law of variation.

9. T Carinæ. Period not yet ascertained. Lacaille 4530.

10. R. Muscæ. Varies through nearly a magnitude in not far from 21h. 20m., the minima preceding the maxima by nine hours; its period is therefore the shortest yet detected amongst the variables, and it becomes an object of unusual interest. At midnight on September 25, 1872, the star was estimated equal

to Lacaille 5079, corresponding to a maximum, and at the same hour on September 30 it was inferior to *i* Muscæ, or very near a minimum. It is Lacaille 5236.

11. R Centauri. The light-curve appears to be irregular; a maximum of 6·1m. occurred about June 28, 1878, and one about August 3 in the preceding year; there would appear to be secondary maxima and minima. A period of 525 days with principal maximum April 18, 1871, and two intermediate maxima following the principal one by 197 and 378 days respectively, reconciles most of the observations, but is incompatible with estimates of 6m. made on June 25 and 26, 1874, with the meridian circle.

12. R Trianguli Australis. Varies between 6·6 and about 8·0 in 3d. 9h. 35m., the minima preceding the maxima by about 48 hours. Well-marked maxima occurred 1871, July 14, at 14h., and September 13 about midnight. Minima were observed 1871, July 12, at 14½h., and September 1 at 8½h. Good determinations were made in 1877, but are not printed in the *Uranometria*; the period 3d. 9h. 35m. is however deduced from a comparison of the observations in 1871 and 1877.

To these stars may be added S Puppis of Lacaille, which designation falls in with Argelander's (R.A. 7h. 43m. 6s., N.P.D. 137° 48'·3); it appears to fall nearly to the ninth magnitude, and to rise to about 7¼, but has never been seen at Cordoba sufficiently bright to be admissible in Gould's Catalogue. It is Lacaille 2999.

Also Lacaille 2691 (L_2 Puppis), a red star varying from 3·6 to 6·3; Gould infers a period of about 135 days, with a variation rapid at the maximum and comparatively slow near the minimum, which apparently occurs about six days nearer to the preceding than the following maximum. Remarkably red near the minimum.

Ceraski's New Variable Star.—Prof. Julius Schmidt, favoured by the fine sky of Athens, has already determined approximately the period of this star, which appears to be 4d. 23h. 35m.; he does not think it probable that this interval can be a multiple of a period. The star is in the same category as Algol, δ Libræ, V Coronæ, λ Tauri, and S Cancri, and is without colour. It may be well to note that for some time to come or until the latter part of December the minima will occur during daylight in this country; one of the first observable may be expected on December 24 about 17h. Greenwich time. The position of the star in the *Durchmusterung* is in R.A. 0h. 49m. 39s., Decl. + 81° 5'·6.

A New Comet.—The discovery of a faint comet by Mr. Lewis Swift is telegraphed from Washington; position August 11, apparently in about R.A. 172°, N.P.D. 22°.

GEOGRAPHICAL NOTES

Dr. Matteucci sends home some interesting details of the observations made by him in Kordofan during the march of the expedition under Prince Borghese. In Kordofan, he says, water is as dear as the wine of Barletta. In the rainy season however things are different; from June to September almost every inch of the country is covered with water, when, if one may not die of thirst, there is a chance of his dying of malaria. Vegetation along the line of march of the expedition was as melancholy and infertile as it could well be; stunted skeleton acacias alternating with a few euphorbias in constant monotony; neither mountains nor hills, and not even plains. In Kordofan the ground presents continuous undulations, no doubt in consequence of the geological formation of the soil, which is a bottom of sand slightly mixed with peroxide of iron. The water of the rainy season is husbanded in wells, but so valuable is it that the expedition had often to force the natives to give them access to these wells. Kordofan is about 600 metres above the level of the sea, and 380 above that of the Nile. Not a river, not a torrent, not a brook waters this immense territory, which is about 500 miles long and a little less broad. The mean temperature is not less than 92°. At the surface the ground is so sandy that animals on the march sink to a depth of 30 centimetres. The rains are irregular and never abundant. Some years ago there were no wells in Kordofan; the want of water was not felt, for the natives, in the rainy season, collected the water in large reservoirs, and a sufficient quantity was found in them at each station and village. But the seasons, even in Africa, tend to change. Eight years ago there was no rainy season in Kordofan, and for several months the people feared they would all die of thirst. Then they thought of digging wells, which gave very good results. Everywhere water was found at a depth of 20 inches. But things have sadly changed during the past eight years, and now, instead of finding water at a depth of 20 inches, it is often not found at a depth of 160 feet. In all the wells Dr. Matteucci found the following succession of strata:—From 50 to 30 metres of depth, sand with traces of sulphate of lime; above 30 extends the granite, with a great abundance of quartz in proportion to feldspath and mica. The granitic mass rarely exceeds one metre in thickness, and above is again found the sand.

By letters from Senegal published in the French papers we learn that the survey of the country between the Senegal and the Niger is in progress. Three different topographical parties have been formed to determine the position of the intended ports and the route of railway intended to connect the two streams. The work must be quite finished by the month of May, 1881.

Recent letters from Ladakh, according to the Indian papers, state that some Yarkand traders have arrived there, having accomplished the journey from Yarkand to Leh, a distance of 515 miles, in thirty-two days. These men report that they met Mr. Ney Elias, the well-known traveller, on the ascent of the Sasser Mountain. The Sasser Pass, which lies at an elevation of 17,500 feet, is nine stages distant from Leh, on the summer route to Yarkand, by way of the Karakoram. The traders also report that the road beyond the Sasser Pass was in good condition and free from snow early in May. They state that the Chinese are quietly established in Yarkand and Kashgar.

M. De La Motte has published as a quarto pamphlet the address which he delivered before the French Geographical Society on July 16, respecting his studies in the basins of the Niles. He has devoted several years to the subject, and has had a special map constructed to illustrate his researches on a scale of 1 : 1,200,000.

Messrs. Cassell, Petter, and Galpin will publish at the end of September the first monthly part of Prof. Ebers' "Egypt: Descriptive, Historical, and Picturesque;" translated by Clara Bell, with notes by Dr. Birch, of the British Museum. The work will be profusely illustrated, and will occupy about three years in publication.

SCIENTIFIC SERIALS

The *Journal of Anatomy and Physiology, Normal and Pathological*, vol. xiv., part 4, July.—Dr. H. S. Wilson, on the rete mirabile of the narwhal (two plates).—W. J. Walsham, observations on the coronary veins of the stomach (a plate).—Note on the same, by Prof. Turner.—F. W. Bennett, a communication between the air-bladder and the cloaca in the herring.—Prof. M. Watson, the curvatores coccygis muscles of man.—Dr. G. A. Gibson, valvular hæmatoma (plate).—R. Maguire, a contribution to the pathology of macroglossia and hygroma (plate).—Dr. J. Dreschfeld, the changes in the spinal cord after amputation of limbs (plate).—Dr. B. C. Waller, the morbid anatomy of certain forms of post-scarlatina nephritis in relation to their bearing on the histogeny of granular kidney (plate).—Dr. J. G. Naismyth, the antagonism of opium and belladonna illustrated by a case of attempted suicide.—Dr. R. J. Anderson, on an astragalo-scaphoid bone in man.—Dr. Foulis, the mode of healing in wounds under antiseptic dressings.—Prof. M'Kendrick, the respiratory movements of fishes (plate).—G. B. Hones, some points in the anatomy of the porpoise (plate).—Prof. Turner on two masks and a skull from islands near New Guinea (plate).—Dr. D. Newman, the effect of certain anæsthetics on the pulmonary circulation.—H. Bendall, a new method of preserving the colour of tissues.—J. Macdonald Brown, variations in myology.—Dr. G. A. Gibson, anatomical and physiological notes.

Bulletin de l'Académie Royale des Sciences (de Belgique), No. 6.—On the application of the second principle of thermodynamics to the variations of potential energy of liquid surfaces, by M. Van der Mensbrugghe.—Structure of the ovary, ovulation, fecundation, and the first phases of development in Cheiroptera, by MM. Van Beneden and Julin.—An original Ctenides of Brazil found at Liége, by M. Van Beneden.—Account of a case of cestodic tuberculosis, with some observations on the eggs of *Tænia mediocanellata*, by the same.—Difference of appreciations of the apparent size of microscopic objects by different observers, by M. Montigny.

Brain, a Journal of Neurology for July, 1880, contains: Original articles, by Prof. J. C. Dalton, on the form and topographical relations of the *corpus striatum*.—R. P. Oglesby, on nystagmus (gives some very interesting facts relative to symptomatic nystagmus).—Dr. A. Waller, on muscular spasms, known as "tendon reflex."—Dr. J. Hughlings-Jackson, on right- or left-sided spasm at the onset of epileptic paroxysms, &c.—Dr. W. Ireland, on left-handedness.—With critical digests and notices of books, clinical cases, and several abstracts of British and foreign journals; among these latter a note by Allen Thomson on Prof. Carlo Giacomini's method of preserving the brain by chloride of zinc, alcohol and glycerine, which he thinks most valuable.

Rivista Scientifico-Industriale, No. 11, June 15.—Concentrated sulphuric acid is volatile at ordinary temperatures, by Prof. Marangoni.

No. 12, June 30.—On a new apparatus for collecting rain and atmospheric dust, by Prof. Sylvestri.—On the development of the *Forficula auricularia*, Linn., by Prof. Camerano.—Some experiments on the discharge in rarefied gas, by Prof. Righi.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, August 23.—M. Wurtz in the chair.—The following papers were read:—Meridian observations of small planets at the Greenwich and Paris observatories during the second quarter of 1880, communicated by M. Mouchez.—Distinctive character of the pulsation of the heart, according as the right or left ventricle is examined, by M. Marey. During a stoppage in respiration the right heart shows a diminution in amplitude of pulsations, owing to pulmonary resistance, while the left heart shows a slight increase. If through any influence lowering the arterial tension (such as muscular exercise, inhalation of nitrite of amyl, &c.), waves be produced in the aorta, these waves cause in the tracing of pressure of the left ventricle a bifurcation or trifurcation of the summit (according as two or three have occurred during systole). The right ventricle does not show these waves, unless in vestige, and by propagation from the neighbouring part.—Remarkable example of vertically-ascending lightning, by M. Trécul. This was during a storm on Aug. 19. The sparks appeared to come from some lightning conductors in the place. Some rose singly and disappeared at a small height, expanding into a magnificent, nearly circular flash, the light of which diminished from centre to circumference. In one case two luminous columns rose simultaneously and parallel, and at a certain height precipitated themselves against each other at a right angle.—The death of M. Godron, correspondent in botany, was announced.—The sun would act inductively on the earth even if its magnetic power were simply equal to that of our globe. Induction of the moon by the earth and diurnal lunar variation of terrestrial needles, by M. Quet. The induction of the earth by the sun could be insensible only if the magnetic power of the latter were much below that of the former, which is not probable. The induction of the moon due to its revolution round the earth produces an electromotive force twenty-one times less than that the effects of which are rendered sensible by an experiment made on the earth, and consequently is itself sensible. As the induction of the satellite by rotation of the earth is about twenty-seven times greater than the foregoing, the resultant will be a sensible force with sensible reaction on particular earth-currents, leading to a daily variation of needles according to lunar hours.—On the variations of the coefficient of dilatation of glass, by M. Crafts.—On tungstoboric acid, by M. Klein.—On the products of distillation of colophony, by M. Renard.—On the project of establishment of a station for hospitable purposes at the sources of the Ogöoue, by the French Committee of the African Association, by M. Mizon.

August 30.—M. Wurtz in the chair.—The following papers were read:—On *Vitis berlandieri*, a new species of American vine, by M. Planchon.—M. de Lesseps reported the proceedings at the inauguration of the statue to Denis Papin at Blois, on August 29 (when he represented the Academy).—On the dilatation and compressibility of gases under strong pressures, by M. Amagat. He gives a series of laws to which his researches have led.—Observations of a solar protuberance on August 30, 1880, by M. Thollon. A thin, very brilliant jet was observed (about 11 a.m.) to rise near the equator, and nearly at right angles to the sun's limb; its velocity was estimated at 35 km. per second, and its height 343,000 km. It rapidly attained prodigious dimensions, while its brightness diminished, especially near the base. About 1 p.m. it was hardly visible. Curiously, while the lower and middle part of the protuberance gave a deflection of the line C towards the violet, the summit presented a nearly equal deflection towards the red.—On the amylamines of inactive amylic alcohol, by Mr. Plimpton.—The star-fishes of the deep regions of the Gulf of Mexico, by M. Perrier. This is a study of star-fishes dredged by Mr. Alexander Agassiz on board the *Blake* in two consecutive years.—Influence of alkaline or acid media on Cephalopoda, by M. Yung. M. Richet's law regarding crayfish (that acid or basic liquids are not toxical in direct ratio of their acidity or basisity); M. Yung verifies for Cephalopoda. The latter are extremely sensitive to mineral acids. With 0·5 cc. sulphuric, nitric, hydrochloric, or oxalic acid in a vessel holding two litres of water, the respirations of four *Eledone moschata* were raised from twenty-four to numbers varying from thirty to fifty-six per minute. Double the quantity of acid was fatal, except in the case of oxalic acid. Of the other three sulphuric acid is least poisonous. Of the much less powerful organic acids, tannic acid acts most rapidly. The alkalies act in the order given by M. Richet. The action of ammonia is extremely rapid.—Influence of coloured lights on the development of animals, by M. Yung. He confirms for marine animals (at the Naples station) the results he formerly obtained with fresh-water animals. The development of eggs of *Loligo vulgaris* and *Sepia officinalis* is stimulated by violet and blue light, retarded by red and green. Yellow light in this respect comes nearest to white. Contrary to former results, the development, though retarded, is well accomplished in red and green vessels.—On the vaso-dilator nerves of the sides of the mouth, by MM. Dastre and Morat.—On a particular mode of asphyxia in poisoning by strychnine, by M. Richet. The asphyxia first relieved by artificial respiration, is due to two causes, viz. contraction of the tetanised respiratory muscles, and exhaustion of the nervous centres of respiration. But there is another asphyxia resulting from the enormous interstitial combustion in the tetanised muscles, shown by the dark hue of the blood. Hence the necessity of practising artificial respiration very energetically so long as there is convulsive tetanus, so as to replace the oxygen that has disappeared. Substances preventing tetanus (such as chloroform, alcohol, or curare) should also be introduced.—On the intensity of some phenomena of atmospheric electricity observed in the north of the Sahara, by M. Amat. Without insulating himself he could, by passing a pocket-comb through his hair or beard, produce sparks 0·05m. to 0·07m. in length. This was best in the evening after a long ride on the arid plains, in hot, dry weather. Horses present even more striking electrical phenomena in their tails, &c. The electricity liberated by the tails is positive. Man in direct communication with the ground does not show much accumulation of the electric fluid, and friction is necessary to develop it. The fluid accumulates much more on the horse, the horn of the hoofs acting as insulators.

THE TOOTHED BIRDS OF KANSAS

Odontornithes: a Monograph of the Extinct Toothed Birds of North America. By Prof. O. C. Marsh, Yale College. Vol. I. of Memoirs of the Peabody Museum of Yale College, New Haven, Conn., and Vol. VII. of the Geological Exploration of the 40th Parallel.

WEST from the valley of the Mississippi the stratified formations which underlie the prairie region spread over thousands of square miles nearly as horizontal as when they were deposited. Here and there they have been ridged up into anticlines, now deeply trenched by denuding agents, or have had wedges of the ancient Archæan rocks thrust through them, along the flanks of which their upturned beds can be examined in detail. Hence in spite of their prevalent flatness opportunities are afforded for tracing their stratigraphical succession from top to bottom. They reach a maximum of thickness of some seven or eight miles. Yet throughout this vast depth of strata the unconformabilities seem to be nearly all of local and unimportant character. The several geological systems follow each other continuously, and generally in such a sequence of insensible gradation as to show that geological history in that part of the globe was marked by comparatively few great and destructive geographical revolutions. The record of this history remains in an almost unbroken series of strata from the Primordial zones up into the older Tertiary formations.

Here surely if anywhere in the world there should be a tolerably ample chronicle of the sequence of living creatures, so far at least as regards marine forms. If the intermediate types, so much desired by the evolutionist, are ever to be found imbedded in the rocks of the earth's crust, surely here we may expect to find them. An area of continuous tranquil deposit, and of slow subsidence, unaffected for almost the whole of geological time by serious upheaval, metamorphism, or unconformability, containing within itself a well-nigh unbroken record of geological changes—a very promised land for the palæontologist! Hardly more than a dozen years have passed since this great region began to be systematically searched for organic remains. Yet during that brief period what treasures have come from its teeming strata! New orders of Vertebrates, some of them of extraordinary types, have thence been added to the long roll of organic forms. Other orders, scantily developed in Europe, and previously but little known, have been ascertained to have teemed in these far western plains. Whether we regard the prodigious number of individual specimens, and the great variety of genera and species, or the marvellously perfect state of preservation in which the remains occur, there is no other known area where facilities for palæontological research of the most minute and thorough kind exist so abundantly.

Thanks to the labours, first of the universally-honoured Joseph Leidy, and then of his younger successors, Marsh and Cope, the firstfruits of that rich palæontological harvest have already been gathered In the Yale College Museum alone about 1,000 new species of extinct Vertebrates have been received from the West during the past twelve years, at least one-half of which remain to be investigated. Mr. Cope's museum at Philadelphia is likewise crowded with new forms. If such results have been achieved merely by expeditions equipped for at most but a few months of such labour as is possible at present in these wilds, what may not be looked for when some of the habitable portions of the fossiliferous regions come to be searched, when quarries, railway cuttings, and other artificial openings add to the opportunities of exploring the rocks, and when systematic fossil-hunting can be carried on from a near centre of supplies, instead of from a base several thousand miles away in the Eastern States!

Among the organic wonders of which from time to time during the past decade announcements have appeared, none have been received with more interest than the discovery of birds with teeth, made by Prof. Marsh near the end of the year 1870, in the middle Cretaceous rocks, which in Kansas and Colorado spread out eastward from the base of the Rocky Mountains. The more striking features of this remarkable transitional ornithic type were described by Mr. Marsh as far back as 1872, and are now tolerably familiar to naturalists from his writings, and to geologists from the descriptions and restorations which have appeared in scientific journals and text-books. But its detailed structure has only now been made known in the splendid monograph on Odontornithes which has just appeared. This work is intended to form volume vii. of the Geological Exploration of the 40th Parallel, carried out by Mr. Clarence King for the Engineer Department, and also to stand as the first of a series of memoirs of the Peabody Museum of Yale College. As a fitting termination to the noble Survey series of quartos, and as a splendid forerunner for what we hope will prove a long and illustrious series of memoirs from Yale, the volume is doubly welcome. The splendour of paper, printing, drawing, and engraving (and in the advanced copy with which we have been favoured, the sumptuousness of binding) that have been lavished on the work bespeak preliminary acknowledgment.

So perfect a matrix do the peculiar buff, chalky, or marly beds of the Kansas middle Cretaceous formations furnish for the preservation of organic remains, that almost every bone of the skeletons of some of the birds has been recovered. The materials for the study of their osteology is thus almost as ample as that for any living bird. Full advantage of this abundant store of material has been taken. The cases and cellars in the Peabody Museum at New Haven contain the remains of about fifty different individuals of a single bird. Every bone of its skeleton, with the exception of one or two terminal toe-bones and the extreme point of the tail, has been recovered, and is here carefully drawn of the natural size. Never before has it been possible, we believe, to reconstruct so perfectly so ancient an organism.

The volume is divided into two parts. In the first of these the detailed structure is given of the bird on which the author has bestowed the name of *Hesperornis*. The skeleton of this animal if extended to its full length would measure about six feet from the point of the bill to the end of the tail. It must have been a typical aquatic bird, without any power of flight, but with strongly developed limbs and a long flexible neck, whereby it was doubtless endowed with remarkable powers of diving and swimming,

and of seizing the abundant fishes of the shallow seas in which it lived. Compared with our modern birds, the two features of this ancient form which most forcibly arrest attention are the teeth and the legs. The teeth were covered with smooth enamel, terminating upward in conical pointed crowns and downward in stout fangs, closely resembling those of mosasauroid reptiles. Their mode of growth and replacement have been determined to have taken place in a manner very similar to that in some reptiles, the young tooth forming on the inner side of the fang of the tooth in use, and increasing in size, while a pit for its reception was gradually made by absorption. The old tooth, being progressively undermined, was finally expelled by its successor, the number of teeth thus remaining unchanged. The teeth were implanted in a common alveolar groove, as in *Ichthyosaurus*. In the upper jaw they were confined to the maxillary and entirely absent from the pre-maxillary bone; in the lower jaw they extended from near the anterior extremity of the ramus along the entire upper border of the dentary bone. Mr. Marsh believes that they were held in position by cartilage which permitted some fore and aft movement, but on the decay of which after death the teeth readily became displaced and fell out of the jaw. This is an important fact in its bearing upon the nature of the teeth found on the same slab of Solenhofen limestone with the well-known *Archæopteryx*. These teeth, it will be remembered, were referred by Mr. Evans to the bird itself—a reference fully confirmed by Mr. Marsh, who says that he at once identified the teeth as those of birds and not of fishes, and by the subsequent discovery of other remains of the bird. In *Hesperornis regalis* there appear to have been fourteen functional teeth in the maxillary bone and thirty-three teeth in the corresponding ramus of the lower jaw. The wings are rudimentary or aborted, a remnant of the humerus alone existing. They may have gradually diminished from disuse until, as the power of flight ceased, the legs and feet increased in proportion, and assumed the massive dimensions shown in the specimens, or, as Mr. Marsh suggests, the bird may have been a carnivorous aquatic ostrich, never having possessed the power of flight, but descended from a reptilian ancestry which is strongly recalled by different portions of the skeleton. Among recent birds, the peculiar legs and feet of *Hesperornis* find their nearest analogues in the Grebes of the genus *Podiceps*. They were admirably adapted for propulsion in water, but scarcely served for walking on land. Locomotion must have been entirely performed by the posterior limbs—a peculiarity which distinguishes *Hesperornis* from all other birds recent or fossil. The tail appears to have been composed of twelve vertebræ, unique in their peculiar widely extended transverse processes and depressed horizontal ploughshare bone. Broad and flat, somewhat like that of the beaver, it must have been a powerful instrument in steering the bird through the water.

The second part is devoted to a description of the remains which have been found of birds belonging to a second order of Odontornithes, termed *Odontotormæ*. Unlike *Hesperornis*, they seem to have been all of comparatively small size and to have possessed powerful wings, but very small legs and feet. From that contemporaneous form, and from all other known birds recent and fossil, they are distinguished by certain types of structure which point back to a very lowly ancestry, lower even than the reptile. Their bones, being mostly air-filled, would enable the carcases to float on water until, by decay or the rapacity of other animals, they were separated and dispersed. Hence skeletons of these flying birds are less entire than those of the massive-boned *Hesperornis*. Nevertheless the remains of no fewer than seventy-seven different individuals have been disinterred. These are included in two well-marked genera, *Ichthyornis* and *Apatornis*, and were all small birds, reminding us by their strong wings and delicate legs and feet of the Terns, like which they were probably also aquatic in habit. Besides the reptilian skull and teeth, the birds of this second order were marked by the character of their vertebræ, which in their biconcave structure recall those of fishes. This is the more remarkable, as in *Hesperornis* the vertebræ are like those of modern birds. Yet these two utterly dissimilar types were contemporaries, and their remains have been preserved in the same strata. Mr. Marsh points out that the transition between the two vertebral types may be traced even in the skeleton of *Ichthyornis* itself, where the third cervical vertebra presents a modification in which the ordinary avian saddle-shaped form appears as it were in the act of development from the biconcave ichthyic form.

In a concluding chapter the author briefly touches upon some of the broader biological questions suggested by the structure of the animals described in the volume. The striking differences between the three orders into which Prof. Marsh divides toothed birds—*Archæopteryx*, *Hesperornis*, and *Ichthyornis*—serve to indicate the high antiquity of the class, and to encourage the search for ornithic remains in the earlier Secondary, if not in the later Palæozoic, rocks. The peculiar character of each of the orders Prof. Marsh believes to have been united in some earlier type, of which no trace has yet been found. This ancestral type may have been almost as much a reptile as a bird. The earliest birds were doubtless closely related to the Dinosaurs and Pterodactyles.

Of the plates, thirty-four in number, which accompany and adorn the monograph it is impossible to speak in terms of too great praise. They are strictly and rigidly scientific diagrams, wherein every bone and part of a bone is made to stand out so clearly that it would not be difficult to mould a good model of the skeleton from the plates alone. And yet with this faithfulness to the chief aim of the illustrations there is combined an artistic finish which has made each plate a kind of finished picture. We heartily congratulate the genial Professor of Palæontology at Yale on the advent of this truly imperial volume. May it be the earnest of many more from the rich store of materials which he has so courageously and enthusiastically gathered among the wilds of the far West!

THE THEORY OF DETERMINANTS

A Treatise on the Theory of Determinants and their Applications in Analysis and Geometry. By Robert Forsyth Scott, M.A. (Cambridge: At the University Press.)

THE list of English text-books on the subject of Determinants is comparatively meagre, and this notwithstanding the fact that the first separate treatise of all

on the subject was the work of an Englishman, now the distinguished president of the Royal Society. Dr. Spottiswoode's "Elementary Theorems Relating to Determinants" appeared in 1851 (4to, pp. viii. + 63, London, Longmans), and, as a pioneer work, was eminently successful; at the honouring request of the editor of *Crelle* it was republished, with additions, in that well-known journal three or four years later (vol. li. pp. 209–271, 328–381). After considerable intervals came Dodgson's "Elementary Treatise" (London, Macmillan, 1867) and a pamphlet by Wright; and here, until quite recently, the list ended. The chapters on the subject by Todhunter and others belong to a different category, but deserve to be mentioned, as it is doubtless in part owing to their existence that separate treatises have been so rare.

In view of the dearth referred to, he would be a very captious critic indeed who would not gladly welcome the handsome volume whose title is given at the head of this notice. In form and general outward appearance it resembles Part I. of Thomson and Tait's "Elements of Natural Philosophy," and extends to about 250 pages. The matter is arranged under fourteen chapters, the first seven being meant to deal with determinants in themselves, the last seven with the so-called applications; the line of separation, however, is not very well maintained.

In the introductory chapter we have the usual account of permutations, inversions of order, &c., and the usual definition of a determinant; but this is followed by something less familiar, viz., a page or two of exposition regarding Grassmann's "alternate units" or "polar elements," and by the establishment of the theorem that a determinant is expressible as a product of alternate numbers linear in the elements.[1] The constant use afterwards made of this theorem—if theorem we can call that which is but a symbolical expression of the ordinary definition of a determinant—is the distinguishing feature of Mr. Scott's mode of treating the subject. There may be room for doubt whether the study of determinants is thus, as he says, much simplified—the example of § 20, p. 15, is not a happy introductory instance of such simplification—and it may certainly be questioned whether beginners should have the subject at first presented to them in this way; but undeniably a freshness is thereby imparted to the book, which will make it pleasant reading to those who already know something of the matters in hand. Chapters II. to V., on "General Properties of Determinants," "The Minors and the Expansion of a Determinant," "Multiplication of Determinants," and "Determinants of Compound Systems," contain proofs and illustrations of *most* of the well-known general theorems. One might, however, fairly expect so large a work as the present to be more complete in this respect; the omissions for example, of Sylvester's beautiful theorem expressing the product of two determinants as a sum of like products is not easily excusable. Chapter VI., on "Determinants of Special Forms," is good, and the same may be said of the next, which treats of "Determinants with Multiple Suffixes." Belonging to the first part, although included under "Applications," are Chapters IX. and XII. The one concerns what are called "Rational Functional Determinants," but which might be more fitly designated as "Alternants"—to use one of Sylvester's happiest coinages; the other concerns "Determinants of Functions of the same Variable," a title again which is anything but sufficiently discriminative. Both chapters are fresh and interesting. To the borderland between the two parts may be assigned Chapter X., on "Jacobians and Hessians;" then there are chapters (VIII., XI., XIII.) dealing with the applications to three departments of Analysis, viz., Theory of Equations, Theory of Quadrics, and Continued Fractions; and, lastly, there is a very readable chapter (XIV.) on "The Applications to Geometry."

No exercises for the student are given under the individual chapters, but a considerable collection is placed towards the end.

Following this is a "List of Memoirs and Works Relating to Determinants," the arrangement being alphabetical according to authors' names. Mr. Scott acknowledges the incompleteness of the list; but, all the same, one cannot help expressing regret that such an excellent opportunity of publishing an exhaustive, or tolerably exhaustive, bibliography of determinants was lost. Had the list been a judicious *selection*, there would have been less cause for regret, but not rarely the worthless are taken and the good left out. Cauchy, who in a sense laid the foundations of the whole subject, is not once mentioned; Grassmann, who laid the foundation of Mr. Scott's method, is not included; Nägelsbach's name occurs, but his most important paper is omitted: and many more such instances might be cited.

Mr. Scott has given us a very acceptable addition to our mathematical text-books: a little more of the conscientious labour he has shown would have produced a work still more worthy of the press which has issued it.

[1] *E.g.* $\begin{vmatrix} a & b & c \\ d & e & f \\ g & h & k \end{vmatrix} = (ae_1 + be_2 + ce_3)(de_1 + ee_2 + fe_3)(ge_1 + he_2 + ke_3)$, where $e_1e_2e_3 = 1$, and e_1, e_2, e_3 are symbols subject to the laws of ordinary algebra, except that $e_1e_2 = -e_2e_1$, and therefore $e_1^2 = 0$.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.]

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

The Stone in the Nest of the Swallow

THE name of swallow's stone was preserved in France even to our days, for Dr. Patrin, a member of the French Institute and of the Academy of Sciences in St. Petersburg, wrote in the "Dictionary of Natural History," Paris, Deterville, 1803 (V° Agate), as follows:—

"On trouve dans les ruisseaux des environs de Sassenage en Dauphiné de très petites Calcedoines ou Agates de forme lenticulaire qu'on a nommées *pierres de Chélidoine*, parce qu'elles ont quelque ressemblance avec les semences de cette plante, *pierres d'hirondelle* parcequ'on en a trouvé dans l'éstomac de ces oiseaux."

Of course this naturalist did not try to throw light on the legend, or to explain the confusion made by some authors between the respective skill of the eagles in geology, and of the swallows in botany, which Phile, in his "Remedies Against Sortileges," clearly sets out in the following verses:

φθορᾶς δὲ τηρεῖ τὰς γονὰς ὑπερτέρας
εἰς τὴν καλίαν ἀετὸς κρύψας λίθον
ὡς ἡ χελιδὼν τοῦ σελίνου τὴν κόμην
Ἐξάψασα δὲ τοῦ τραχήλου τὸν λίθον
κυοῦσα γυνὴ κερδαινεῖ ζῶν τὸ βρέφος.

"A stone which the eagle conceals in her nest (aery) preserves

her lofty breed from destruction, just as the top of a parsley sprig does for the swallows. This stone worn by a woman round her neck during pregnancy will procure her a living child."

This use of parsley is mentioned by Ælianus *de Natura Animal.* lib. i. chap. 37, as follows :—

Αἱ σίλφαι καὶ τουτῶν τὰ ὠὰ ἀδικοῦσιν οὐκοῦν αἱ μητέρες σελίνου κόμην προβάλλονται τῶν βρεφῶν καὶ ἐκείναις τὸ ἐντεῦθεν ἄβατά ἐστιν.

"As the beetles injure their eggs the mothers throw tops of parsley sprigs in front of their young, which become inaccessible to the beetles."

But this parsley must not be confounded with the miraculous herb giving sight to the young swallows. (Ælianus, lib. iii. chap. 25).

Βραδέως δὲ ἐκβλέπει καὶ τὰ ταύτης βρέφη ὡς καὶ τὰ τῶν κυνῶν σκυλάκια· πόαν δὲ κομίζει καὶ προσάγει τὰ δὲ ὑπαναβλέπει εἶτα ἀτρεμήσαντα ὀλιγὸν ἐκπετήσιμα ὄντα πρόεισι τῆς καλίας ἐπὶ τὴν νομήν. ταύτης τῆς πόας ἄνθρωποι γενέσθαι ἐγκρατεῖς διψῶσι· καὶ οὐδέπω νῦν τῆς σπουδῆς κατέτυχον.

"Like whelps, the young swallows are late endowed with sight, but on the application of a certain herb by their mother they begin to see; and after some rest leave the nest to seek their food. Men, though longing for this herb, could never get it."

Dionysius gives in his "Ornithology" some information about this eagle's stone (lib. i. ch. 3).

Ἢν δὲ ἀποτεκεῖν δέῃ κομίσαντές τινα λίθον ταῖς κοίλαις ἐντιθέασι καλιαῖς ἵνα ἐν καιρῷ τίκτωσι, καὶ μὴ τὸ τικτόμενον πρὸ τῆς ὥρας ἀτέλεστον ὠθοῖτο ὑπ' ἰσχύος· οὐ μὴν ἐστὶ τι σαφὲς περὶ τοῦ λίθου τούτου γινώσκειν, ἀλλ' οἱ μὲν αὐτὸν ἀπὸ τῶν Καυκασίων ὀρῶν οἱ δὲ ἀπὸ τῆς τοῦ ὠκεανοῦ ὄχθης φασὶ κομίζεσθαι λευκὸν ὑπερφυῶς ὄντα καὶ μεστὸν ἔνδοθεν πνεύματος ὡς καὶ ἦχον ἀποτελεῖν εἰ κινοῖτο. τικτούσῃ δ' εἴ τις αὐτὸν γυναικὶ περιάψειε, ὀλισθαίνειν διακωλύσει τὸ βρέφος. κἂν ἐνλέβητι παφλάζοντος ὕδατος ἐπιψαύσῃ τὴν τοῦ πυρὸς νικήσει πάντω ἰσχύν.

"They bring this stone in their nests to avoid a premature and forcible delivery. Nothing positive is known about this stone, which some suppose brought from the Caucasus, and others from the sea-shore. It is exceedingly white, full of air, so as to resound when moved. It prevents miscarriage in those who wear it. And if it does but touch the surface of a caldron of boiling water, it overpowers entirely the might of fire."

The confusion made by some writers between swallows and eagles is evident by the fact of their faulty quotation from Pliny.

For Pliny, chap. iv. lib. x. says—

"Tribus primis et quinto aquilarum generi inædificatur nido lapis *ætites* quem aliqui dixere gangitem ad multa remedia utilis nihil igne deperdens. Est autem lapis iste prægnans intus, cum quatias alio velut in utero sonante. Sed vis illa medica non nisi nido direptis."

And in chap. xxxix. vol. 36, he gives further particulars on these very stones, which he divides into males and females, and into four kinds, according to their origin.

Whilst in lib. viii. chap. 41, he says—

"Chelidoniam visui saluberrimam hirundines monstravere vexatis pullorum oculis illa medentes," and lib. xxv. ch. 50, "Animalia quoque invenere herbas, in primis que chelidoniam. Hac enim hirundines oculis pullorum in nido restituunt visum ut quidam volunt [see Aristotle *de Animal. Gen.* l. iv. ch. 6] etiam erutis oculis"; clearly tracing the distinction followed by Phile between the respective proficiency of eagles in geology and swallows in botany.

Jersey CHATEL

A Peat Bed in the Drift of Oldham

WE have here lately discovered a bed of peat intercalated with beds of undisturbed "glacial drift." I believe this phenomenon, if not unique, is very rare in England, and may, therefore, be interesting to your readers. In the depth of a section of 14 feet there are two thick beds of drift with washings of fine clay, and, midway in the section, a well defined bed of peat with a maximum thickness of 18 inches. Another bed of peat, somewhat less clearly defined, and not so true as the former, is likewise present, the two beds having beneath them a thin band of exceedingly fine clay of a bluish grey colour, which evidently is the equivalent of the "seatings" or "floor clays," which so invariably accompany our seams of coal. The beds of drift that inclose the peat are alike in some of their main features, but unlike in others. In both boulders are in great abundance. In the bed beneath the peat there are bands of fine clay, coarse sand, or grit, pebbles, and boulders; the upper, with very little variation, is uniformly made up of arenaceous clay and a great number of boulders. It is almost certain that at the close of the pleistocene period the upper deposit, that is, the one above the peat, could not have had a thickness of less than 75 feet. These deposits are the "upper drift" of the geologist. The beds beneath the peat, judging from their composition—boulders, pebbles, gravel, and fine sand—and the presence in the latter of "current bedding," probably represent the "middle drift." The "lower drift" beds are absent here. May I add that some of the mosses, which seem to make up the bulk of the peat, are in an excellent state of preservation, and are now under examination for identification. A considerable number of fragments of beetles, of undetermined species, are likewise amongst the finds. JAS. NIELD

29, Radclyffe Street, Oldham, September 13

On the Asiatic Alliances of the Fauna of the Congenian Deposits of South-Eastern Europe

HERR THEODOR FUCHS of Vienna has pointed out some important mistakes in the abstracts of his memoir in NATURE, vol. xxi. p. 528. In view of remedying these regrettable errors some revised extracts are here given. At p. 528, line 32, the passage should read thus :—"The genus *Neritina* at present shows a predilection for islands. Thus from Tahiti alone Reeve gives 8 species, and 11 from the Sandwich Islands; from the Philippines there are 39, and 40 from New Caledonia alone, according to Gassies. Further, according to Kobelt there are 11 in the Mediterranean; and, according to Reeve, 7 in the West Indies, and 10 in Central America. The great continental areas are strangely poor in *Neritinæ*. In North America the genus seems to be wanting, since the two or three known species are found only in the borderlands on the south. The genus *Melanopsis* has a very peculiar distribution. Twenty species, nearly all strongly ornamented, belong to the Mediterranean. This genus is wanting in Africa, East India, the Malay Islands, Australia, and the whole of America; but it occurs quite locally, with 19 species, in New Caledonia; and 2 species are found in New Zealand."

Again, at line 60, read :—"A very peculiar characteristic, hitherto overlooked, in the inland-water faunas of the later tertiaries in South Europe, is the absence of the African element (such as the Achatina, Etheria, Ampullaria, Iridina, Galatea, &c.); and this is the more remarkable because the mammalian fauna of the period, on the contrary, has a strongly-pronounced African character. The same may be said of the flora and for the whole tertiary period, since the tertiary flora of Europe had, in succession, an Australian, Indian, Japanese, and Mediterranean character, but never an African character. The tertiary land and freshwater shells of Europe show analogies to New Caledonia, India, China, and Japan, but not to Africa; although the last not only lies so very much nearer to our continent, but in its mammalian fauna, until the Diluvial period, kept so close a connection with Southern Europe." T. R. J.

Prosopistoma punctifrons

MY colleagues, Messrs. Joly and Vayssière, in announcing with justifiable pride (in the *Comptes Rendus* of the French Academy and elsewhere) the discovery of the perfect insect of *Prosopistoma*, attribute to me the former possession of an opinion that the insect might be an Ephemerid suited for a continuous aquatic life. I am not sensible of having published such an opinion, nor of having held it. In remarks on *Oniscigaster*, in the *Journal* of the Linnean Society of London, vol. xii. (Zoology) p. 145, footnote (1873), I ask, "Can there be apterous *Ephemeridæ*?" and "Can the imago of *Prosopistoma* be in that condition?" It did not occur to me that these words could be so translated as to bear the interpretation put upon them by Messrs. Joly and Vayssière. In congratulating my colleagues upon their discovery, I remark that I make this explanation solely because certain of my correspondents ask *where* I have published the opinion attributed to me. R. MCLACHLAN

Lewisham, September 9

Mosquitoes

IN NATURE, vol. xxii. p. 338, an inquiry is made as to the best means of preventing the attacks of mosquitoes. I am

informed that the smell of American pennyroyal (*Hedeoma pulegioides*), when sufficiently strong, drives them away at once. A few drops of the essential oil extracted from this plant added to an ointment and rubbed upon the skin will secure relief from these pests; likewise a sleeping apartment may be freed from them by strewing about a quantity of the leaves of the plant; or by allowing a quantity of the essential oil to evaporate in it. European pennyroyal (*Mentha pulegium*) is said to be very similar, and might possibly have the same effect.

Lyons, New York, August 30 M. A. VEEDER

Hardening of Steel

IN NATURE, vol. xxii. p. 220, Mr. H. T. Johnston-Lavis supposes the absorption of hydrogen to be necessary for steel to get hard.

The following facts seem to prove that this absorption can be very well dispensed with in hardening:—

1. Small pieces of steel wire can be hardened by moving them swiftly through the air when red hot, or by pressing them against a piece of cold metal.

2. Steel can be hardened very well by cooling in quicksilver.

Both facts seem to state that only rapid cooling is wanted for steel to get hard. T. W. GILTAY

Dordrecht, September 8

THE NEW ZEALAND INSTITUTE

PROBABLY none of our colonies have done so much for the promotion of the higher interests of their people as New Zealand; in this respect, indeed, it will compare favourably with almost any other country in the world. Its university is wonderfully complete and well organised; all the faculties are well represented; science, as well as literature, has its right place in the curriculum; the best men are tempted to go out as professors from the old country; and laboratory research is fairly encouraged. Quite recently we referred to a proposed system of education, which in its comprehensiveness and completeness will hold its own with any national system of education in Europe. The New Zealand Institute, again, is probably one of the best organised, and for its purpose, among the most efficient scientific bodies to be found anywhere. It is virtually a Government institution, and was organised by a special Act in 1867. It seems to bear the same relation to its incorporated societies that a university does to its affiliated colleges; it is independent of these societies, which must comply with certain rules imposed upon them by the Institute, and yet without these societies its occupation would seem to be gone. One part of its duty is the publication of summaries of the *Proceedings* of the societies, and of such papers and records in full as the Institute may deem of permanent scientific value. The societies at present incorporated with the Institute are the Wellington Philosophical Society, the Auckland Institute, the Philosophical Institute of Canterbury, the Otago Institute, the Westland Institute, and the Hawkes Bay Philosophical Institute. It must be gratifying in the highest degree to those who have the best interests of New Zealand at heart to find a love for culture so widespread as the existence of these societies indicate. And it must be remembered that, as a condition of incorporation with the Institute, each society must come up to a certain standard of membership and contribute a considerable sum yearly to the promotion of science, art, and literature, which is the aim of the Institute.

The genuine good work which the Institute is doing, and its efficiency in promoting not only science, but through that the practical interests of the colony, is evident from the handsome volume of *Transactions* which it publishes yearly, and which are entitled to take their place among the best class of similar publications. Some idea of the work which the Institute is doing, and of the value of its *Transactions*, may be obtained from the two last volumes, for 1878 and 1879, which we have just received.

Of course the first aim of a society like this, in a fresh country like New Zealand, should be the working out of its natural history (in its widest sense) in a scientific method. This the Institute has done and is doing, and its publications, and the publications of the separate societies, are already a mine of information on all subjects connected with New Zealand. The volumes before us contain a large number of papers on zoology, botany, chemistry, and geology, all of them important contributions to these various departments of science. Prof. Hutton, whose name is well known in this country, contributes a number of valuable papers on the various divisions of the fauna of New Zealand. Prof. von Haast (another name well known to science) has other various contributions of special value, and Mr. T. W. Kirk, of the Colonial Museum, has a long list of papers both on zoology and botany, all of them of novelty and interest, and several of them on such practically important subjects as Grasses and Fodder Plants. Other able workers in these departments are Mr. D. Petrie, Mr. W. Colenso, Mr. Charles Knight, Mr. Buchanan, and Mr. Buller. From Mr. J. C. Craufurd and Mr. W. Collie we have valuable contributions relating to the geology of New Zealand. Several of the papers classed under the head of Miscellaneous are of the greatest importance and interest. Thus we have papers of immense practical value to the colony on the Forest Question in New Zealand, by Mr. A. Lecoy; on the Influence of Forests on Climate and Rainfall, by Mr. F. S. Peppercorne; and on Forest Planting and Conservation, by Mr. G. W. Wilkins. Equally important from a colonial as well as a scientific standpoint is Commander Edwin's paper on the Principle of New Zealand Weather Forecast. We have several excellent papers on the New Zealand natives of much ethnological value: "Notes on Port Nicholson and the Natives in 1839," by Major Heaphy; "On the Ignorance of the Ancient New Zealander of the Use of Projectile Weapons," by Mr. Coleman Phillips; "Contributions towards a Better Knowledge of the Maori Race," by Mr. W. Colenso; "Notes on an Ancient Manufactory of Stone Implements," by Prof. von Haast, F.R.S.; and "Notes on the Colour-Sense of the Maori," by Mr. J. W. Stack. Mr. W. Colenso contributes papers on the Moa, a subject of great scientific interest. Mr. J. H. Pope's "Notes on the Southern Stars and other Celestial Objects" is a valuable contribution to astronomy. Prof. Bickerton has several papers on subjects of wide scientific interest,—on "Partial Impact," the "Genesis of Worlds and Systems," the "Birth of Nebulæ"; while Prof. F. W. Frankland writes interestingly on "The Doctrine of Mind-Stuff." There are several good chemical papers by Mr. W. Skey. In the *Proceedings* of the several societies there are numerous shorter papers of varied interest, as on Moa Feathers, by Dr. Hector; on Musical Tones in the Notes of Australian Birds, by Mr. C. W. Adams; on a new fish, by Prof. Hutton; and many others on subjects of wide and varied interest. We have besides meteorological, earthquake, and other records, and a variety of miscellaneous matter, all of real importance.

An institution capable of producing so much valuable work year after year deserves every encouragement from the government of the country. The New Zealand Government has hitherto granted a subsidy of 500*l.* yearly to the Institute, just sufficient, we believe, to defray the expenses of printing the *Transactions*, which are freely distributed to other societies all over the world. We are therefore astounded to learn that the Government has decided to withdraw this grant, thus suddenly bringing these valuable *Transactions* to a standstill. We can scarcely credit the statement; it is difficult to believe that so enlightened a Government as that of New Zealand

would so seriously cripple one of its most valuable institutions, and so discourage an activity which produces results not only of the greatest value to science, but to the practical interests of the colony. The affiliated societies themselves contribute, we believe, 1,275*l.* annually to support the work of the Institute, the whole of which is spent in keeping up valuable museums and laboratories, and an interest in science in nine centres of population in New Zealand. Without the annual volume, we fear it is impossible to get members to keep up their subscriptions, and thus the organisation of the Institute, which has stood the test of twelve years, given universal satisfaction at home and abroad, and reflected the greatest credit on the colony, is in danger of breaking up and possibly expiring altogether. This would be little less than a calamity to the colony. Not a penny of the 500*l.* is spent in salaries; the editing, drawing of illustrations, and all else is a mere labour of love. The names of von Haast, Hector, Hutton, and others, are known to men of science all over the world. Dr. Hector especially has acquired a high reputation for his activity, zeal, and the results he has obtained. It is greatly owing to him that New Zealand has done for science far more than any colony of its age. The Institute itself is a model of organisation. The grant of the annual 500*l.* was a wise step worthy of general imitation, and its sudden extinction is a cruel blow to science. We can scarcely believe that New Zealand is capable of persisting in carrying out so shabby and short-sighted a policy, a policy of which any country should be ashamed. We trust that later news will show that there has been some misunderstanding, or that the Government has thought better of it, and continued a grant that could not possibly be better spent.

ALBERT J. MYER

THE young science of meteorology has sustained another heavy loss in the death of General Myer, of the Signal Service of the United States, at Buffalo, New York, on August 24, in the fifty-second year of his age. In 1854 he entered the United States army as an assistant surgeon, was assigned to special duty in the Signal Service in 1858, and in 1860 was made chief signal officer of the army, a position he held till his death.

The distinguished services rendered by General Myer to meteorology may be considered as having been made chiefly during the last ten years. Americans claim for the late Prof. Henry, of the Smithsonian Institution, the honour of having originated, upwards of thirty years ago, the idea of using the telegraph for conveying information regarding coming changes of weather. But it was reserved to General Myer, as respects the United States, to translate the idea into the action of every-day life, in devising, developing, and extending a system of telegrams and reports for the benefit of commerce and agriculture, which as regards the completeness of its organisation, the thoroughness with which it is worked, and its effective success, stands out as a model system of weather telegraphy. Three large weather maps are prepared and issued daily, along with three daily forecasts of the weather, which the telegraph at once sends through all the towns, villages, and hamlets of the States; and no time is lost, on the expiry of each month, in preparing and widely circulating a Weather Review, accompanied with maps showing the storm-tracks, the geographical distribution of the atmospheric pressure, temperature and rainfall for the month; together with occasional weather-maps of the highest importance in their bearing on the meteorology of America, Europe, and the rest of the northern hemisphere.

The other great service rendered by General Myer to practical science is the system of international meteorology established by him, one of the important outcomes of which is the series of United States weather-maps now appearing in NATURE, showing the meteorology of the globe for each month. When the scheme was first proposed to the Meteorological Congress at Vienna, in 1873, it was difficult to regard it in any other light than as an impracticable, if not wholly visionary, proposal; but the feeling quickly changed as General Myer unfolded the details of its practical working, and explained that what he required from his brother meteorologists, in addition to their approval of the scheme, was one daily observation at a selected few of their stations, he being authorised by the American Government to say that they would undertake the expense of collecting and discussing the observations.

As our readers are aware, the scheme in General Myer's hands has been a pre-eminent success; and a body of facts is being thereby amassed, destined to furnish the key to the larger problems of meteorology, a science which, from the complex intricacies it presents, requires more than any other science a whole hemisphere at least as its basis of observation. Perhaps the most important of the practical questions which will thus fall to be dealt with are those abnormal distributions of the mass of the earth's atmosphere, short continued or more permanent, from which arise great storms or devastating tornadoes, excessive heat or cold, fine seasons or their opposites, and long-continued rains or droughts, so terrible for the famines which attend them. The explanation of these anomalies will doubtless be the immediate precursor of an intelligent and practically successful forecasting of the character of coming seasons.

This magnificent work General Myer could not have accomplished unless he had been backed by the moral and material assistance so generously and readily accorded him by his Government. With a settled conviction that this national work, if undertaken at all, should be carried out in a spirit and manner worthy of the great Republic, the Government of the United States relegated the work to the Signal Service of the War Department, with an annual vote from the Exchequer, which, while not too large for the work to be done, no Government on this side the Atlantic has yet thought of emulating.

While writing this brief notice of General Myer's work, we have been repeatedly reminded of the name of Leverrier—probably because, though widely different in many ways, both rendered services to meteorology to a great extent identical, both possessed the rare genius of organising and the resolute will that easily sets obstacles aside, both secured the support of their respective Governments, both were animated by large views of the capabilities and requirements of the science, and both were successful in an eminent degree in largely extending the sphere of its operations.

PHYSICS WITHOUT APPARATUS[1]

V.

THE Science of Electricity may be regarded in several different aspects. Firstly, there is the study of the simple phenomena such as schoolboys delight to see: the attractions and repulsions of rubbed bodies, the sparks, the shocks, the heating of wires, and rotation of diminutive electric engines. Secondly, there is the exact measurement of electrical quantities, and the verifying of the great laws of the science, involving exact manipulation and standard instruments. Thirdly, there is the technical study of the applications of the science, the details of telegraphic apparatus, the necessities of construction and maintenance, the management of electric lights, and other branches of electrical engineering. Lastly, comes the high mathematical theory cultivated only by the few.

Of the practical portions of this vast mine of scientific wealth, the greater part is only to be reached by the aid

[1] Continued from p. 440.

of special instruments of an expensive character. Only the first and simplest of the elementary *phenomena* of the science can be shown without apparatus. Yet even here the rudest means suffice in the hand of the master to produce the desired ends.

In his lessons on Frictional Electricity, delivered to juvenile audiences at the Royal Institution, Prof. Tyndall has shown in his unrivalled way how with the commonest objects, tumblers, egg-cups, needles, sealing-wax, pewter-pots, eggs, apples, and carrots, may lend themselves to produce the sparks, the shocks, the movements of attraction and repulsion which are more commonly obtained by the use of large and expensive electrical machines. No doubt these lessons—masterly examples of elementary science teaching—are familiar to many of the readers of "Physics without Apparatus." To the science teacher they are an indispensable primer of instructions how to impress common objects into the service of science. The only matter for regret is that they stop so far short of the

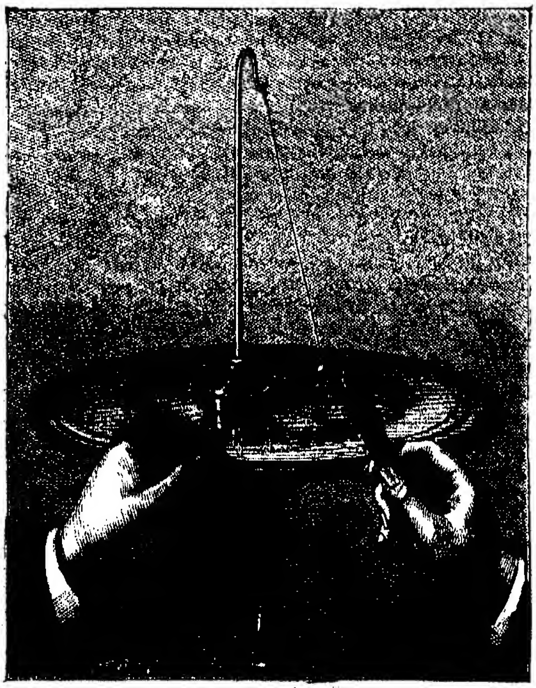

Fig. 16.

entire subject, and do not touch the kindred branches of voltaic electricity or magnetism.

The experiments we lay to-day before our readers are mere repetitions of ordinary lecture experiments, but require no apparatus of a technical kind for their performance. To show the attractions and repulsions due to electrification requires only the appliances depicted in Fig. 16. A stick of sealing-wax rubbed briskly through a dry warm piece of cloth or flannel suffices as a source of electricity. A small light ball cut out of pith or cork is attached by a drop of sealing-wax to a silk thread and thus suspended to any suitable support. It is first attracted toward the electrified stick of wax; and then repelled when by contact it has received a portion of the charge. The repulsion is not very easy to show if the ball is not exceedingly light. For this purpose a small feather, or bit of down out of a pillow, answers far better. A support from which to hang it may be improvised out of a penholder and a couple of books. The electricity excited on the wax by friction with a woollen fabric is of the *negative* kind. *Positive* electricity is no less easily obtained from a warm glass tumbler by exciting it with a warm and dry silk handkerchief. And, if both these sources are at hand the further experiment may be made

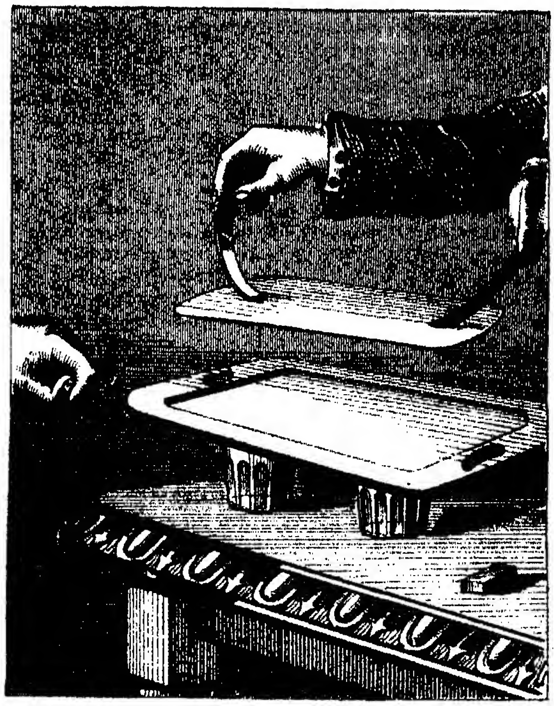

Fig. 17.

of charging the feather with either kind of electricity and then showing that though it is then repelled by electricity

Fig. 18.

of the same kind, the opposite kind of electricity attracts it. The mutual repulsion of two similarly electrified bodies is beautifully shown by means of two silk ribbons,

as follows :—The two ribbons, about a foot long, are both side by side on the table, held at one end between the finger and thumb, and then electrified by drawing along them several times a piece of indiarubber. They are then lifted up from the table, when, if care has been taken that all is warm and dry, they are found no longer to hang straight down side by side, but to stand out and repel each other.

To obtain an electric *spark* requires preparations on a larger scale. M. Tissandier recommends the following method :—A piece of stout drawing-paper (warm and dry, of course) is laid upon a table—or upon a warm dry board. It is then rubbed with the dry hand, or with a silk handkerchief, or with a clothes-brush, or, best of all, with a piece of indiarubber. It will stick slightly to the table in consequence of its electrification. Now throw down on to it a bunch of keys, and grasping two corners lift up the sheet from the table. If at the very moment of lifting any one holds out his knuckle to the keys he will receive a small pale spark perhaps three-quarters of an inch long.

A more certain way we have found with what we may call a *Tea-tray Electrophorus* (Fig. 17). A common tea-tray of metal is supported on two dry glass tumblers. A piece of common brown paper cut so as to be a little smaller than the tray, and with rounded corners, is warmed, laid on the table and rubbed briskly with a piece of indiarubber, or with a clothes-brush. It is then laid down for an instant on the tray and the tray is touched with the hand. The brown paper is then lifted a few inches above the tray. If at this juncture some person

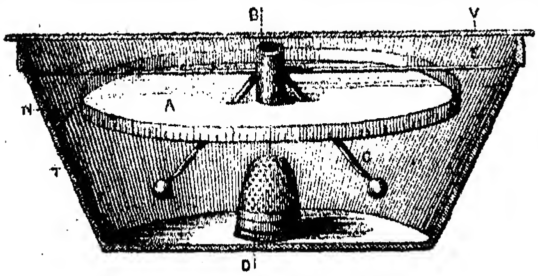

FIG. 19.

presents his knuckle to the tray he will receive a bright spark, which under favourable circumstances may be a couple of inches long. By simply putting the paper down, touching the tray, and again lifting up the paper the tray is again charged : and a large number of sparks may be thus drawn one after the other in rapid succession. The paper may be lifted by the hands, but it will be found better if a couple of ribbons or strips of paper be fixed on with wax to serve as handles, as shown in our figure.

The sparks obtained by the tea-tray electrophorus may produce a slight pricking sensation, but to give a regular electric *shock* will oblige us to store up a charge in a Leyden jar. This important piece of apparatus we have found possible to improvise in the following fashion. A round-bottomed glass tumbler is procured—if of thin glass it is preferable—and is filled to about three-quarters of its height with leaden shot. If shot is not at hand *dry* coal-dust will answer, but not so well, and great care must be taken to wipe clean the upper part of the tumbler. Everything must be warm and scrupulously dry. Into the shot a silver spoon is stuck to serve the place of a rod and knob. This is held as shown in Fig. 18, by grasping it well in the hollow of the hand, so that the hand may cover the whole of the rounded bottom of the glass. Having thus prepared and grasped our Leyden jar we must charge it with sparks from the tea-tray electrophorus. It should be held with the spoon handle near to, but not quite touching the edge of the tea-tray, while another person performs the operations of lifting the brown paper up and putting it down, then touching the tray, then lifting up again—and so on until a dozen sparks have been sent into the jar. On touching the knob a smart little shock is experienced in the wrists and elbows, and a short bright snapping spark announces the discharge of the jar.

The subject of currents of voltaic electricity is somewhat beyond the province of "Physics without Apparatus," and so is the greater part of the subject of magnetism. We may however conclude this article by presenting our readers with a simple mariners' compass described some time ago in a French magazine (Fig. 19). A short knitting- or darning-needle, E, which has been magnetised by rubbing it on a magnet, is pushed into a small cork, B, and balanced in the following way :—A sewing-needle is fixed, point downwards, in the lower end of the cork, and this is poised on a sewing-thimble. To balance it about the point of the needle a couple of matches pointed at the ends are thrust into the sides of the cork obliquely, and weighted at their lower ends with little balls of sealing-wax. A circle of paper or thin card marked with the "points" of the compass may be attached to the cork; and to prevent draughts of air from blowing the needle round it should be placed in a deep saucer or dish of glass or porcelain.

(*To be continued.*)

NOTES

WE are glad to be able to state that Mrs. Clifford is to receive a pension from the Civil List in recognition of the eminent services to mathematics of her husband, the late Prof. W. K. Clifford, F.R.S.

IN the absence of precise information as to the cause of the lamentable explosion at Seaham Colliery, we cannot say anything useful on the occurrence. When such terrible "accidents" occur, Science is invariably asked if she cannot do anything to prevent them, anything to render the miner's occupation less dangerous than it is. Those who ask such questions seem to be ignorant of the fact that, while much remains to be done, science has already done not a little to point out the causes of such explosions and provide the miners with remedies. But it is well known that a large proportion of such explosions are due to the wilful neglect on the part of the miners of the means which science has put into their hands to prevent such calamities. We are in a fair way of finding out the real nature of the connection between meteorological conditions and explosions in mines; it is in this direction that investigations should be carried out with thoroughness and zeal.

THE Sir Josiah Mason's Science College, Birmingham, is to be opened on October 1 next, with an introductory lecture by Prof. Huxley. The classes for students will commence on Tuesday, the 5th. The course of instruction, as at present arranged, includes mathematics, chemistry, physics, and biology. Further details may be learned from our advertising columns.

TWO eminent foreign botanists will, the *Gardener's Chronicle* states, shortly visit this country—Dr. Asa Gray and M. Alphonse de Candolle.

WE are glad to learn that the Gilchrist Trustees have given two engineering scholarships to University College, London, to be awarded by competition. There is an entrance scholarship (this year two are offered) of the value of 35*l.*, tenable for two years, to be competed for by those who have not previously been students of the College, and who are not more than eighteen years of age. The examination takes place this year on September 28, and candidates must send in their names to the secretary on or before the 23rd. The subjects of the entrance examinations will be as follows :—Mathematics, mechanics,

mechanical drawing, essay on one of three given subjects connected with mechanics or engineering, French or German, the use of tools, either carpenters' tools, *or* the lathe (wood *or* metal), *or* the file. There is also a senior scholarship of the value of 80*l*. to be awarded at the close of each session from 1881-82 inclusive. Candidates for this scholarship must, to the satisfaction of the Faculty of Science, have attended during the whole of the session immediately preceding the award College classes in the following subjects:—Applied mathematics, practical physics, junior engineering, engineering drawing, geology. The scholarship will be awarded on the results of the ordinary class examinations in these subjects.

REFERRING to a short announcement in NATURE, vol. xxi. p. 306, of prizes offered by the Venetian Institute, we have been desired to point out that the limit of time for the first (that relating to the mechanical equivalent of heat) is March 31, 1881 (not 1880). In further explanation we may say that the task proposed is "to discuss minutely the determinations of the equivalent hitherto made, to investigate the causes of the considerable differences that have appeared in the results, to indicate what is the most probable value that may be deduced from these, and to determine the equivalent by new experiments, adopting the method which the competitor shall have proved to be most exact." Many writers of great authority assume 424 or 425 kilogrammetres as the mean value; but Joule's more recent experiments, based on observation of electric phenomena, give 430, and Violle has obtained a value approximating 435. The importance to physical science of a settlement of the question is obvious.

THE Vienna Academy (Section of Mathematics and Natural Science) has proposed as subject for the Baumgärtner prize of 1,000 florins the microscopic investigation of wood of living and fossil plants. By such investigation and the comparison of all known recent and fossil woods, it is desired to ascertain characters whereby it will be possible to determine the genus and species with certainty from microscopic sections. Papers must be sent in before December 31, 1882, and the prize will be awarded at the anniversary meeting in 1883. For further conditions see the *Anzeiger*.

THE *Philadelphia Record* deserves all the credit that has been accorded it for its public-spirited and successful efforts to break up the sale of bogus medical diplomas in that city. These diplomas were chiefly sold abroad, and it is appalling to learn, on the authority of the *Times* correspondent, that 11,000 of them have been issued during the past few years. "It was well known," the correspondent writes, "that Dr. John Buchanan, the Dean of 'The American University of Philadelphia,' and several other similar institutions, was engaged in this traffic; but as they were all properly chartered medical schools, and, though disreputable, existing under the sanction of law, the difficulty was to get evidence of the sale of the diplomas. Diplomatic complaints about the traffic came from various Governments of Europe, and our people began to be restive under the stigma." By the clever tact of the city editor of the *Record*, however, Buchanan has been brought within reach of the law, and the detectives are on his track. He attempted to put them off the scent by getting a man looking like himself to pretend to drown himself; this bogus case of drowning, however, has deceived nobody.

MR. A. L. SILER, the *American Naturalist* informs us, has discovered at Malley's Nipple Ranch, near Pahreah, Kane county, Utah, remains of cliff-structures, which he describes as follows:—The remains seem to have been the foundations of small huts built on ledges of red sandstone under overhanging cliffs. The walls were about six inches thick, made of thin flat sandstone brought up from the valley below, and laid in adobe. The structures are divided into rooms about four feet square, leaving all the space between the building and the back of the cliff, usually about ten feet, entirely free. Upon digging into one of the rooms, Mr. Siler found parched corn and rope in a good state of preservation.

THE August number of the *American Entomologist* contains an interesting article by the editor (Prof. C. V. Riley) on the effects of *Pyrethrum* (either as powder or fumes) on injurious insects, and the author believes this otherwise harmless substance is destined to entirely supersede the use of Paris green and other arsenical compounds. Experiments were made upon various insects, and on some the effect was remarkably rapid, the powder killing them in a very short time. "Squash bugs" appeared to resist the longest. Amongst other articles and notes is one on a luminous elaterid larva from Maryland, accompanied by figures; and an important one by Prof. W. S. Barnard on the larva of a *Simulium*, which forms black masses on the rocks in rapids near Ithaca, N.Y., the pupa being furnished with external breathing apparatus. This magazine still suffers from the inconvenient absence of any indication of the contents of each number, a want the editors will do well to supply.

THE members of the Geological Society of France arrived at Boulogne on Thursday last. At their reception in the Collége Communal, adjoining the museum, a *vin d'honneur* was offered them by the municipality. Among those present were Professors Prestwich and Seeley. The first meeting took place in the Salle Daunou, at the museum, where an opening address was delivered by M. de Lapparent, president of the Society.

ON August 18 and 24 storms of almost unprecedented violence swept over Kingston, Jamaica, and its neighbourhood. The destruction has been widespread and terrible, reminding one of the dire effects sometimes experienced from storms at Mauritius.

PROF. SILVESTRI, in a recent ascent of Etna, found that, as a result of recent volcanic activity, the summit has been lowered to the extent of 12 metres, so that its present height above sea-level is 3,300 metres, and that the interior edge of the crater, which was formerly 1,500 metres in circumference, is now 1,800. The platform which was formerly seen on the east side, at 60 metres below the edge of the crater, has completely fallen into the heart of the volcano, and the eruptive axis, which before the eruption of 1879 was situated on the west side of the crater, is now right in the centre. Thus the interior walls of the crater of Etna now present the virtually characteristic form of a great funnel.

ON September 5 the adherents of the Positive Philosophy went in procession to the Père Lachaise to the tomb of Auguste Comte, the founder of this system. Their number was about 200. Three speeches were pronounced on the spot, and in the evening a banquet took place in the very rooms that Auguste Comte occupied during his lifetime and which have been preserved in their former state.

TRACES of the last exceptionally cold winter are now visible in Paris, a large number of trees in the squares and streets having lost their foliage at an early period. Many of them are showing leaves belonging to a second formation, and which are probably doomed to a speedy death. We daresay many of our readers will have noticed a similar result in London.

ACCORDING to the *Révue Scientifique* a change has taken place in the Observatory of Algiers, but of a very unusual character. M. Balard, who has been during so many years director of this establishment, has been reduced to the grade of astronomical *attaché*, and M. Trepied, adjoint member of the Bureau des Longitudes, and one of the staff of the *Révue Scientifique*, has been appointed director.

MONSIGNOR ELIGIO COSI, Bishop *in partibus infidelium* at Chang-Tong in China, is said to have invented a new alphabet, composed of thirty-three letters, with which all sounds of the Chinese tongue can be clearly expressed; until now 30,000 were requisite. The Emperor of Austria, to whom Monsignor Cosi communicated his invention, presented him with a complete typographical apparatus for a printing establishment.

THE boring of the Arlberg Tunnel is in active progress on the Austrian side of the mountain, and ground will shortly be broken on the Swiss side. The St. Gothard line in its entire length is expected to be in running order in April next.

A RATHER smart earthquake shock was felt at Zermatt on the 3rd inst., and other two on Friday last.

ON Wednesday, September 8, lightning fell on the Sorbonne at about half-past two o'clock. A globe of fire was observed by persons present on the spot. Some of them say it was seen coming from the point of the north-western conductor, which was struck, as well as the south-western, with a great noise. The Sorbonne had, until recently, no lightning conductor, and never, as far as is known, has any thunderbolt struck the venerable abode of the French University. But within the last few months six stems have been erected and connected by an iron bar, making a circuit which goes all over the roof of the immense building. Unfortunately the pit where the earth conductor has been placed is situated at a great distance from the main building, in a courtyard adjoining the laboratory of M. Jamin, and the conductor which connects the roof with this is a square iron box of less than 15 mm. on each side, so that there is not sufficient conductibility in it to establish an efficient connection with the earth. This accident proves the sagacity of M. Karsten, the Schleswig-Holstein physicist, who published a table giving a formula for regulating the dimensions of the connecting-rods with their lengths, as is taught by Ohm's laws. It shows also how little the knowledge of lightning-conductors is spread in France, in spite of the several official commissions which have been established by the Government.

DURING the severe thunderstorm which passed over North London on Monday, a peculiar phenomenon was witnessed in the grounds of the Welsh Harp, Hendon, by some gentlemen boating on the lake. A vivid flash of lightning was succeeded by a tremendous peal of thunder, a great ball of fire at the same time descending from the heavens into the water. When the storm had abated over 100 fish of various kinds, including two fine carp, weighing together 23 lb., were found floating dead on the lake.

THE elevation of temperature which has been so remarkable in Paris during the end of August and the beginning of September has been accompanied by the production of a putrid odour spread all over the city, and which has been obnoxious to the public health. A report has just been published by the Prefect of Police, explaining that it must be attributed to the want of water for flushing the sewers, and also to the existence of a number of establishments where sulphate of ammonia is produced, and matters extracted by night-men are dried to be turned into manure. The Prefect of Police says that measures will be taken for producing an enlarged supply of water, and that gradually all the sewage will be conducted to Clichy by the sewers. The completion of this scheme involves the purchase by the city of a large tract of land for utilising these matters, which could not be thrown into the Seine without poisoning the stream.

THE *Daily News* Naples correspondent writes that since the 4th instant Vesuvius has again become more active, and has launched his projectiles in greater number and to a greater height. The seismograph at the observatory is also more animated, and new lava has issued from the side of the cone, flowing, fortunately for the railway, to the north-east.

THE new number of the *Canadian Naturalist* (which, we believe, is kept up with difficulty) contains a paper by Mr. G. M. Dawson on the Distribution of the more Important Trees of British Columbia, which has also been printed separately, and another by Principal Dawson, on the Geological Relations and Fossil Remains of the Silurian Ores of Pictou, Nova Scotia. Mr. G. F. Matthew has a paper on Tidal Erosion in the Bay of Fundy. Are such specimens of etymological jugglery as the Rev. J. Campbell's paper on the "Hittites in America" supposed in Canada to have any connection with science? Unfortunately some of our own scientific societies are guilty of encouraging similar elaborate trifling.

FURTHER excavations, the *Times* Geneva correspondent states, made in the ancient glacier bed near Solothurn have produced some very interesting results, and the spot is being daily visited by geologists and sightseers. The *débris* removed consisted of 4½ metres of drift mixed up with boulders and crystalline erratic blocks. The rock bared measures 20 metres long by 7 wide. It is highly polished by the action of the ice, and traversed by channels, through which the glacier-water found its way into the so-called "giants' pots," or "kettles." These, so far as has yet been ascertained, are three in number. The largest measures 8 metres from west to east, 3·7 from north to south, and is 3¼ metres deep. The second is 5½ metres across, and still contains the great boulder or mill-stone by which it was hollowed out. The third is smaller and oval-shaped, and there is reason to suppose that, if the excavations were continued, several more would be brought to light. This interesting relic of the great ice-age, or rather of the last glacial epoch, is at present private property, but a project is on foot for its acquisition by the canton, and preservation as a glacier garden in the manner of that of Lucerne.

WE have on our table the following publications:—"Familiar Wild Flowers," by F. E. Hulme (Cassell); "On the Educational Treatment of Incurably Deaf Children," by W. B. Dalby (Churchill); "Brain and Nerve Exhaustion," by Mr. Stretch Dowse (Baillière); "Lectures on the Science and Art of Education," by Joseph Payne (Longmans); "The Morals of Evolution," by M. J. Savage (Trübner); "Animal Magnetism," by R. Heidenhain (Kegan Paul); "Stonehenge Plans, Descriptions, and Theories," by W. M. F. Petrie (E. Stanford); "Ambulance Lectures," by Lionel A. Weatherly, M.P. (Griffith and Farren); "Astronomy, Text-Books of Science," by R. S. Ball (Longmans); "The Land and Freshwater Shells of the British Isles," by R. Rimmer (Bogue); "British Wild Flowers by Natural Analysis," by J. Messer (Bogue); "Glimpses of England," by J. R. Blakiston (Griffith and Farran); "Radical Mechanics of Animal Locomotion," by Mr. Wainwright (Van Nostrand).

THE additions to the Zoological Society's Gardens during the past week include a Common Cuckoo (*Cuculus canorus*), European, presented by Mr. G. Chandle; a Stock Dove (*Columba œnas*), European, presented by Mr. A. Basil Brooke; a Common Raven (*Corvus corax*), European, presented by Mr. W. A. Mitchison; a Rufescent Snake (*Leptodira rufescens*) from South Africa, presented by the Rev. G. H. R. Fiske, C.M.Z.S.; a Horned Lizard (*Phrynosoma cornutum*) from Texas, presented by Mrs. Budgett; a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, two Bull Frogs (*Rana mugiens*) from Nova Scotia, deposited.

OUR ASTRONOMICAL COLUMN

FAYE'S COMET.—The following places of this comet are adapted, like those previously given in this column, to Berlin midnight or to about 11h. Greenwich time:—

	R.A. h. m. s.	N.P.D. ° ′	Log. distance from Earth.	Sun.
Sept. 23	23 53 48	83 24·3	0·0422	0·3174
25	— 52 45	83 46·9	0·0406	
27	— 51 46	84 10·0	0·0393	0·3134
29	— 50 51	84 33·3	0·0384	
Oct. 1	— 50 2	84 56·8	0·0379	0·3094
3	— 49 18	85 20·5	0·0377	
5	— 48 40	85 44·1	0·0378	0·3054
7	— 48 9	86 7·7	0·0383	
9	23 47 46	86 31·0	0·0390	0·3015

It will be seen that the nearest approach of the comet to the earth (1·09) occurs within this period, and the circumstances are as favourable for observation as they can be at this appearance. An observation by M. Pechüle at Copenhagen on September 1 shows that the ephemeris of Prof. Axel-Möller requires only the small correction of − 1·6s. in R.A., and + 15″ in N.P.D. In no case has the motion of a comet of short period been followed with more striking success than that of Faye's comet has been during the thirty-seven years which have elapsed since its discovery, through the masterly investigations of the Swedish astronomer. Nor has he confined himself to following the comet during this interval: he has confirmed in a great degree the inferences drawn by Leverrier with respect to the conditions attending the near approach of the comet to Jupiter, about the time of nodal passage in the year 1816, having previously calculated with precision the effect of an approximation of the two bodies within 0·64 in March, 1841, and assigned accurate elements for December 25, 1838. (See the *Proceedings* of the Academy of Sciences at Stockholm, January, 1873.)

SCHABERLE'S COMET (1880, APRIL 6).—The theoretical brightness of this comet, discovered seven months since, is on the increase, and we subjoin an extract from the ephemeris calculated by M. Bigourdan, from elements founded upon normal places for April 10, 28, and May 16. It is for Paris midnight, and the intensity of light at discovery is taken = 1.

	R.A. h. m. s.	N.P.D. ° ′	Log. distance from Earth.	Intensity of light.
Sept. 28	6 39 45	76 35·5	0·2882	1·03
30	6 37 16	77 32·0	0·2817	
Oct. 2	6 34 35	78 30·3	0·2751	1·06
4	6 31 42	79 30·4	0·2685	
6	6 28 38	80 32·3	0·2620	1·10
8	6 25 20	81 35·9	0·2556	
10	6 21 50	82 41·4	0·2494	1·14
12	6 18 6	83 48·6	0·2434	
14	6 14 9	84 57·6	0·2376	1·17

The maximum brightness is attained about November 4, near which date the following are the comet's approximate positions:—

12h. G.M.T.	R.A. h. m. s.	N.P.D. ° ′	Log. distance from Earth.	Sun.
Nov. 2	5 25 23	96 51	0·2029	0·3762
6	5 12 52	99 21	0·2024	0·3819
10	4 59 53	101 46	0·2047	0·3875
14	4 46 35	104 1	0·2108	0·3931

SWIFT'S NEW COMET.—Mr. Lewis Swift, writing from Rochester, New York, on August 18, gives some particulars of his observation of a cometary object on August 11, and explains the cause of his delay of a week in notifying his discovery. On the 11th he observed a nebulous object elongated in the direction of the sun in the field with and about 1° distant from the small bright nebula H. I. 262, the position of which for 1880 is in R.A. 11h. 20m. 32s., N.P.D. 22° 45′·2, and having been familiar with the neighbourhood for many years, he supposed it to be a comet, but cold detect no motion before the sky clouded. On the morning of the 17th, the sky being clear after the moon had set, he examined the spot, but the nebulous object was missing, and a search until daylight failed to recover it. He then cabled his discovery and made it known to astronomers in the United States. The position, he says, would not differ much from R.A. 11h. 28m., N.P.D. 22°. The comet was first detected with his comet eyepiece, power 25, and examined with powers 36 and 72; it was faint, but not very faint. We have not heard that it has yet been seen elsewhere. The place given is not upon the track of Pons' comet of 1812, the return of which is shortly expected, and for which it is much to be desired that a strict search should be maintained. Sweeping-ephemerides prepared under Prof. Winnecke's direction will be found in the *Vierteljahrsschrift der Astronomischen Gesellschaft*, 12. Jahrgang, 2. Heft.

THE BINARY STAR 85 PEGASI.—By five nights' recent measures of the close stars in this system, Mr. Burnham has satisfactorily established their binary character, which had been rendered probable by his earlier measures; the mean result is—

1880·59 ... Position, 298°·3 ... Distance, 0″·65.

For the distant companion Mr. Burnham finds from six nights' observations—

1880·57 ... Position, 25°·0 ... Distance, 15″·41.

GEOGRAPHICAL NOTES

THE sixth issue of Behm and Wagner's "Population of the Earth" has just been issued. Since the last issue several censuses have been taken, and the results of these, combined with the natural increase of the population, have added something like seventeen millions to the inhabitants of the globe. The population of the earth is now stated to be 1,455,923,550, as compared with 1439 millions two years ago. Europe has 315,929,000 inhabitants, or 32·5 per square kilometre; Asia, 834,707,000, or 18·7 per sq. kil.; Africa, 205,679,000, or 6·9 per sq. kil.; Australia and Polynesia, 4,031,300, or 0·4 per sq. kil.; and the Polar Regions 82,000, mostly divided between Iceland and Greenland. The *Bevölkerung* is just too soon to be able to utilise the results of the censuses of the United States and of Austria, which are taken this year, and that of our own country will not of course be available for at least two years. The editors have, however, made a very careful calculation of the present population of the States, on the basis of registration and emigration statistics, and find the probable population of the present year to be 48,000,000. The section of the work relating to Roumania and the Balkan Peninsula is specially valuable, and must have cost the editors a vast amount of trouble, considering the untrustworthy and imperfect nature of the data at their command. The areas of these countries, as well as of several other regions on the globe, including Africa, are mainly given from careful planimetrical measurements made under the direction of the editors. The area of Roumania is given as 129,947 square kilometres, and the population as 5,376,000; Servia, 48,657 sq. kil., 1,589,650 population; Montenegro (after the Berlin Treaty), 9,475 sq. kil., population 286,000; European Turkey, including the dependencies of East Rumelia, Bulgaria, Bosnia, and Herzegovina, 339,211 sq. kil., population 8,866,500; of Asiatic Turkey the area is given as 1,899,206, and the population 16,320,000. For Afghanistan, the *Bevölkerung* gives the details of the various tribes and populations contributed to NATURE by Mr. Keane in January last. It also gives Mr. Keane's table of the Turkoman tribes (NATURE, vol. xxi. p. 111), which is wrongly attributed to Prof. Vámbéry. The statistics of the Indian Archipelago have cost the editors great trouble, mainly owing to the confused and unsystematic way in which the Batavian Government compile their statistics. There is a very detailed and careful *résumé* of the areas and populations of the various Polynesian island groups. The result reached by the new estimation of the area of Africa in the *Bevölkerung* is 29,283,390 square kilometres, of which about 6½ millions are forest and cultivable land, the same are in prairies and light woods, 1¼ million bush, 4¼ millions steppe, 10½ millions desert, and 170,000 lakes. A new planimetric measurement of South America made by Dr. Wisotzki gives the area as 17,732,128 square kilometres. The total area of the North Polar lands is given as 1,301,100 square kilometres, and of the South as 666,000.

THE French scientific expedition headed by Prof. d'Ujfalvy, the celebrated French explorer of Central Asia, has arrived at Nijni Novgorod, on its way to Turkestan, to explore Bokhara and the whole of Afghanistan north of the Hindoo Koosh. The expedition will proceed to Tashkend, where it will pass the winter, *viâ* Siberia, taking the steamer from Nijni Novgorod to Perm, the train thence to Ekaterinburg, the post-road to Turmin, the steamer again to Semipalatensk, and completing the distance to Tashkend by post-road. As soon as possible in the spring the expedition will set out for Samarcand, and, after exploring the antiquities in the Zerafshan district, will cross the border into Bokhara, proceeding thence, at the completion of the exploration of the Khanate, to the Pamir Wakhan, Badakshan, and other little known Afghan possessions in the Hindoo Koosh.

It will depend on the state of affairs in that region whether the expedition afterwards crosses the Hindoo Koosh to Cabul and Candahar, and proceeds to India and China, or whether it takes the road to Pekin through Kashgaria and Thibet. Persia and Asia Minor will be touched on the way home, and Prof. d'Ujfalvy hopes to reach Paris by the beginning of 1882. D'Ujfalvy has received a subsidy of 80,000 francs from the French Government, and is accompanied by two salaried officials connected with the Ministry of Public Instruction, Gabriel Bonvalo, a naturalist, and Guillaume Kapius, a doctor of natural science.

THE current number of the Geographical Society's *Proceedings* opens with Sir R. Temple's lecture on the highway from the Indus to Candahar (illustrated by woodcuts from his own sketches), which is most appropriately followed by Capt. Beavan's "Notes on the Country between Candahar and Girishk." The map, which will embody new material, is promised with next number. The other paper is an account by Mr. Coppinger, R.N., of a visit to Skyring Water, Straits of Magellan. In the geographical notes much prominence is naturally given to Mr. Thomson's letters describing the concluding part of his very successful journey in East Africa, the only disaster of which has been the sad death of Mr. Keith Johnston at the very outset. In the letters now before us Mr. Thomson tells us how he vainly —owing to the opposition of his own men—endeavoured to trace the course of the Lukuga Creek from Lake Tanganyika to the Congo, failing in which he returned to his camp at the south of the lake, and then, having examined the previously unseen Lake Hikwa (or Likwa), made the best of his way back to Zanzibar through Unyanyembe. Among the other notes we find one on the French expedition from the Senegal to the Niger, under Capt. Galliéni, followed by others on routes between Kurram and Ghazni, Russian Manchuria, Saghalin Island, the Indo-Chinese peninsula, and the affluents of the Rio Purûs. Sir J. H. Lefroy's address to the Geographical Section of the British Association is also given, together with a few notes on new books and maps, the whole forming an exceedingly good number for the time of the year.

AFTER spending two years in South Africa, Lieut. Een, a Swedish traveller, has lately returned to Europe, bringing with him valuable collections which he has formed in Damara-land, in the departments of natural history and ethnography.

CAPT. CASATI, an Italian traveller, is going to the Bahr-el-Ghazal, whence he will endeavour to reach Lake Chad through the Niam-Niam country, with the view of thoroughly investigating the interesting problem of the relations between the Rivers Welle and Shari.

M. LOMBARD has gone to Abyssinia on a mission from the French Government, to study the topography of the country, as well as its civil and military organisation.

THE last issue of *Le Globe* contains a paper on "La Topographie comme Base de l'Enseignement géographique," and another by M. Th. Vernet, on South Africa.

THE current number of *Les Missions Catholiques* contains three papers of interest, viz., the conclusion of the narrative of a journey in West Africa, part of the particulars respecting the march of the Algerian Missionary Society's last expeditions to Lake Tanganyika and the Victoria Nyanza, and the first instalment of a paper communicated by the Very Rev. Father Dominique of Aden, on Somali-land, a region which is gradually attracting a good deal of attention at the hands of travellers as well as of missionaries.

THE most noteworthy contributions to the new number of *Les Annales de l'Extrême Orient* are a notice of M. Aymonnier's Khmer-French Dictionary, and a vocabulary collected by the well-known Thibetan traveller, Abbé Desgodins, of words in use among several tribes on the Lan-tsang-kiang, or Upper Me-kong, the Lou-tsé-kiang, or Upper Salween, and the Upper Irrawaddy.

A TELEGRAM from San Francisco, dated the 1st inst., states that a despatch has been received at that port from Victoria, a district at the northern extremity of America, to the effect that the barque *Malay* has arrived there from Ounalaska, bringing no tidings of the *Jeannette*, the vessel despatched some months ago by the United States Government upon a voyage of Polar discovery. The *Malay* reported that at Ounalaska the *Jeannette* was given up for lost, on account of the severity of last winter. A despatch from Washington, in reference to the above rumour, ridicules the idea that the *Jeannette* has met with a mishap, inasmuch as she was made as strong as human ingenuity could contrive, and specially equipped and provided for the service on which she was sent. Officers, says the *Herald*, who have had experience of the Arctic seas, say they know of no reason why Lieut. De Long should not be as successful as Nordenskjöld was in his Northern voyage.

THE series of letters from the enterprising correspondent of the *Daily News* in Central Asia are well worthy of attention; they contain many valuable observations both on the country and the people. The Burmese correspondent of the same paper, in a long letter in last Friday's issue, describes a journey into the interior, giving much fresh information on a little known region.

THE FRENCH DEEP-SEA EXPLORATION IN THE BAY OF BISCAY[1]

I FEEL that I am indebted for the opportunity of giving an account of the French Expedition which forms the subject of this paper to my esteemed friend and colleague, the Marquis de Folin of Bayonne. He was until lately the Commandant of that port, and is a most zealous and excellent naturalist. I may indeed say that the Expedition originated with him. For more than ten years he had at his own expense assiduously and carefully explored the sea-bed lying off Cap Breton, in the Department of the Landes, as well as could be done in a fishing-boat; and the result of his researches among the marine Invertebrata has been described, with illustrations by his pencil, in a useful work called "Les Fonds de la Mer," published at Bayonne under his direction. M. de Folin has from time to time sent me the mollusca procured in his dredgings for my opinion; and our correspondence, with a visit which I paid him in December, 1878, led to his making an application to the French Government for the grant of a vessel to explore the depths which were known to exist at a comparatively short distance from the northern coasts of Spain in the Bay of Biscay. This evidently could not be done in a fishing-boat; and naturalists have much less money than science. It was in fact a project for a nation, and not for an individual. The application was, I believe, referred to the Dean of the Academy of Sciences, M. Milne-Edwards, whose reputation as an eminent zoologist has been universally recognised for more than half a century. His report was favourable; and a Government vessel was ordered to be placed at the disposal of a Commission, of which M. Milne-Edwards was appointed president. The other members of the Commission were the Marquis de Folin, Prof. Alphonse Milne-Edwards, Prof. Vaillant, Prof. Marion of Marseilles, Dr. Paul Fischer, and M. Perier of Bordeaux. The selection of these savants augured well for the success of the Expedition, and it has been fully justified. At the suggestion of M. de Folin, the Minister of Public Instruction graciously invited me and the Rev. A. M. Norman (a well-known zoologist) to take part in the expedition. Mr. Norman had been my valued companion for many years past in similar but less important excursions to Shetland and Norway. It was to me a great pleasure to be again associated with him. I regarded the invitation as far more than a compliment: it was a great honour.

I may here mention that immediately before the commencement of the Expedition M. de Folin, Mr. Norman, and I had some preparatory boat-dredging in the Fosse de Cap Breton. This was done at the expense of the French Government. When has our own Government shown such generosity in the cause of science to French naturalists?

The vessel assigned for the purposes of the Expedition was the *Travailleur*, a paddle-wheel steamer of over 900 tons, of 150 horse-power, and carrying four guns. She is an "aviso," or despatch-boat, and is stationed at Rochefort for occasional service. She was supplied with a capital donkey-engine and immense stores of cordage, sounding-wire, and other apparatus. She had a very happy name, being an indefatigable worker. Capt. E. M. F. Richard was the commander, or "Lieutenant de Vaisseau;" and the other officers were Lieutenants Mahieux, Jecquet, Villegente, and Bourget, Aide-Commissaire Gousselin, and Doctor Duplouy. Let me now express my sincere thanks to the officers for their great kindness and urbanity. They took a great interest in the work, and materially promoted the welfare of the Expedition. The crew consisted of 128 men; the usual number was between eighty and ninety, but

[1] Paper read at the British Association by J. Gwyn Jeffreys, LL.D., F.R.S.

extra hands were taken in consequence of the heavy work entailed by sounding during the night. All these men seemed to be well conducted, as well as good sailors; and although they had only two meals a day, their physique was quite equal to that of our best British seamen. Mr. Norman and I took with us as dredger a steady and intelligent man, John Wilson; and Prof. Marion had his dredger, named Armand. These men were of great use in sifting the material brought up by the dredges. For the Captain, I can only echo the opinion expressed by Prof. A. Milne-Edwards in his Preliminary Report, that his arrangements were first rate, and his skill admirable, especially considering that the kind of work was new to him, and that he had not previously made or even seen any deep-sea dredging.

The members of the Commission assembled at Bayonne, and the *Travailleur* arrived there on July 16th. The next morning she went to sea, with all the party on board except the President, who was obliged to return to Paris, and might also have justly claimed exemption from active service, being in his eightieth year. Until August 1st (with the exception of Sundays, the 18th and 25th, which we spent at San Sebastian and Santander) we were hard at work sounding, dredging, and trawling. The weather was very fine; and the dreaded Bay of Biscay lost its stormy character on this occasion.

The principal object of the Expedition was to ascertain the nature of the fauna which inhabits at considerable depths this part of the Bay of Biscay; and this object was thoroughly and successfully accomplished. Twenty-three dredgings were made for that purpose at depths ranging from 337 to 2600 mètres, each mètre being about thirty-nine inches, or rather more than half a fathom. The dredgings between 600 and 1,000 fathoms were the most important. Every department of the Invertebrata was well represented; and novelties were discovered in Mollusca, Crustacea, Echinoderms, Annelids, Actinozoa, and Sponges.

As regards myself, this Expedition had a peculiar charm. Having had the scientific charge of similar expeditions for the Royal Society in H.M.S. *Porcupine* in 1869 and 1870, and in H.M.S. *Valorous* in 1875, and having examined the collections made during the voyages in H.M.SS. *Shearwater* and *Challenger*, as well as those made in nearly all the Swedish, Norwegian, Dutch, and American deep-sea and exploring expeditions in the North Atlantic, I was naturally glad to participate in the French Expedition, and particularly as it embraced that part of the sea which was at no great distance from the scene of my former labours in the cruise of the *Porcupine* along the western coasts of Spain and Portugal, and which cruise was so unusually productive. Impelled by this recollection, I made last year a verbal and informal application to the late First Lord of our Admiralty for the use of one of Her Majesty's ships to explore the Bay of Biscay this summer. The answer I received was very favourable; but the pecuniary resources of our Government were then at a very low ebb, and I was encouraged to renew the application when commerce revived and times became more prosperous. I hope our new Government will avail itself of the now improved finances, and not neglect this genuine and beneficial method of instructing the nation and maintaining its credit for maritime discovery.

The fauna observed during the *Travailleur's* cruise closely resembled that which I ascertained during the *Porcupine* cruise in 1870 to exist at corresponding depths. This will be shown, so far as the Mollusca are concerned, in the list of species appended to the present paper; and I have no doubt that the other branches, when they have been worked out by the experienced naturalists to whom they have been assigned, will confirm my opinion.

In a physical and geological point of view this French Expedition has borne good fruit. No less than 103 soundings were made. They have proved the existence, within a few miles of the coast, of a submarine valley opening from the Fosse de Cap Breton and extending to a point opposite Cap Pēnas. The large diagram and chart which I now exhibit will give a better explanation than I can do by any words. The diagram was prepared for me when I presented to the Royal Society my Reports of the *Porcupine* Expeditions of 1869 and 1870; and the chart has been filled up and given to me by my kind friend the Hydrographer.

The striking inequalities of depth within a narrow area which thus appear were noticed in a Bayonne newspaper of August 4th, as "des grands fonds sous-marins, qui continuent sous les eaux de l'Atlantique les vallées pyrénéennes." As a general rule, it may be said that where mountains or high land approach the sea the depth of water is greater off that coast than where the land lies low. But this must depend in a great measure on the geological nature of the land adjacent to the sea. If the formation be granitic or gneissic, the wear and tear or denudation must be slower than if the formation be sandstone, Cretaceous, or Tertiary; and the action of rivers and streams on the surface of the land must be proportionally increased or decreased, and must cause the sea-bed to be more or less filled up in the course of time. Everywhere during the dredgings of the *Travailleur* in deep water the sea-bed was found to be covered by a thick layer of mud, of a different colour from that of the Atlantic ooze; and this mud has probably accumulated from untold ages by the incessant efflux of the Gironde, the Adour, and numerous other rivers and streams into the Bay of Biscay. As may be supposed, the fauna which inhabits such mud is very scanty; and it required a considerable amount of patience and perseverance to extract a few organisms from the unpromising material. No wonder that Dr. Carpenter was discouraged, as a zoologist, by what he termed "the singular barrenness of this deposit in regard to animal life," when he described the Mediterranean cruise of the *Porcupine* in 1870.

Within a few days after the return of the Expedition Prof. A. Milne-Edwards presented to the Academy of Sciences at Paris a Preliminary Report of the zoological results of the Expedition, which was published in the *Journal Officiel de la République Française*. As most of the departments of the marine Invertebrata have been so fully and carefully treated by him in this Report, I will content myself with a few supplementary remarks as to the Mollusca, which especially engaged my attention during the cruise. At the request of Dr. Fischer, who will undertake this department, and with the sanction of the President, I was entrusted with all the more critical specimens of Mollusca; and these specimens I have now cleaned, assorted, and compared with my own collection from the *Porcupine* Expedition of 1870, on the western coasts of Spain and Portugal. I subjoin a complete list of the *Travailleur* Mollusca, distinguishing in separate columns those species which are *Porcupine*, those which were previously known to me from Norway or the Mediterranean only, and those which I consider new to science. The total number of the species in this list is 152, out of which 138 are *Porcupine*, three only appear to be peculiarly northern, one peculiarly southern or Mediterranean, and eleven new to science.

The results, especially in the last-mentioned category, are most noteworthy. They serve to show how little we know of the deep-water Mollusca, when we reflect that the area of the sea-bed lately explored in a short period of time, and in a necessarily cursory manner, is but a very small corner of the Atlantic, and that it would take many years to complete the exploration so auspiciously commenced. The area traversed by the dredge during this cruise represents probably much less than a ten-thousandth part of the sea-bed lying between Cape Breton and Cape Pēnas; and our means of exploration by the dredge are by no means satisfactory, particularly on muddy ground, of which the deep-water zone is mainly composed. Instead of our being able to scrape a few inches of the surface of the sea-bed at considerable depths, so as to collect in the dredge all the animals which inhabit the superficial layer, we find too often, to our disappointment, that the dredge, when it reaches the bottom, sinks into the mud from its own weight and from the momentum given to it by the motion of the ship, and that it then acts as a subsoil plough, and not as a scraper. I must ask one of my engineering friends to devise some instrument more efficient than the modern dredge.

Although it cannot be positively stated that the abyssal zone, or even the benthal zone, is inhabited only by certain species of Mollusca, some species observed by me during the preparatory excursion to Cap Breton and the *Travailleur* cruise bear out the statement to some extent. For instance, *Nucula nitida*, *Dischides bifissus*, *Rissoa abyssicola* (a now inappropriate specific name), and *Defrancia decussata* occurred only in the shallow water excursion; while *Nucula corbuloïdes*, *Siphodentalium olivi*, *Rissoa deliciosa*, and *Defrancia hispidula*, occurred only in the deep-water cruize.

Several deep-water species of Mollusca occurred in this Expedition, which had been until lately supposed to be extinct; they are fossils of the Upper Tertiaries of Europe. For the Geological definition of this term see "British Conchology," vol. i. pp. 315, 316.

A curious provision of nature—if we may in these philosophical days use such a phrase—was observable in the case of

a deep-water mussel of considerable size, which I propose to name *Mytilus luteus*. It inhabits the layer of mud which I have above described, and moors or fixes itself by means of a large and densely-matted byssus which is spun by the foot. This byssus is capable of being spread over a considerable extent of surface; and it not only prevents the mollusk sinking into the soft mud and being smothered or buried alive, but enables it to feed comfortably on the innumerable animalcula which swarm on the surface of the sea-bed. It is of the same use to the mollusk as the snow-shoe is to the Arctic traveller. This species of Mytilus I at first took to be the *Modiola incurvata* of Philippi—*M. martorelli* of Hidalgo, which lives on the south coast of Spain in rather shallow water; but on comparison I am satisfied that they differ essentially in shape, sculpture, colour, and epidermis.

I cannot conclude this account without acknowledging my most grateful thanks to the French Government for their extremely generous conduct in my case and for the excellent hospitality which I enjoyed on board the *Travailleur*, as well as to the President and Members of the Scientific Commission for their obliging and friendly companionship.

The zoological results of this French Expedition are fully equal to those made by Capt. Baudon in 1801, M. d'Urville in 1829, the *Recherche* in 1835, the *Astrolabe* in 1841, and other French expeditions; and I sincerely hope that a further expedition of the present kind may take place next year in the Mediterranean, where our good and gallant neighbours have such an important stake.

The list of Mollusca referred to in this paper includes the following new species named or recognised by the author:—*Pecten obliquatus*, *Lima Jeffreysi* (Fischer), *Mytilus luteus*, *Modiolaria cuneata*, *Axinus tortuosus*, *Mytilimeria* (?) *Fischeri*, *Thracia tenera*, *Cadulus semistriatus*, *Rimula asturiana*, *Odostomia lineata*, and *Bullina elongata*. The species which he considers peculiarly northern are *Chiton alveolus*, G. O. Sars, *Fusus turgidulus*, Jeffreys, and *Pleurotoma nivalis*, Lovén; and the species which he considers peculiarly southern or Mediterranean is *Odostomia fasciatus*, Forbes.

THE SHOWER OF AUGUST PERSEIDS, 1880

THE August meteors were observed under peculiarly favourable circumstances this year. Not only was the moon entirely absent during the display, but the weather, which so frequently interrupts such observations, remained fine night after night, thus allowing an unbroken series of watches to be maintained from the 6th to the 13th, and enabling the rise and fall of the display to be distinctly traced from a comparison of the results obtained each night. On the 10th, however, when the maximum was expected, the state of the sky scarcely admitted of successful observation, and the number of shooting-stars recorded that night was below the experiences of past years, but it must be remembered that, this being leap year, the chief intensity of the shower was due earlier than usual, so that it may have occurred before the evening of the 10th, when observers generally were watching for its reappearance.

At Bristol the following summary was derived from observations by the writer:—

Date, 1880.	Length of watch.	Time of watch.	No. of meteors seen.	No. of Perseids.	Horary Nos. for one observer.		Chief radiant point.
					All meteors.	Perseids.	
	h.	h. h.					° °
August 6	1½	10 –11½	19	5	13	3	38 +56
7–8	4½	11 –14	112	54	25	12	41 +55
9	2½	11 –13½	111	71	44	28	44 +55
10	1½	10 –11½	50	41	34	28	45 +57
11	2½	10½–13	64	43	26	17	48 +57
12	2½	10½–13	45	19	18	8	
13	1½	10½–12	18	7	12	5	49½+57½
Aug. 6–13	16½	10–14	419	240	24·6	14·4	44 +56

The observed maximum occurred on the 9th, when, during a watch of 2½ hours, meteors were falling at the rate of 44 per hour (for one observer), and the proportion of Perseids was nearly two-thirds of the aggregate number visible. On the 10th the horary number of 34 was determined under less favourable conditions. A fog partially overspread the sky, rendering the stars dim, so that many small meteors passed unrecorded, and at 11½h. it was found impracticable to continue observations. The horary number of Perseids found on the 10th coincides with that of the preceding night, and it is obvious that, allowing for the clearer atmosphere of the 9th, the maximum of the display really occurred as usual on the 10th. It is fair to assume from the numbers actually counted in the fog-shrouded sky of the 10th that later in the night, as the radiant attained greater elevation, the meteors from Perseus were as numerous as during the few preceding apparitions of the shower. The brightest meteor observed at Bristol appeared at 13h. 37m., on August 8. The sky had become overcast except near the western horizon, where a few stars could still be distinguished. A vivid flash startled the observer, who, on looking towards the direction indicated, at once saw a brilliant meteor streak attached to the star γ Ophiuchi, and its position was such as to leave no doubt that it had been left by a magnificent Perseid. Other large meteors were registered as follows:—

	Time.	Mag.	Path		Length.
			From	To	
	h. m.				
August 6	10 52½	♂	51 +66	60 +70	6
7	10 49	♂	265 −10	261½ −19	10
7	12 0	♂	329 +10	327½ ± 0	12
7	12 25	< ♀	55 +53	64 +50	6
7	12 54	♂	52 +48½	55 +45	4
8	10 5	♂	61 +72	109 +76	13
8	11 14	♂	314½ − 2	306 −18	17
8	11 32	♂	16 +46	2 +36½	14
8	12 8	♂	324 +43	310 +30	17
8	12 49	< ♃	28 +44	24 +39½	5
9	11 35	♂	36 +33	35 +27	6
9	12 5	♂	36 +34	33½ +28	7
9	12 23	> ♀	332 + 7	320 −10	20
9	12 40	♃	122 +73	158 +66½	14
10	10 29	♃	316 +81	259 +67	19
10	11 11	♃	327 +55	303 +37	24
11	9 20	♃	291 +12	292 − 3	15
11	10 40	♂	331 +47	312 +28	23½
11	11 10	♂	322 +15	304 −10	30
11	11 52	♂	343 +20	332 + 3	19
12	11 15	♂	322 +49	328 +30	19½

These meteors all belonged to the shower of Perseids. Motions very swift. They all left bright streaks.

The radiant point showed a displacement on nearly every successive night of observation. It was noted at $38° + 56°$ on the 6th, yet on the 13th a few meteors indicated it very exactly at $49\frac{1}{2}° + 57\frac{1}{2}°$. This corroborates observations made by the writer in 1877, and reported in NATURE, vol. xvi. p. 362. A large number of Perseids were seen that year, and from an exact record of their flights the radiant point was seen to advance in R.A. as follows:—

$$\begin{array}{rl} & \quad\alpha \quad\;\; \delta \\ \text{1877, August } 3\text{–}7 & = 40° + 56° \\ 10 & = 43° + 58° \\ 12 & = 50 + 56° \\ 16 & = 60° + 59° \end{array}$$

This is further borne out by Mr. Henry Corder's extensive observations at Writtle, near Chelmsford, during the recent display, which may be tabulated as under:—

1880.	Watch.	Time.	Meteors seen.	Perseids.	Radiant point.
	h.	h.			
August 1	2½	9½–12	25	9	35 + 56
2	1¾	10½–12¼	21	7	35 + 56
4	2	10 –12¼	35	13	46 + 57
6	¾	10 –10½ 14 –14¼	13	6	43 + 56
8	2½	10 –13	59	26	45 + 59
9	4½	9 –13½	120	84	45 + 58
10	1	9 –12	46	39	—
11	3	9 –13	76	50	46 + 58
Aug. 1–11	17½	9 –14½	395	234	

Mr. Corder places the average position of the radiant of the true Perseids at $45° + 58°$. On the first few nights of August he found it well defined at $35° + 56°$, though on the 11th it had apparently shifted to $46° + 58°$. And it is to be remarked that

on July 29-30 Mr. Corder had seen a shower of twenty meteors from the point 29° + 56°, which no doubt represented the first on-coming of the Perseids.

The night of August 10 at Mr. Corder's station was very hazy and generally overcast, so that though he was watching during the three hours preceding midnight, he estimated that his observation was not more than an equivalent to one hour of clear sky. He reckoned that under favourable conditions of the atmosphere the Perseids were falling at the rate of 40 per hour. Only one meteor he saw on the 10th was a fine one about = ♃. It appeared at 11h. 23m. rather low in Ursa It was rich orange in colour, with a long narrow streak broken in the middle. On August 11 Mr. Corder found meteors scarce; the shower had evidently fallen off considerably. The horary numbers found at Bristol were 26 of all meteors and 17 of Perseids, which very closely corresponds with Mr. Corder's figures, for, observing for three hours, he saw 76 meteors, amongst which were 50 Perseids. He mentions several instances in which the Perseid streaks were broken, and the same feature was frequently observed at Bristol. In such cases the nucleus had several maxima, and the streak-producing power seemed intensified at the point of each outburst.

Mr. Corder mentions a bright aurora as visible on the 11th and 12th instant. They were seen at Bristol also, but the phenomenon of the 12th was by far the most conspicuous. At about 10h. 20m. there was a vivid arch of crimson light spanning the horizon below the stars $\beta - \gamma$ of Ursa Major, and the whole northern quadrant was aglow with streamers. But it soon lost its striking character, though there were indications of streamers at a much later period, and an auroral glow was apparent above the north-west horizon as late as 14h. It was also seen by the Rev. S. J. Johnson at Mitcheldean, Glos., who writes:—"On the 12th there was a somewhat striking display of aurora. It began at 10h. 29m., and was bounded on the east by Capella, and on the west by Arcturus. The columns were often very vivid, but the brilliant character of the phenomenon only lasted 12 minutes."

Major Tupman observing at Cookham, near Maidenhead, Berks, reports the weather very cloudy on August 8, after 11h. 34m. In one hour (10h. 34m.—11h. 34m.) 13 meteors were seen, of which all but 2 were Perseids. August 9 very clear, and the sky watched from 9h. 56m. to 12h. 5m., when 31 meteors were seen, including 28 Perseids and 3 Cygnids. August 10—watch sustained from 9h. 5m. to 10h. 43m., when 15 or 16 Perseids were noted, and a few other small meteors. Sky clouded up at 10h. 43m. August 11 cloudy. Partly clear at 10h. 55m., and 3 Perseids observed, but at 11h. 9m. it again became overcast, and prevented further observation. The radiant point derived from a number of very accurately observed paths on August 9 was at 44° + 56°, with indications of a sub-radiant 4° higher in declination.

The Rev. G. T. Ryves, of Stoke-on-Trent, writes as follows:—

"August 8—10h. to 11h.—19 meteors seen, of which not more than 10 or 11 were Perseids. Soon after 11h. clouds formed, and interrupted further watching.

August 9, 9h. 45m. to 11h., 65 meteors seen.
,, 11h. to 12h. 45m., 30 meteors seen.

"From 80 to 85 were Perseids. The falling off in numbers after 11h. is only apparent, as up to that time I had been assisted by two pairs of eyes, and owing to my defective sight many of the smaller meteors would have escaped me afterwards,

"August 10, 9h. 30m. to 11h. 30m., 126 meteors seen. Nearly all of these were Perseids. During the whole of this period I was assisted by the two young observers above alluded to. Several brilliant meteors were recorded. On August 9, 12h. 25m., one was imperfectly seen in the Milky Way near horizon, in S.W., moving about S.W." This is obviously the same as one described at Bristol at 12h. 23m. the same night.

Another was seen by Mr. Ryves at 12h. 35m., August 9, moving very slightly west of, and parallel to, the stars δ and γ of Cygnus, and at 11h. 2m., August 10, a fine meteor shot towards Aquila, the end point being noted slightly below and west of Altair. These meteors were evidently Perseids, though Mr. Ryves saw only a small proportion of brilliant meteors. He remarks: "The most noticeable feature in this year's display has been the great falling off in the average brightness of the meteors as compared with former years. Of the 240 meteors seen here not more than a dozen were such as would have attracted the attention of any one but trained observers, the great majority requiring rather exceptionally keen eyes to detect them at all."

Mr. Cornish, at Debenham, Suffolk, gives the following summary of watches between August 1 and 12:—

		Meteors.		Observers.
August 1, 10h. 15m. to 11h. 40m.	...	13	...	V. Cornish
9, 10h. to 11h.	...	23	...	H. Heather
9, 10h. 40m. to 11h. ...	...	13	...	V. Cornish
11, 9h. 48m. to 11h. 38m.	...	56	...	V. Cornish
12, 9h. 3m. to 9h. 33m. ...	...	6	...	H. Heather

On the 11th no less than 24 were noted during the first half-hour's observation. The sky was partly cloudy after 11h. A 1st mag. stationary meteor was seen at 348½ − 23 on August 4, at 13h. 48m. On August 9, 10h. 23m., a meteor = Sirius shot from 0° + 37° to 349° + 28°, and it appears to be identical with a fine meteor registered by Mr. Ryves at Stoke-on-Trent, August 9, 10h. 25m., path from α Andromedæ to α Pegasi. Mr. Cornish remarks that "the recent display of Perseids was not equal to that of last year, even supposing the circumstances to have been as favourable." It must be remembered, however, that on the all-important night of August 10 few observations could be obtained, owing to the generally unfavourable state of the sky, and that under these conditions a comparison cannot fairly be instituted. Mr. Corder estimated the horary rate of Perseids as 40 per hour on the 10th; and at Bristol, where the stars could only be seen in dim outline through the fog-laden atmosphere, the number actually counted at an early period of the night was 28 per hour. This compares favourably with the last successful observation of this shower obtained by the writer in 1877, when, with a perfectly clear sky, 57 Perseids were noted between 9½h. to 11h., = 38 per hour. Making allowance for the difference of weather, the recent display, though it cannot be regarded as in any way exceptional, may yet be classed as a fairly active return of the shower; and it is fortunate that on the several nights immediately preceding and following the 10th, the state of the sky allowed its progress to be traced with unusual distinctness.

The Rev. S. J. Johnson, at Abbenhall Rectory, Mitcheldean, Glos., saw 20 meteors during an hour's watch (10h. 57m. to 11h. 57m.) on August 9. The following night there was much cloud about at times, especially in the eastern sky, so that only 16 meteors were seen between 10h. 3m. and 11h. 3m. On the 11th the night was very clear, and 12 meteors seen between 10h. and 11h. Mr. Johnson gives a list of the brighter meteors, which includes several nearly equal to Jupiter, and many 1st magnitude.

The night of the 9th appears to have been very favourable at all stations, and more shooting-stars were seen on that date than on the 10th, when the sky was in part overcast. On the 11th there was a very evident falling-off in the number of meteors observed at Chelmsford and Bristol, the horary rate of apparition of the Perseids being noted as 17 at both places. The following night it had fallen to 8, and on the 13th to 5, as derived from observations at Bristol, and the absolute cessation of the shower was evidently near at hand.

W. F. Denning

INTERNATIONAL METEOROLOGY

The International Meteorological Committee appointed by the Congress of Rome held its first meeting at the Observatory, Berne, from the 9th to the 12th ultimo. All the members of the Committee, nine in number, were present. Their names are as follows:—

Prof. H. Wild (president), Mr. R. H. Scott (secretary), Professors Buys Ballot and Cantoni, Capt. de Brito Capello, Professors Hann, Mascart, and Mohn, and Dr. Neumayer. The following is a brief notice of the most interesting results of the meeting:—

The International Comparison of Standard Instruments.—The original scheme for this undertaking was based on the supposition that thirty-six European observatories would take part in it, each paying a contribution of about 15*l*. The number of acceptances of the proposal up to the date of the meeting was, however, insufficient to justify the Committee in commencing the comparison, and it was therefore determined to recommend each country to carry out a careful comparison of its own standard instruments with those of neighbouring countries.

The International Simultaneous Observations.—The proposal recently made by the Chief Signal Office, Washington, to change

the time of this observation from 0h. 43m. to 0h. 8m. p.m. was discussed, and it was resolved to accede to the proposal, notwithstanding the inconvenience which the change might entail in individual systems of observation.

The Proposal for Concerted Arctic Observations.—The International Polar Commission appointed at Hamburg, in October, 1879, presented a report of a meeting it had recently held at Berne, and announced that Count Wilczek and Lieut. Weyprecht had consented to postpone their expedition to Nova Zembla until 1882 in order to allow of more time for the organisation of the other expeditions destined to co-operate with them. The International Committee resolved to aid the scheme by all the means in their power.

The Publication of Data referring to Rain, &c.—A proposal made by Dr. Köppen for an improved method of publication of information relating to rain, snow, &c., was ordered to be circulated among the different observatories, in order to obtain opinions as to its suitability.

Telegraphic Communication with the Atlantic Islands.—Capt. Hoffmeyer submitted a resolution as to the desirability of laying cables to the Faroes, Iceland, Greenland, and to the Azores. The Committee expressed their hope that it might be found possible to lay these cables, which would be of very great importance for the weather service of Europe.

The Publicaeion of Average Values for Meteorological Data.—The Committee, at Capt. Hoffmeyer's suggestion, recommended that all meteorological organisations should publish regularly the mean values for the most important elements for the telegraphic and international stations.

The Catalogue of Meteorological Literature.—A proposal made by Dr. Hellmann of Berlin for the preparation of such a catalogue was considered. Dr. Hellmann stated that he had calculated the cost of preparation of the catalogue of printed books and memoirs at about 550*l.*, and that of printing and publication (1,000 copies) at about 750*l.*

Several of the members of the Committee promised to aid in carrying out the scheme, if it were seriously undertaken, by the preparation of catalogues of the literature which exists in their own individual languages. The subject was finally referred to Mr. Scott and Dr. Hellmann, with power to act if they found sufficient encouragement.

As to the catalogue of unpublished records of observations, no definite resolution was adopted.

International Tables for the Reduction of Observations.—It was stated that a publishing firm in Leipzig was prepared to print and publish such tables at its own risk if the "copy" were delivered to them. The subject was referred to Prof. Mascart and Prof. Wild for the preparation of a definite plan for the calculation of the tables.

The Committee will include in its Report, which will shortly appear, a notice of the progress made in each country in carrying out the resolutions of the Congress of Rome.

It only remains to say that the members of the Committee were most hospitably entertained by the Federal Council and by the Municipality of Berne.

AGRICULTURAL CHEMISTRY[1]

SOME of my predecessors in this chair, whose duties as teachers of chemistry lead them to traverse a wide range of the subject every year, have appropriately and usefully presented to the Section a *résumé* of the then recent progress in the manifold branches of the science which have now such far-reaching ramifications. Some, on the other hand, have confined attention to some department with which their own inquiries have more specially connected them.

But it seems to me that there is a special reason why I should bring the subject of Agricultural Chemistry before you on the present occasion. Not only is the application of chemistry to agriculture included in the title of this Section, but in 1837 the Committee of the Section requested the late Baron Liebig to prepare a report upon the then condition of Organic Chemistry, and it is now exactly forty years since Liebig presented to the British Association the first part of his report, which was entitled "Organic Chemistry in its Applications to Agriculture and Physiology"; and the second part was presented two years later, in 1842, under the title of "Animal Chemistry, or Organic Chemistry in its Application to Physiology and Pathology." Yet, so far as I am aware, no President of the Section has, from that time to the present, taken as the subject of his address the Application of Chemistry to Agriculture.

[1] Opening Address in Section B (Chemical Science), at the Swansea meeting of the British Association, by J. H. Gilbert, Ph.D., F.R.S., V.P.C.S., F.L.S., President of the Section.

Appropriate as, for these reasons, it would seem that I, who have devoted a very large portion of the interval since the publication of Liebig's works, above referred to, to agricultural inquiries, should occupy the short time that can be devoted to such a purpose in attempting to note progress on that important subject, it will be readily understood that it would be quite impossible to condense into the limits of an hour's discourse anything approaching to an adequate account, either of the progress made during the last forty years, or of the existing condition of agricultural chemistry.

For what is agricultural chemistry? It is the chemistry of the atmosphere, the chemistry of the soil, the chemistry of vegetation, and the chemistry of animal life and growth. And but a very imperfect indication of the amount of labour which has been devoted of recent years to the investigation of these various branches of what might at first sight seem a limited subject will suffice to convince you how hopeless a task it would be to seek to do more than direct attention to a few points of special interest.

From what we now know of the composition and of the sources of the constituents of plants, it is obvious that a knowledge of the composition of the atmosphere and of water was essential to any true conception of the main features of the vegetative process; and it is of interest to observe that it was almost simultaneously with the establishment, towards the end of the last century, of definite knowledge as to the composition of the air and of water, that their mutual relations with vegetation were first pointed out. To the collective labours of Black, Scheele, Priestly, Lavoisier, Cavendish, and Watt, we owe the knowledge that common air consists chiefly of nitrogen and oxygen, with a little carbonic acid; that carbonic acid is composed of carbon and oxygen; and that water is composed of hydrogen and oxygen; whilst Priestly and Ingenhousz, Sennebier and Woodhouse, investigated the mutual relations of these bodies and vegetable growth. Priestly observed that plants possessed the faculty of purifying air vitiated by combustion or by the respiration of animals; and, he having discovered oxygen, it was found that the gaseous bubbles which Bonnet had shown to be emitted from the surface of leaves plunged in water consisted principally of that gas. Ingenhousz demonstrated that the action of light was essential to the development of these phenomena; and Sennebier proved that the oxygen emitted resulted from the decomposition of the carbonic acid taken up.

De Saussure concluded that air and water contributed a much larger proportion of the dry substance of plants than did the soils in which they grew. In his view a fertile soil was one which yielded liberally to the plant nitrogenous compounds, and the incombustible or mineral constituents; whilst the carbon, hydrogen, and oxygen, of which the greater proportion of the dry substance of the plant was made up, were at least mainly derived from the air and water.

Perhaps I ought not to omit to mention here that, each year for ten successive years, from 1802 to 1812, Sir Humphry Davy delivered a course of lectures on the "Elements of Agricultural Chemistry," which were first published in 1813, were finally revised by the author for the fourth edition in 1827, but have gone through several editions since. In those lectures Sir Humphry Davy passed in review and correlated the then existing knowledge, both practical and scientific, bearing upon agriculture. He treated of the influences of heat and light; of the organisation of plants; of the difference, and the change, in the chemical composition of their different parts; of the sources, composition, and treatment of soils; of the composition of the atmosphere, and its influence on vegetation; of the composition and the action of manures; of fermentation and putrefaction; and finally of the principles involved in various recognised agricultural practices.

With the exception of these discourses of Sir Humphry Davy, the subject seems to have received comparatively little attention, nor was any important addition made to our knowledge in regard to it during the period of about thirty years from the date of the appearance of De Saussure's work in 1804 to that of the commencement of Boussingault's investigations.

In 1837 Boussingault published papers on the amount of gluten in different kinds of wheat, on the influence of the clearing of forests on the diminution of the flow of rivers, and on the

meteorological influences affecting the culture of the vine. In 1838 he published the results of an elaborate research on the principles underlying the value of a rotation of crops. He determined by analysis the composition, both organic and inorganic, of the manures applied to the land, and of the crops harvested. In his treatment of the subject he evinced a clear perception of the most important problems involved in such an inquiry; some of which, with the united labours of himself and many other workers, have scarcely yet received an undisputed solution.

Thus, in the same year (1838), he published the results of an investigation on the question whether plants assimilate the free or uncombined nitrogen of the atmosphere; and although the analytical methods of the day were inadequate to the decisive settlement of the point, his conclusions were in the main those which much subsequent work of his own, and much of others also, has served to confirm.

The foregoing brief historical sketch is sufficient to indicate, though but in broad outline, the range of existing knowledge on the subject of agricultural chemistry prior to the appearance of Liebig's memorable work in 1840. It will be seen that some very important and indeed fundamental facts had already been established in regard to vegetation, and that Boussingault had not only extended inquiry on that subject, but he had brought his own and previous results to bear upon the elucidation of long recognised agricultural practices. There can be no doubt that the data supplied by his researches contributed important elements to the basis of established facts upon which Liebig founded his brilliant generalisations. Accordingly, in 1841, Dumas and Boussingault published jointly an essay which afterwards appeared in English under the title of "The Chemical and Physiological Balance of Organic Nature;" and in 1843 Boussingault published a larger work, which embodied the results of many of his own previous original investigations.

The appearance of Liebig's two works, which were contributions made in answer to a request submitted to him by the committee of this Section of the British Association, constitute a very marked epoch in the history of the progress of agricultural chemistry. In the treatment of his subject he not only called to his aid the previously existing knowledge directly bearing upon it, but he also turned to good account the more recent triumphs of organic chemistry, many of which had been won in his own laboratory. Further, a marked feature of his expositions was the adoption of what may be called the *statistical* method—I use the word statistical rather than quantitative, as the latter expression has its own technical meaning among chemists, which is not precisely what I wish to convey.

The discussion of the processes of fermentation, decay, and putrefaction, and that of poisons, contagions, and miasms, constituted a remarkable and important part of Liebig's first report. It was the portion relating to poisons, contagions, and miasms, that he presented to this Section as an instalment, at the meeting of the Association held at Glasgow in 1840. It was in the chapters relating to the several subjects here enumerated that he developed so prominently his views on the influence of contact in inducing chemical changes. He cited many known transformations, other than those coming under either of the heads in question, in illustration of his subject; and he discussed with great clearness the different conditions occurring, and the different results obtained, in various processes—such as the different modes of fermenting beer, the fermentation of wine from different kinds of grapes, the production of acetic acid, &c. As is well known, he claimed a purely chemical explanation for the phenomena involved in fermentation. He further maintained that the action of contagions was precisely similar. In his latest writings on the subject (in 1870) he admits some change of view; but it is by no means easy to decide exactly how much or how little of modification he would wish to imply.

Liebig's second report, presented at the meeting of this Association in 1842, and published under the title of "Animal Chemistry, or Organic Chemistry in its Applications to Physiology and Pathology," perhaps excited even more attention than his first; and, probably from the manner as much as from the matter, aroused a great deal of controversy, especially among physiologists and physicians. Liebig was severe upon what he considered to be a too exclusive attention to morphological characters in physiological research, and at any rate too little attention to chemical phenomena, and, so far as these were investigated, an inadequate treatment of the subject according to strictly quantitative methods.

Omitting the fat which the carnivora might receive in the animals they consumed, he stated the characteristic difference between the food of carnivora and herbivora to be, that the former obtained the main proportion of their respiratory material from the waste of tissue; whilst the latter obtained a large amount from starch, sugar, &c. These different conditions of life accounted for the comparative leanness of carnivora and fatness of herbivora.

He maintained that the vegetable food consumed by herbivora did not contain anything like the amount of fat which they stored up in their bodies; and he showed how nearly the composition of fat was obtained by the simple elimination of so much oxygen, or of oxygen and a little carbonic acid, from the various carbohydrates. Much less oxygen would be required to be eliminated from a quantity of fibrine, &c., containing a given amount of carbon, than from a quantity of carbohydrates containing an equal amount of carbon. The formation of fatty matter in plants was of the same kind; it was the result of a secondary action, starch being first formed from carbonic acid and water.

He concluded from the facts adduced that the food of man might be divided into the *nitrogenised* and the *non-nitrogenised* elements. The former were capable of conversion into blood, the latter incapable of such transformation. The former might be called the *plastic elements of nutrition*, the latter *elements of respiration*. From the plastic elements, the membranes and cellular tissue, the nerves and brain, cartilage, and the organic part of bones, could be formed; but the plastic substance must be received ready-made. Whilst gelatine or chondrine was derived from fibrine or albumen, fibrine or albumen could not be reproduced from gelatine or chondrine. The gelatinous tissues suffer progressive alteration under the influence of oxygen, and the materials for their re-formation must be restored from the blood. It might however be a question whether gelatine taken in food might not again be converted into cellular tissue, membrane, and cartilage, in the body.

Apparently influenced by the physiological considerations which have been adduced, and notwithstanding in some passages he seemed to recognise a connection between the total quantity of oxygen inspired and consumed and the quantity of mechanical force developed, Liebig nevertheless very prominently insisted that the amount of muscular tissue transformed—the amount of nitrogenous substance oxidated—was the measure of the force generated. He accordingly distinctly draws the conclusion that the requirement for the azotised constituents of food will be increased in proportion to the increase in the amount of force expended.

It will be obvious that the question whether in the feeding of animals for the exercise of mechanical force, that is, for their labour, the demands of the system will be proportionally the greater for an increased supply of the nitrogenous or of the non-nitrogenous constituents of food, is one of considerable interest and practical importance. To this point I shall have to refer further on.

So far, I have endeavoured to convey some idea of the state of knowledge on the subject of the chemistry of agriculture prior to the appearance of Liebig's first two works bearing upon it, and also briefly to summarise the views he then enunciated in regard to some points of chief importance. Let us next try to ascertain something of the influence of his teaching.

Confining attention to agricultural research, it may be observed that about the year 1843, that is very soon after the appearance of the works in question, there was established the Chemico-Agricultural Society of Scotland, which was, I believe, broken up, after it had existed about five years, because its able chemist, the late Prof. Johnston, was unable to find a remedy for the potato disease. Shortly after this, the Highland and Agricultural Society of Scotland appointed a consulting chemist; somewhat later the Royal Agricultural Society of England did the same; and later still followed the Chemico-Agricultural Society of Ulster. Lastly, the very numerous "Agricultural Experimental Stations" which have been established, not only in Germany, but in most Continental States, owe their origin directly to the writings, the teachings, and the influence of Liebig. The movement seems to have originated in Saxony, where Stöckhardt had already stimulated interest in the subject by his lectures and his writings. After some correspondence, in 1850–51, between the late Dr. Crucius and others on the one side, and the Government on the other, the first so-called "Agricultural Experimental Sta-

tion" was established at Möchern, near Leipzig, in 1851-52. In 1877 the twenty-fifth anniversary of the foundation of that institution was celebrated at Leipzig, when an account (which has since been published) was given of the number of stations then existing, of the number of chemists engaged, and of the subjects which had been investigated. From that statistical statement we learn that in 1877 the number of stations was 122.

Besides these stations on the Continent of Europe, the United States are credited with one, and Scotland also with one.

Each of these stations is under the direction of a chemist, frequently with one or more assistants. One special duty of most of them is what is called manure- or seed- or feeding-stuff-control; that is, to examine or analyse, and report upon such substances in the market, and it seems to have been found to the interest of dealers in these commodities to submit their proceedings to a certain degree of supervision by the chemist of the station of their district.

But agricultural research has always been a characteristic feature of these institutions. It is stated that the investigation of soils has been the prominent object at 16 of them, experiments with manures at 24, vegetable physiology at 28, animal physiology and feeding experiments at 20, vine culture and wine making at 13, forest culture at 9, and milk production at 11. Others, according to their locality, have devoted special attention to fruit culture, olive culture, the cultivation of moor, bog, and peat land, the production of silk, the manufacture of spirit, and other products.

Nor does this enumerations of the institutions established as the direct result of Liebig's influence, and of the subjects investigated under their auspices, complete the list either of the workers engaged, or of the work accomplished in agricultural research. To say nothing of the labours of Boussingault, which commenced some years prior to the appearance of Liebig's first work, and which are fortunately still at the service of agriculture, important contributions have been made by the late Professors Johnston and Anderson in Scotland, and in this country both by Mr. Way and Dr. Voelcker, each alike in his private capacity, and in fulfilment of his duties as Chemist to the Royal Agricultural Society of England. Nor would it be fair to Mr. Lawes (who commenced experimenting first with plants in pots, and afterwards in the field, soon after entering into possession of his property in 1834, and with whom I have myself been associated since 1843), were I to omit in this place any mention of the investigations which have been so many years in progress at Rothamsted.

So much for the machinery; but what of the results achieved by all this activity in the application of chemistry to agriculture?

The more I have looked at the subject with the hope of treating it comprehensively, the more I have been impelled to substitute a very limited plan for the much more extended scheme which I had at first hoped to be able to fill up. I propose then to confine attention to a few special points, which have either some connection with one another, or to which recent results or discussions lend some special interest.

First as to the sources and the assimilation of the carbon, the hydrogen, and the oxygen of vegetation. From the point of view of the agricultural chemist, the hydrogen and the oxygen may be left out of view. For, if the cultivator provide to the plant the conditions for the accumulation of sufficient nitrogen and carbon, he may leave it to take care of itself in the matter of hydrogen and oxygen. That the hydrogen of the carbohydrates is exclusively obtained from water, is, to say the least, probable; and whether part of their oxygen is derived from carbonic acid, and part from water, or the whole from either of these, will not affect his agricultural practice.

With regard to the carbon, the whole tendency of subsequent observations is to confirm the opinion put forward by Dr. Saussure about the commencement of the century, and so forcibly insisted upon by Liebig forty years later—that the greater part, if not the whole of it, is derived from the carbonic acid of the atmosphere. Indeed, direct experiments are not wanting—those of Moll, for example—from which it has been concluded that plants do not even utilise the carbonic acid which they may take up from the soil by their roots. However this may be, we may safely conclude that practically the whole of the carbon which it is the object of the cultivator to force the plants he grows to take up is derived from the atmosphere, in which it exists in such extremely small proportion, but nevertheless large actual, and constantly renewed amount.

Judging from the more recent researches on the point, it would seem probable that the estimate of one part of carbon, as carbonic acid, in 10,000 of air, is more probably too high than too low as an estimate of the average quantity in the atmosphere of our globe. And, although this corresponds to several times more in the column of air resting over an acre of land than the vegetation of that area can annually take up, it represents an extremely small amount at any one time in contact with the growing plants, and could only suffice on the supposition of a very rapid renewal accomplished as the result, on the one hand, of a constant return of carbonic acid to the atmosphere by combustion and the respiration of animals, and, on the other, of a constant interchange and equalisation among the constituents of the atmosphere.

It will convey a more definite idea of what is accomplished by vegetation in the assimilation of carbon from the atmosphere if I give, in round numbers, the results of some direct experiments made at Rothamsted, instead of making general statements merely.

In a field which has now grown wheat for thirty-seven years in succession there are some plots to which not an ounce of carbon has been returned during the whole of that period. Yet, with purely mineral manure, an average of about 1,000 pounds of carbon is annually removed from the land; and where a given amount of nitrogenous manure is employed with the mineral manure, an average of about 1,500 pounds per acre per annum more is obtained; in all an average of about 2,500 pounds of carbon annually assimilated over an acre of land without any return of carbonaceous manure to it.

In a field in which barley has been grown for twenty-nine years in succession, quite accordant results have been obtained. There smaller amounts of nitrogenous manure have been employed with the mineral manure than in the experiments with wheat above cited; but the increase in the assimilation of carbon for a given amount of nitrogen supplied in the manure is greater in the case of the barley than of the wheat.

With sugar-beet again, larger amounts of carbon have been annually accumulated without the supply of any to the soil, but under the influence of a liberal provision of both nitrogenous and mineral manure, than by either wheat or barley.

Lastly, with grass, still larger amounts of carbon have been annually accumulated, without any supply of it by manure.

Many experiments have been made in Germany and elsewhere, to determine the amount of the different constituents taken up at different periods in the growth of various plants. But we may refer to some made at Rothamsted long ago to illustrate the rapidity with which the carbon of our crops may be withdrawn from the atmosphere.

In 1847 we carefully took samples from a growing wheat crop at different stages of its progress, commencing on June 21, and in these samples the dry matter, the mineral matter, the nitrogen, &c., were determined. On each occasion the produce of two separate eighths or sixteenths of an acre was cut and weighed, so that the data were provided to calculate the amounts of the several constituents which had been accumulated per acre at each period. The result was that, whilst during little more than five weeks from June 21 there was comparatively little increase in the amount of nitrogen accumulated over a given area, more than half the total carbon of the crop was accumulated during that period.

I should say that determinations of carbon, made in samples of soil taken from the wheat-field at different periods during recent years, indicate some decline in the percentage of carbon in the soils, but not such as to lead to the supposition that the soils have contributed to the carbon of the crops. Besides the amount of carbon annually removed, there will of course be a further accumulation in the stubble and roots of the crops; and the reduction in the total carbon of the soil, if such have really taken place, would show that the annual oxidation within the soil is greater than the annual gain by the residue of the crops.

Large as is the annual accumulation of carbon from the atmosphere over a given area in the cases cited, it is obvious that the quantity must vary exceedingly with variation of climatal conditions. It is, in fact, several times as great in the case of tropical vegetation—that of the sugar-cane, for example. And not only is the greater part of the assimilation accomplished within a comparatively small portion of the year (varying of course according to the region), but the action is limited to the hours of daylight, whilst during darkness there is rather loss than gain.

But it is remarkable that whilst the accumulation of carbon, the chief gain of solid material, takes place under the influence

of light, cell-division, cell-multiplication, increase in the structure of the plant, in other words, what, as distinguished from assimilation, vegetable physiologists designate as *growth*, takes place, at any rate chiefly, during the night; and is accompanied, not with the taking up of carbonic acid and the yielding up of oxygen, but with the taking up of oxygen and the giving up of carbonic acid. This evolution of carbonic acid during darkness must obviously be extremely small, compared with the converse action during daylight, coincidentally with which practically the whole of the accumulation of solid substance is accomplished. But as the product of the night action is the same as in the respiration of animals, this is distinguished by vegetable physiologists as the respiration of plants.

I suppose I shall be considered a heretic if I venture to suggest that it seems in a sense inappropriate to apply the term *growth* to that which is associated with actual loss of material, and that the term *respiration* should be applied to so secondary an action as that as the result of which carbonic acid is given off from the plant. It may, I think, be a question whether there is any advantage in thus attempting to establish a parallelism between animal and vegetable processes; rather would it seem advantageous to keep prominently in view their contrasted, or at any rate complementary characteristics, especially in the matter of the taking up of carbonic acid and the giving up of oxygen on the one hand, and the taking in of oxygen and the giving up of carbonic acid on the other.

But it is obvious that in latitudes where there is comparatively continuous daylight during the periods of vegetation, the two actions—designated respectively assimilation and growth—must go on much more simultaneously than where there is a more marked alternation of daylight and darkness. In parts of Norway and Sweden, for example, where during the summer there is almost continuous daylight, crops of barley are grown with only from six to eight weeks intervening from seed-time to harvest. And Prof. Schübeler, of Christiania, after making observations on the subject for nearly thirty years, has recently described the characteristics of the vegetation developed under the influence of short summers with almost continuous light. He states that, after acclimatisation, many garden flowers increase in size and depth of colour; that there is a prevailing tinge of red in the plants in the fields; that the aroma of fruits is increased, and their colour well developed, but that they are deficient in sweetness; and that the development of essential oils in certain plants is greater than in the same plants grown in other latitudes. Indeed he considers it to be an established fact that light bears the same relation to aroma as heat does to sweetness.

In connection with this question of the characters of growth under the influence of continuous light, compared with those developed with alternate light and darkness, the recent experiments of Dr. Siemens on the influence of electric light on vegetation are of considerable interest.

In one series of experiments he kept one set of plants entirely in the dark, a second he exposed to electric light only, a third to daylight only, and a fourth to daylight and afterwards to electric light from 5 to 11 p.m. Those kept in the dark acquired a pale yellow colour, and died; those exposed to electric light only maintained a light green colour, and survived; those exposed to daylight were of a darker green colour, and were more vigorous; and, lastly, those submitted to alternate daylight and electric light, and but a few hours of darkness, showed decidedly greater vigour, and, as he says, the green of the leaf was of a dark rich hue. He concluded that daylight was twice as effective as electric light; but that, nevertheless, "electric light was clearly sufficiently powerful to form chlorophyll and its derivatives in the plants."

In a second series of experiments one group of plants was exposed to daylight alone; a second to electric light during eleven hours of the night, and was kept in the dark during the day; and a third to eleven hours day, and eleven hours electric light. The plants in daylight showed the usual healthy appearance; those in alternate electric light and darkness were for the most part of a lighter colour; and those in alternate daylight and electric light far surpassed the others in darkness of green and vigorous appearance generally.

I have carefully considered these general descriptions with a view to their bearing on the question whether the characters developed under the influence of electric light, and especially those under the influence of almost continuous light, are more prominently those of assimilation or of growth; but I have not been able to come to a decisive opinion on the point. From some conversation I had with Dr. Siemens on the subject, I gather that the characteristics were more those of dark colour and vigour than of tendency to great extension in size. The dark green colour we may suppose to indicate a liberal production of chlorophyll; but if the depth of colour was more than normal it might be concluded that the chlorophyll had not performed its due amount of assimilation work. In regard to this point attention may be called to the fact that Dr. Siemens refers to the abundance of the blue or actinic rays in the electric arc, conditions which would not be supposed specially to favour assimilation. On the other hand, the vigour, rather than characteristic extension in size, would seem to indicate a limitation of what is technically called growth, under the influence of the almost continuous light.

Among the numerous field experiments made at Rothamsted, we have many examples of great variation in depth of green colour of the vegetation growing on plots side by side under known differences as to manuring; and we have abundant evidence of difference of composition, and of rate of carbon-assimilation, coincidently with these different shades of colour. One or two instances will strikingly illustrate the point under consideration.

The point of special interest is, however, that all but identically the same amount of nitrogen has been taken up by the herbage growing with the deficiency of potass as by that with the continued supply of it. The colour of the vegetation with the deficiency of potass has been very much darker green than that with the full supply of it.

An equal amount of nitrogen was taken up in both cases, chlorophyll was abundantly produced, but the full amount of carbon was not assimilated. In other words, the nitrogen was there, the chlorophyll was there, there was the same sunlight for both plots; but the assimilation-work was not done where there was not a due supply of potass.

It may be stated generally that, in comparable cases, depth of green colour, if not beyond a certain limit, may be taken to indicate corresponding activity of carbon assimilation; but the two instances cited are sufficient to show that we may, so far as the nitrogen, the chlorophyll, and the light are concerned, have the necessary conditions for full assimilation, but not corresponding actual assimilation.

It cannot, I think, fail to be recognised that in these considerations we have opened up to view a very wide field of research, and some of the points involved we may hope will receive elucidation from the further prosecution of Dr. Siemens's experiments. He will himself, I am sure, be the first to admit that what he has already accomplished has done more in raising than in settling important questions. I understand that he proposes to submit plants to the action of the separated rays of his artificial light, and the results obtained cannot fail to be of much interest. But it is obvious that the investigation should now pass from its present initiative character to that of a strictly quantitative inquiry. We ought to know not only that, under given conditions as to light, plants acquire a deeper green colour, and attain maturity much earlier than under others, but how much matter is assimilated in each case, and something also of the comparative chemical characters of the products. As between the action of one description of light and another, and as between the greater or less continuity of exposure, we ought to be able to form a judgment whether the proper balance between assimilation on the one hand, and growth and proper maturation on the other, has been attained; whether the plants have taken up nitrogen and mineral matter and produced chlorophyll in a greater degree than the quantity and the quality of the light have been able to turn to account; or whether the conditions as to light have been such that the processes of transformation and growth from the reserve material provided by assimilation have not been normal or have not kept pace with the production of that material.

But one word more in reference to Dr. Siemens' results and proposed extension of his inquiries. Even supposing that by submitting growing crops to continuous light by the aid of the electric light during the night, they could be brought to maturity within a period shorter than at present approximately in proportion to the increased number of hours of exposure, the estimates of the cost of illuminating the vegetation of an acre of land certainly do not seem to hold put any hope that agriculture is likely to derive benefit from such an application of science to its needs. If, however, the characters of growth and of maturation should

prove to be suitable for the requirements of horticultural products of luxury and high value, it may possibly be otherwise with such productions.

The above considerations obviously suggest the question: What is the office of chlorophyll in the processes of vegetation? Is it, as has generally been assumed, confined to effecting, in some way not yet clearly understood, carbon assimilation, and, this done, its function ended; or is it, as Pringsheim has recently suggested, chiefly of avail in protecting the subjacent cells and their contents from those rays of light which would be adverse to the secondary processes which have been distinguished as growth?

Appropriate as it would seem that I should attempt to lay before you a *résumé* of results bearing upon the points herein involved, so numerous and so varied have been the investigations which have been undertaken on the several branches of the question in recent years, that adequately to discuss them would occupy the whole time and space at my disposal. I must therefore be content thus to direct attention to the subject, and pass on to other points.

(*To be continued.*)

THE BRITISH ASSOCIATION

REPORTS

Report on the Tertiary Flora of the Basalts of the North of Ireland, by Mr. W. H. Baily.—Described the plants of Miocene deposits, consisting of variegated marls, resting on a leaf-bed near Glenarm. Amongst the plants were *Sequoia couttsiæ*, *S. lyelli*, *Fagus deucalium*, *Nyssa ornithobroma*, *Aralis brownia*, *Fraxinus guillelmæ*. These and others have been drawn and described.

Report on the Viviparous Nature of the Ichthyosauri, by Prof. H. C. Seeley.—Dr. Channen Pierce had formerly described a specimen of Ichthyosaurus in the Museum at Bristol which he considered contains a fœtus in the act of coming into the world, which view is supported by Prof. Seeley, who showed, reasoning by the analogy of the stomach of a crocodile, it was impossible that this animal could have swallowed a smaller ichthyosaurus, and its remains been retained in the stomach in a perfect form, and alludes to the spiral structure of the coprolite, pointing to a small intestine, and thought it is impossible that the animal could have passed through them in the process of digestion; and alluded to the fact that all German specimens show the head of the smaller projecting towards the tail of the larger, though the reverse is the case in a specimen at Madrid. But in Tübingen the most perfect specimens occur, in which the smaller animals are found lying completely preserved between the ribs of the parent animal; though, he suggests, in all cases viviparous characters may not have obtained in all forms of ichthyosauri.

The Sixth Report of the Underground Water Committee was read by Mr. De Rance, who pointed out that the watershed separating the basins of the Thames and Eastern Counties from those of the Humber and the Severn also divides the area of heaviest rainfall on the Palæozoic rocks, which are nearly all impermeable, from those of Secondary age, receiving a rainfall of about 30 inches. West of this line, with the exception of the Trias, no Secondary rocks occur. In Lancashire, Cheshire, and the Midlands the Triassic Sandstones absorb about one-third of the rainfall, giving a daily average of 400,000 gallons to each square mile of country: wells in these rocks are capable of drawing on several square miles, and in suitable situations of yielding from 2 to 3 million gallons per day. The discovery of the Manchester coalfield beds at Winwick, near Warrington, under the New Red Sandstone, at a depth of only 540 feet, was described. He referred to the position of the New Red boring at Bootle, for the Liverpool Corporation water supply, as very badly chosen, being close to one of the existing wells. He then showed the gradual attenuation in thickness of the Bunter Sandstones, in a southerly direction, against the old Palæozoic axis, ranging from the Belgian coalfield to the Mendips.

Report on the Present State of our Knowledge of the Crustacea, by C. Spence Bate, F.R.S.—This is Part v. of the Report, and deals with the subjects of fecundation, respiration, and the green gland.

SECTION A.—MATHEMATICAL AND PHYSICAL

Improved Apparatus for the Objective Estimation of Astigmatism, by Tempest Anderson, M.D., B.Sc.—Astigmatism has been defined as that condition of the eye in which refraction is unequal in the different meridians. In order to obtain suitable spectacles for correcting this defect, it is necessary to know accurately the focal adjustment of the meridians of maximum and minimum curvature, whence the focal lengths of glasses, generally either cylindrical or cylindrical on one side and spherical on the other, are readily calculated. Many plans have been adopted for determining this; some subjective, depending on observations made by the eye itself, and generally using a point of light or a series of radiating lines as an object. From their appearances when viewed at different distances, and with lenses of different powers, the focal adjustment of the different meridians is at last obtained.

The advantage of this group of methods is their theoretical delicacy, as they work by judging of the perfection of certain images refracted on the retina in a manner not very dissimilar to that in which they are usually formed; the practical disadvantage, that accurate observations are required from one who has never been accustomed to make them. Hence objective methods have been introduced. Their advantages are, substituting trained for untrained observation. Their disadvantages—

1. The vessels of the retina and the optic nerves, which are mostly employed as objects, are seldom in exactly the position desirable for estimating the refraction in different meridians, and are often at a different distance from the optical system of the eye from that at which the sensitive layer of the retina lies.

2. They mostly require the optical defects, if any, and the accommodation of the observing eye to be taken into account and allowed for, thus introducing risk of error.

In the author's two instruments, an image of a suitable object thrown on the retina of the observed eye, is used as an object by the observer, with the following advantages:—

1. The patient's sensations may be entirely disregarded, or only used as confirmatory.

2. The image used is necessarily at the retina, and not before or behind it.

3. The accommodation or any defects in the refraction of the observer's eye does not enter into the result, as the only function of this eye is to observe the formation of the image on the retina.

In the first plan a lamp *l* is provided with a condensing lens *c*, and a series of radiating wires *w* (supposed to be seen edgeways in the figure), thus giving a bright field with black lines on it.

The whole slides on a graduated bar *C*, at the other end of which is a convex lens *y* (4 and 10 dioptrics are the most convenient powers, *i.e.* 10 and 4 inch focus). Close to the lens, and at an angle of 45° to its axis, is a plane mirror (*m*), which reflects the rays at right angles to their former path. The instrument is to be held so that this pencil of rays enters the observed eye, and when the wire screen is at the proper distance, an image of it is formed on the retina. The mirror has the centre left unsilvered, as in an ordinary ophthalmoscope, and has a disk of correcting lenses behind it, to render the retina, and the image on it, visible by the direct method. The observed eye should have its accommodation relaxed by atropine.

The bar is so graduated that when an image of the whole or part of the screen is sharp on the retina, the figure opposite the screen expresses the refractive error of the meridian by which the image is produced. Hence if the image of the whole screen is seen to be equally sharp, the eye is known to be not astigmatic, and the graduation given the number of dioptrics by which it is myopic or hypermetropic. If the lines be not all sharp at once, then the most distant point at which a distinct image of any of the wires is formed on the retina gives the refractive error of the meridian of minimum refraction (expressed in dioptrics), and the point at which the line at right angles to this is best defined gives that of the meridian of maximum refraction. The least of these gives the spherical element of the correcting lens required for distant objects, and the difference between the two gives that of the cylindrical part. The meridian of maximum refraction is that in which the line is visible when the wires are at the greatest distance.

In the second plan the lamp, *l*, condensing lens, *c*, and wire screen, *w*, are similar, and only differ in size, the front lens, *y*, and mirror, *m*, are also similar, but the lamp and wires are permanently fixed by a tube, so that the wires are accurately in

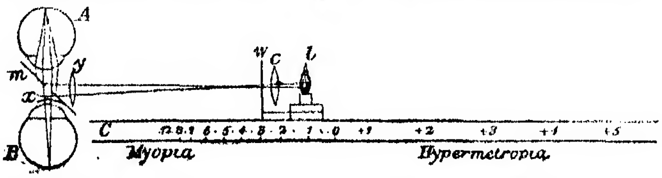
the principal focus of the front lens, y. By this means the rays from the wires (or rather from the interval between them), after refraction through the lens and reflection by the mirror, are parallel. If received by an eye which is emmetropic, and with its accommodation relaxed, an image of the wires is formed on the retina. The light radiating from the image passes out through the optical system of the eye; is rendered parallel and able to form an accurate image on the retina of an emmetropic eye observing through the hole in the mirror.

If the observed eye be not emmetropic, it is only necessary to introduce lenses of different powers close in front of it, so as to correct the rays both entering and leaving the eye. If the refraction be the same in all meridians, the image of all the wires is sharp with the same lens, and this lens is the one required to correct the ametropia. If any astigmatism exists, different lenses are required for rendering the images of the different wires sharp.

The strongest and weakest of these are the measures of the errors of refraction of the two principal meridians, and the difference of their numbers of dioptrics gives the cylindrical element of the correcting glass required.

In this form of apparatus a disc of correcting lenses behind the mirror is not required, as the single correcting lens near the observed eye corrects the rays both entering and leaving the eye.

For rapidly finding the proper lens a disk of lenses is used,



each a centimetre in diameter, and with intervals of one dioptric; a smaller disc is attached containing the quarter dioptrics, so that by their combination intervals of one quarter of a dioptric can be read—a degree of accuracy greater than the estimation is generally susceptible of.

The proper lens being calculated, its spherical and cylindrical elements are combined and put together before the eye. It it be the correct one, all the lines are seen sharp at the same time; if not, further examination is made.

The principal advantage of the first plan is that the adjustment, being made by the motion of the wire screen, is continuous, and correcting lenses are not required for measuring the refraction, but only for rendering the retinal image visible; its disadvanatge that, as the rays are not parallel as they pass from the front lens, past the mirror to the eye, it is necessary for the apparatus to be very near, and at a determinate distance from the observed eye, otherwise the readings of the scale are vitiated. This, however, is not a serious objection.

In the second plan the rays in the corresponding position are parallel, and the instrument can be held at any convenient distance, say one or two feet from the observed eye, and the observer can get a view of the cornea at the same time as he views the image, so that he can estimate the refraction at different points of the cornea.

It is hoped that this may eventually lead to the determination of the refraction at different parts of conical cornea and other eyes with irregular astigmatism, and the application of suitable lenses to them.

Since writing the above, I find mention of an instrument by Coccius Stimmel, with an optical arrangement on the same plan as my second, but I have not heard of its being in use in this country.

The makers are T. Cook and Sons, York.

SECTION D.—Biology

After Dr. Sclater hadread report of Socotra Committee, Dr. J. B. Balfour gave a very interesting account of his visit to the island. The zoological and botanical collections have not yet been examined by specialists, but are expected to yield results of great interest. As not nearly sufficient time had been allowed for a complete exploration of the island, which is almost entirely unknown to Europeans, Dr. Balfour hoped that another similar expeditionwould be organised; but in that case it should be earlier in the season than the last, which was in the island during February and the early part of March. During the latter part of the time the heat was too great for it to be possible to do anything in the middle of the day. Dr. Sclater mentioned that the ornithological collection indicated distinct African affinities.

Further Remarks on the Mollusca of the Mediterranean, by J. Gwyn Jeffreys, LL.D., F.R.S.—This is a supplement to a paper by the author, which was published in the Report of the Association for 1878. Since that time many of the species which were supposed to be exclusively Mediterranean have been discovered in the North Atlantic. The number of such Mediterranean species, which were given in the former paper, was 222. In the present paper 41 of those species are enumerated as also Atlantic, thus reducing the number of exclusively Mediterranean species to 181, and it was remarked that the Atlantic nudibranchs and Cephalopods had not been completely worked out, these anounting to 58, and being included in the above residue of 181.

On the Migration of Birds, and Messrs. Brown and Cordeaux's Method of obtaining Systematic Observations of the same at Lighthouses and Lightships, by Prof. Newton, M.A., F.R.S. (Abstract).—Citing a passage from an article by the Duke of Argyll (*Contemp. Rev.*, July, 1880, p. 1), the author met with a direct denial the Duke's assertion that of "the army of the birds" it might be said that "it cometh not with observation," pointing out that all we know of the migration of birds arises from observation, and all we do not know from the want of it, remarking also that if it were not for observation we should not know that birds migrate at all, and inquiring whether it is not by renewed observation alone that we can hope to know more of their migratory movements. The author then proceeded to describe briefly the nocturnal passage of migratory birds as noticed by himself at Cambridge for the past seventeen years, and urged the importance of simlar. but more systematic observations being made at other stations Remarking upon the especial advantages of lighthouses and lightships for this purpose, he recounted the successful attempt made in the autumn of 1879, with the sanction of the Trinity House authorities and the Commissioners of Northern Lights, by Mr. Harvie Brown and Mr. Cordeaux, to obtain a series of observations from the lighthouses and lightships on the coast of Scotland and the east coast of England, the results of which were embodied in a Report (noticed in NATURE, vol. xxii. p. 25), and showed that returns were obtained from nearly two-thirds of the English stations, and as regards the Scottish stations, from about two-thirds on the west and one-half on the east coast, thus proving the intelligent interest taken by the men employed in the inquiry. This single Report naturally did not throw any new light on the subject, but it would be contrary to all experience if a series of such reports would not, and he therefore strongly urged the Association to countenance the renewed attempts which Messrs. Brown and Cordeaux were making, and to encourage with its approval them and their fellow-workers, the men of the lighthouses and lightships, who could best answer the question whether knowledge of "the army of the birds" and its movements "cometh not with observation."

On Anthropological Colour-Phenomena in Belgium and elsewhere, by J. Beddoe, M.D., F.R.S.—In Germany, Switzerland, and Belgium, through Governmental assistance, the colours of the eyes and hair of all the children in the primary schools have been observed and tabulated. The writer is very desirous that our own officials should lend similar assistance to the Anthropometric Committee of this Association. The results hitherto obtained have been of considerable importance, and those for Belgium are well shown in the monograph and maps of Prof. Vanderkindere. These bring out a remarkable contrast between the Flemish and the Walloon provinces of Belgium, and tend strongly to prove the persistently hereditary character of even such physical characters as the colour of the hair and the iris.

Pocket Registrator for Anthropological Purposes, by Francis Galton, M.A., F.R.S.—The author exhibited a small instrument a quarter of an inch thick, four inches long and one and three quarters wide, furnished with five stops, each communicating by a ratchet with a separate index arm that moves round its own dial-plate. The registrator may be grasped and held unseen in either hand with a separate finger over each stop. When any finger is pressed on the stop below it, the corresponding index arm moves forward one step. Guides are placed between the stops to insure the fingers occupying their proper positions when the instrument is seized and used in the pocket, or when it is slipped inside a loose glove or other cover. It is possible by its means to take anthropological statistics of any kind among crowds of people without exciting observation, which it is otherwise exceedingly difficult to do. The statistics may be grouped under any number of headings not exceeding five. If it should ever be thought worth while to use a registrator in each hand, ten headings could be employed. The instrument that was exhibited worked well, but it was the first of its kind, and might be improved. It was made by Mr. Hawkesley, surgica linstrument maker, 300, Oxford Street, London. The author also drew attention to the ease with which registers may be kept by pricking holes in paper in different compartments with a fine needle. A great many holes may be pricked at haphazard close together, without their running into one another or otherwise making it difficult to count them afterwards. The mark is indelible, and any scrap of paper suffices. The needle ought to project a very short way out of its wooden holder, just enough to perforate the paper, but not more. It can then be freely used without pricking the fingers. This method, however, requires two hands, and its use excites nearly as much observation as that of a pencil.

Dr. Phené, F.S.A., F.R.G.S., read a paper *On the Retention of Ancient and Prehistoric Customs in the Pyrenees*. He said he could now repeat more confidently the peculiar features which indicate beyond question that the customs of the Gallic population of the South of France agreed, so far as they might judge from their lithic monuments, with those who came farther north and settled in Britain. On the crests and sides of the mountains on both sides of the Pyrenees, *i.e.* in Spain and France, are found sepulchral arrangements of stones somewhat different to any distinctly recorded amongst our antiquities. These consist of a number of circles adjoining each other; in the centre of each is a cist with an urn, having burnt bones, and the form of the circle is that of a wavy or serpentine cross. The quaint old customs of early Celtic life are kept up all along the Pyrenees, but not in the towns, in the plains, or champagne country. One of these, which he described last year as still existing in Brittany, that of a wooden tally, in lieu of a bill or account, on which the baker marked by notches the number of loaves he supplied, and which attracted the attention of the President of the section last year, was also existent in the Pyrenees. He purchased a baker's bill at Perpignan a few months ago, and though not so rustic as that of Brittany, it approached more to our old Exchequer tally, and to the Welsh stick of writing described in "Bardas," as well as to some elaborate and really wonderful calendars, still to be seen in the Cheetham Museum at Manchester, than to the rustic tally of Brittany. On crossing into Spain and prosecuting inquiries, he found the serpent or dragon emblem everywhere prominent, and even learned that the Tarasque, the ceremony of which is performed at Tarascon, in Provence, was a well-known dragon with the Spanish people. He was told that, though used as a popular diversion at *fêtes*, it had always a religious meaning. At Luchon living serpents are consumed in the flames. The youths of the village had miniature cloven pines which they burn. These they brandish while flaming, in serpentine curves, and cry loudly, "hilla-hilla"—pronounced "*ella*." But the Basque *l* often stands for *v*, and if we used it here, we had the old classic cry of the Bacchanals, who with serpents in their hands rushed about wildly crying "Eva, eva." The place where these cries are mostly practised has most remarkable sculptures of serpents. After the burning of the pine a rush is made by the more powerful, and the burning embers carried off in their hands regardless of pain. Pieces are then distributed to every household, and kept religiously during the year, as was the custom with the ancient Britons.

Mr. Thomas Plunkett contributed a paper *On an Ancient Settlement found about Twenty-one Feet beneath the Surface of the Peat in the Coal Bog near Bohoe, County Fermanagh.*—This interesting discovery consisted of the remains of two log huts found in a primitive crannage. Flint implements, hand-made pottery, and other objects, but no metal of any kind, were found in connection with the huts, which, the author was of opinion, were formed before the age of bog pine, as no pine occurred below the level of the site on which the huts stood. The fact that twenty-one feet of dark, compact peat had grown since the structures were formed was substantial evidence of their great antiquity.

Prof. Dawkins remarked that this discovery did not stand alone, but in connection with others showed that in various parts of Ireland we might look for log houses in this way, pointing back to a series of ancient wooden houses which belonged to the Neolithic people.

Prof. Rolleston read papers *On the Structure of Round and Long Barrows*, his remarks being illustrated by a number of diagrams. Premising that one of his objects was to preserve barrows from being spoilt, and thus to prevent the destruction of certain links in the history of our species, he described the construction of barrows which he had explored, and urged the absolute necessity of very great care being exercised in such exploration. Speaking of urn burials in round barrows, the Professor briefly referred to the question of the cremation of bodies, and the idea of it. Why did the people burn their dead? He believed the idea was this—that all savage races, when they had to deal with an enemy, were exceedingly prone to wreak certain ignominies on dead bodies. Burning the bodies put it right out of the power of the enemy to do this, and the urn enabled people to carry away their friends who were so burnt. In time of pestilence it b came actually necessary for sanitary considerations to burn the dead, and it was only in time of plague or war that we found that cremation or burning became the order of the day, and that was readily explicable by the fact that men always did what they could on the principle of least action, because burning was a troublesome process. Any universality of burning was explained by the fact that ancient history was simply one great catalogue of plague and pestilence and war and the like. Of course he was an enemy to cremation, because it did a great deal of harm, preventing us from knowing what sort of people our predecessors were. Prof. Rolleston chronicled the finding in a barrow of the Bronze period of a man laid out at full length, the general rule being that of burial in a contracted position. As regarded the date to be assigned to these things, he might give it as his opinion that no Roman ever used a bronze sword, nor crossed swords with an enemy using a sword of that material. As regarded the long barrows, that mode of burial stretched all the way from Wales to the Orkneys, and in them was found not a scrap of metal. His opinion was that the idea of the construction of these barrows was taken from limestone mountain headlands projecting into the sea, such as might be seen by a little trip in their immediate locality. The men lived in caves, and the idea for the place of burial was taken from the place of living, it being often found that a man made the house in which he lived his burial-place.

A short discussion having taken place on Prof. Rolleston's paper, Dr. Schaafhausen, of Bonn, exhibited the Neanderthal skull which was found in 1857, and which, he submitted, was not the skull of an idiot, but of a man of the lowest development. Prof. Rolleston agreed that the man whose skull it was was not an idiot, and said that the abnormal development in connection with it consisted in the frontal ridges.

A paper by Miss A. W. Buckland *On Surgery and Superstition in Neolithic Times* was read. Miss Buckland said it had been proved by the late Dr. Broca that the system of trepanning prevailed in Neolithic times, and the paper was to show the extent of the practice, the superstitions associated with it, and its connection with the use of cranial amulets. The surgical operation known as trepanning consisted in making an opening in the skull (chiefly of infants) in order to cure them of certain internal maladies, and the individuals who survived were considered to be endowed with properties of a mystic character. Dr. Broca stated that the custom died out with the introduction of bronze. Miss Buckland said the custom still existed among the South Sea Islanders, the Kabyles of Algeria, and the mountaineers of Montenegro. The other papers read in this department were: *On Bushmen Crania*, by Prof. Rolleston; *The Salting Mounds of Essex*, by Mr. H. Stopes; *The Hittites*, by Mr. W. St. C. Boscawen; *Further Researches on the Prehistoric Relations of the Babylonian, Chinese, and Egyptian Characters, and Languages, and Culture*, by Mr. Hyde Clarke;

The Mountain Lapps, by Lieut. G. T. Temple; *Note on a Chilian Tumulus*, by Mr. J. H. Madge; and *India the Home of Gunpowder on Philological Evidence*, by Dr. Gustav Oppert.

SECTION E.—GEOGRAPHY.

The President read some letters of a very interesting character from Mr. Joseph Thomson, received by the Royal Geographical Society's East African Expedition. The following are passages from this correspondence:—

"Karema, or Musamwira, Lake Tanganyika,
"March 27, 1880.

"I have failed in my attempt to reach Jendwe by way of the Lukuga and Kabuire. I left Kasenga (or Mtowa) on January 19, with all the confidence of a young lion which had not yet known a reverse, and six weeks after I returned to the same place as meek as a lamb. From the very first I had great difficulties with the men, as they believed I was taking them to Nanguema, where they would be eaten up. They tried every means in their power to throw obstacles in my way and retard my movements, two of them deserting near Meketo, and the others threatening to do the same. For six days I continued my course along the Lukuga, in spite of their opposition, but I was then obliged to give in. It flows in a general west-north-west direction to that place, and then about west into the great westerly bend of the Congo, all the way through a most charming valley, with hills rising from 600 to 2,000 feet in height. Above the lake the current is extremely rapid, and quite unnavigable for boats or canoes of any description, owing to the rapids and rocks. From Makalumbi I crossed the Lukuga into Urua, and struck south-west for the town of Kiyombo, who is the chief of all the Warna on the eastern side of the Congo." "We reached Mtowa on March 10, destitute of almost everything. To my delight, however, I heard that Mr. Hore was expected every day on his way by canoe to the south end of the lake. On the 23rd we started, crossed the lake to Kungwe, and reached Karewa on the night of the 26th. As we neared the shore, we were hailed by the jolly voice of Capt. Carter, whom we found gun in hand and bursting with stories of his wonderful adventures in sport and war, keeping us fixed on our seats all night in his tent as he launched them forth. We went over to visit the Belgian international party at their temporary quarters to-day. Capt. Carter had his elephant ready to take us across the marsh. Karema is one of the most extraordinary places for a station that could be found on the lake—a wide expanse of marsh, a small village, no shelter for boats, only shallow water dotted with stumps of rock, no room to be got, and natives hostile; far from any line of trade. The party have commenced building forts and walls, digging ditches in regular military fashion. At table there sat down an Englishman, an Irishman, a Scotchman, a Frenchman, a Belgian, and a German, representing five expeditions, and you will doubtless be pleased to learn that of all these (thanks to yourself) the Scotchman, though the smallest, and having to travel through entirely new country, had been the most successful of all. After leaving Karema we had a moderately good voyage across the lake to Jendwe, at which we arrived on April 7." "Passing round the south end of Tanganyika along the shore as far as the mouth of the Kilambo, then striking about N.N.E. through Ulungu and Fipa, we reached by easy ascents the town of Kapufi, situated in lat. 8° S. and long. 32° 25′ E. Best of all, however, while at this place, I had the honour to settle the problem of Lake Hikwa, or rather Likwa, and give it some shape and place in our maps. It has run itself in the hearsay accounts of successive travellers into various protoplasmic shapes, and, will-o'-the-wisp like, danced about on the map to the tunes of various geographers. I, of course, saw only a part of it, but from all I could gather it must be from sixty to seventy miles in length and fifteen to twenty in breadth. It lies two days east of Makapuli, in a deep depression of the Lambalamfipa Mountains. A large river called the Mkafa, which rises in Kawendi, and which by its tributaries drains the greater part of Khonongo and Fipa and all Mpimbwe, falls into it. I can almost say with certainty that it has no outlet, certainly not any towards the west. The Kilambo rises near Kapufi. I was surprised and pleased to find that my bearings and estimated distances, as laid down on my sketch map every two days, had actually brought me within one or two miles of Tabora as laid down by Speke and Cameron. I can hardly, however, call it anything but a curious coincidence."

The colleagues of Major Serpa Pinto in the Portuguese expedition to West Central Africa (Capt. H. Capello and Lieut. R. Ivens) were warmly received in the Geographical Section. They had thoroughly explored the elevated watersheds of Bihe. Major Serpa Pinto went on his famous journey towards Mozambique, and Messrs. Capello and Ivens struck towards the north-east, nearly reaching Congo. They descended the great tributary of the Congo till they reached more than 6¼° S. lat., where there is a great forest-belt inhabited by tribes of hostile and ferocious negroes. Not far from the shores of this river there dwells one of the most powerful potentates of this part of Africa, but the country is very unhealthy, and the people inferior in every respect to the Highlanders of Bihe. The President and Sir Henry Barkly and other members of the Section congratulated the Portuguese on their renewed geographical enterprise, and acknowledged in particular the indebtedness of geography to the explorers, from one of whom (Lieut. Ivens) the Section had heard an account of their travels.

Mr. Lawrence Oliphant described the results of his recent travels east of the Jordan, and particularly of his visits to labyrinthine subterranean cities. The object of his visit was described as that of selecting country for colonisation, and he reported that there was much pasture, wooded, and arable land capable of the highest degree of development.

Mr. Butler proposed a scheme for supplying pictorial aid to geographical teaching. The travels of a Jersey gentleman, Mr. W. Mesny (who was so useful to Capt. Gill in his journey across China), up the Canton River, and Mr. Carl Bock's account of his exploring expedition in Borneo for the Dutch-Indian Government, were other subjects before this Section.

Col. Tanner read some interesting *Notes on the Dara Nur, Northern Afghanistan, and its Inhabitants*. He described the inhabitants of the Dara Nur valley as differing little in appearance from the Afghans. "Their features are softer, and they are more trustworthy and less given to fanatical outbreaks than the Pathans, and though they continually fight among themselves, they have never given us trouble in Afghanistan. The forts of the Dara Nur were similar to those of the Jellalabad plain, and the interior arrangement the same. The people still retain the custom of sitting on stools, and, as a rule, are not at home when squatting on the ground. Among the Kohistanis and Kafirs stools are in general use." Then followed a description of a people residing in the upper part of this valley called the Chuganis. "They live in the highest habitable parts of the Kund range. East and west they are hedged in by the powerful race of Safis, their hereditary enemies, and peace is seldom known between them. The appearance of a Chugani is quite different from that of an Afghan or a Dar Nuri. He is shorter in stature, and has more pleasing features. The Chuganis are the only Mohammedans I know who allow to the women perfect and unconstrained freedom. Young and old, married and single, they go about as they do in Europe, without any of the false modesty of the ordinary Indian and Afghan females. The wife of my host and her daughters used to ask me every morning how I fared, and became at last quite friendly. In one other place only have I been allowed to converse without restraint with the women, and that was in a remote and wild part of the Brahti country, where mollahs are unknown and the tenets of the Prophet but imperfectly understood. The Chugani young lady takes a pride in her appearance. . . . . The town of Aret is one of the most remarkable collections of houses I have ever seen. It is built on the face of a very steep slope, and the houses, of which there must be 600, are ranged in terraces one above another. From the roof of one of the lower ones I gazed with astonishment at a vast amphitheatre of carved wood, there being in sight thousands of carved verandah posts, and tens of thousands of carved panels, with which the upper storeys of the houses are constructed. These panels, which are arranged similarly to the shutters of Indian shops, are ornamented with every conceivable variety of carved patterns. The carving completely covered the woodwork of the upper storey of every house. . . . . From one of the numerous native visitors I heard much about the Sanu Kafirs, with whom the Kordar Chuganis carry on much traffic. The little-known people whom the Afghans are pleased to call Kafirs are now confined to a tract bounded on the north and north-west by the Hindu-Kush, on the east by the Hindu range, and on the south and south-west by the Kund range, and by the Laghman. The tribes are very numerous, and speak many different languages. The great tribe of

the Katawas live in a country sufficiently open and level to admit of their becoming good horsemen. The Samus number some five or six hundred families, and live at the upper end of the Pech Dara. They are described as a merry people, given much to dancing, singing, music, and wine-bibbing. At their meals they sit in a circle and eat sedately, and with dignity, the silver wine goblet placed in a stand conveniently near being passed round the company from time to time. They shake hands in the English fashion. The women tie up the hair with a silver band. Long massive silver chains presented by the tribe are worn over the shoulders of warriors who have deserved well of their clan. Their religion is simple; the men invoke the aid of their gods in battle, vowing offerings if they are successful in the fight, and these offerings are stored up in the temples. The Kafirs are being continually encroached upon by the surrounding Afghans. Raids on a large scale are constantly made into their mountain valleys, partly to secure the women as slaves, and partly by fanatical Mohammedans on religious grounds."

A Visit to the Galapagos Islands in H.M.S. "Triumph," 1880, by Capt. Markham.—Capt. Markham gives an account of a visit he paid to the Galapagos Islands on board H.M.S. *Triumph*, in the beginning of the present year. The Admiralty chart, compiled from a rough survey made nearly half a century ago, is not very accurate, so that it was not safe for a large ironclad like the *Triumph* to extend the cruise in the numerous channels between the islands. Her visit was therefore confined to Post Office Bay in Charles Island, and the paper records the observations that were made during several inland excursions.

The Galapagos Islands, being 600 miles from any other land, have a peculiar fauna, and Capt. Markham devoted all the time at his command to the collection of birds, skins, insects, and shells. These specimens have been placed in the hands of Mr. Salvin, and it is anticipated that they will form an addition to our knowledge of the natural history of this isolated archipelago.

In our report of Mr. Weldon's paper, read before the Chemical Section of the British Association, it is stated :—"Molecular heats of formation of elements of the same group divided by the atomic volumes of the electro-negative elements give numbers either identical with, or bearing some simple relation to, each other." This should read :—"Molecular heats of formation of *compounds* of positive elements of the same group with the same electro-negative element, divided by the atomic volumes of the positive elements, give quotients either identical with, or bearing some simple relation to, each other. Thus :—

$$\frac{\text{Mol. heat of formation of } PbCl_2,\ PbBr_2,\ PbI_2,\ PbO}{\text{Atomic volume of Pb}} : \frac{\text{Mol. heat of formation of } Cu_2Cl_2,\ Cu_2Br_2,\ Cu_2I_2, \text{ and } Cu_2O}{\text{Atomic volume of Cu}} :: 1 : 1.$$

Dana.—Observations on Mount Etna, by S. P. Langley.—Antiquity of certain subordinate types of freshwater and land mollusca, by C. A. White.—Description of a new position micrometer, by L. Waldo.—Boltzman's method for determining the velocity of an electric current, by E. H. Hall.—Mineralogical notices, by C. U. Shepard.—Improvement in the Sprengel pump, by O. N. Rood.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, September 6.—M. Wurtz in the chair.—The following papers were read :—Researches on basic salts and on atakamite, by M. Berthelot.—Contributions to the history of ethers, by the same.—On the etiology of anthracoid affections, by M. Pasteur. He cites some facts in support of his theory. On a spot in a meadow where an anthracoid cow had been buried in 1878, a small enclosure was formed, and four sheep put in it; in another enclosure, a short way off (3m. or 4m.), four other sheep. In seven days one of the former set died of the disease; none of the latter set were affected. (Germs of *charbon* had been found on the ground over the buried cow, but not a few metres off.) M. Pasteur differs from M. Toussaint's opinion that acute septicæmia is identical with chicken cholera.—M. Bouley gave some account of recent experiments of M. Toussaint, apparently showing the efficacy of preventive inoculation of sheep and rabbits against *charbon* by his method. He hopes that once preventive inoculation has become practical, it will be possible to make, not races, but generations, refractory to the disease, by inoculating the mothers during the last period of gestation.—Planet (217), discovered by M. Coggia at the Observatory of Marseilles, on August 30, 1880, by M. Stephan.—On the part taken by Claude Jouffroy in the history of the applications of steam, by M. de Lesseps. This refers to a regret expressed by the granddaughter of the inventor that M. de Lesseps had not, at the inauguration of Papin's statue, recalled the services of Jouffroy, who, in 1783, invented the pyroscaph, which steamed on the Saone sixteen months, making two leagues per hour. M. de Lesseps had thought it his *rôle* only to recall the inventions anterior to Papin, and those of Papin himself.—The enemies of the gallicolar phylloxera, by M. Coste.—Observations of solar protuberances, faculæ, and spots, during the first half of 1880, by P. Tacchini. The increase of solar activity is evident. The observations as to distribution agree well with those of previous quarters. The maximum of frequence of groups of faculæ is nearer the equator than that of protuberances. There are more groups of faculæ in the north than in the south hemisphere (nearly double the number); the protuberances are equally distributed in the two hemispheres. The maximum of frequence of spots and faculæ is produced in the same zones in the two hemispheres.—On the law of magneto-electric machines, by M. Joubert.—On the variations of fixed points in mercury thermometers, and on the means of taking account of them in estimation of temperatures, by M. Pernet. He confirms M. Crafts' views, and gives a formula for calculating the minima of zero, &c. He states that he can restrict to $\frac{1}{100}$ of a degree for several hours the variations of zero in a thermometer whose zero has undergone a depression of $0^{\circ}.8$ C. after determination of the 100° point.—On borodecitungstic acid and its salts of sodium, by M. Klein.—Inoculation of the rabbit with glanders; destruction of the virulent activity of the matter of glanders by desiccation; transmission of glanders by inoculation with the saliva, by M. Galtier. This points to the possibility of healthy cavalry horses being contaminated by drinking from the same trough with horses in which the disease is present in a latent state. M. Larrey called attention to a disease that was once very common in the army, where soldiers ate out of a common porringer; it is an inflammatory and ulcerous affection of the mouth. The disease disappeared after the practice was given up in 1852.

THE PHOTOPHONE

EARLY in the summer of the current year it was announced in the columns of NATURE that Prof. Graham Bell had made a discovery which, for scientific interest, would rival the telephone and phonograph, and that he had deposited in a sealed packet, in the custody of the Smithsonian Institute, the first results of his new researches; that announcement has now received its due fulfilment in the lecture by Prof. Bell to the American Association for the Advancement of Science, on Selenium and the Photophone, which will be found on another page. In spite of those who ingenuously attempted at the time of our announcement to forestall Prof. Bell and to discredit the idea that he had done anything new, the discovery, which he has now published, is a startling novelty. The problem which he has attacked is that of the transmission of speech, not by wires, electricity, or any mechanical medium, but by the agency of light. The instrument which embodies the solution of this principle he has named the Photophone. It bears the same relation to the telephone as the heliograph bears to the telegraph. You speak to a transmitting instrument, which flashes the vibrations along a beam of light to a distant station, where a receiving instrument reconverts the light into audible speech. As in the case of that exquisite instrument, the telephone, so in the case of the photophone, the means to accomplish this end are of the most ridiculous simplicity. The transmitter consists of a plane silvered mirror of thin glass or mica. Against the back of this flexible mirror the speaker's voice is directed; a powerful beam of light is caught by a lens from the sun and directed upon the mirror, so as to be reflected straight to the distant station. This beam of light is thrown by the speaker's voice into corresponding vibrations. At the distant station the beam is received by another mirror, and concentrated upon a simple disk of hard rubber fixed as a diaphragm across the end of a hearing-tube. The intermittent rays throw the disk into vibration in a way not yet explained, yet with sufficient power to produce an audible result, thus reproducing the very tones of the speaker. Other receivers may be used, in which the variation in electrical resistance of selenium under varying illumination is the essential principle. The experimental details have been worked out by Prof. Bell in conjunction with Mr. Sumner Tainter. They have discovered that other substances beside hard rubber, gold, selenium, silver, iron, paper, and notably antimony, are similarly sensitive to light. This singular production of mechanical vibrations by rays of light is even more mysterious than the production of vibrations in iron and steel by changes of magnetisation. It was indeed this latter fact which led the discoverers to suspect the analogous phenomenon of photophonic sensibility in selenium and in other substances. Hitherto, in consequence of the mere optical difficulties of managing the beam of light, the distance to which sounds have been actually transmitted by the Photophone is less than a quarter of a mile, but there is no reason to doubt that the method can be applied to much greater distances, and that sounds can be transmitted from one station to another wherever a beam of light can be flashed; hence we may expect the slow spelling out of words in the flashing signals of the heliograph to be superseded by the more expeditious whispers of the Photophone.

We congratulate Prof. Bell most sincerely on this addition to his well-won laurels, and venture to predict for his photophone a great, if not a widely-extended, future of usefulness.

SILVANUS P. THOMPSON

THE GEOLOGY OF LONDON

Guide to the Geology of London and the Neighbourhood. (An Explanation of the Geological Survey Map of "London and its Environs," and of the Geological Model of London, in the Museum of Practical Geology.) By William Whitaker, B.A., F.G.S. Third Edition. (London: Longmans and Co. and Edward Stanford, 1880.)

SINCE the appearance of the second edition of this most useful little work, some valuable additions have been made to our knowledge of the rocks which underlie the London Basin. The deep borings at Turnford, near Cheshunt, and at Ware, which were executed by the New River Company in 1879, have furnished new data to geologists for determining the position and characters of that great underground ridge of palæozoic rocks, the probable existence of which was so long ago indicated by Mr. Godwin-Austen. This underground ridge of palæozoic rocks has now been reached in no less than six borings, those of Kentish Town, Harwich, Crossness, Meux's Brewery, Turnford, and Ware. In four of these cases the age of the rocks which have been found unconformably underlying the Cretaceous strata is placed beyond question, by the discovery of the well-preserved and characteristic fossils, lists of which have recently been published by Mr. Etheridge. At Harwich the cores of dark-coloured indurated shale yielded *Posidoniæ*, which proved that the rock belongs to the lowest part of the Carboniferous system; at Meux's Brewery and at Turnford the purple shales yielded the characteristic fossils of the Upper Devonian; while at Ware cores were brought up crowded with the well-known fossils of the Wenlock shale.

But in the case of the Kentish-Town and Crossness borings no fossils have been detected in the cores of rock brought up from the infra-cretaceous rocks, and in these cases geologists have had to fall back upon the far less satisfactory evidence afforded by their mineral characters. Under these circumstances there has arisen considerable diversity of opinion as to the age of red, mottled, and variegated strata which have been reached in these two borings. While Prof. Prestwich is inclined to refer the rocks in both cases to the Old Red Sandstone, the officers of the Geological Survey are in favour of regarding them as belonging to some part of the New Red Sandstone or Poikilitic. Mr. Whitaker has so well stated the objections to the view that the rocks at Kentish Town and Crossness are of Old-Red-Sandstone age, that we cannot do better than quote what he says upon the subject:—

"I may here remark that there is a strong reason

against the classification of the bottom beds at Kentish Town and Crossness with the Old Red Sandstone, which seems to have escaped notice. Having the series unmistakably present in the Devonian type at Cheshunt and at Meux's, it would be strange indeed were it to occur in its wholly distinct Old Red Type at Kentish Town, between those two places, and at Crossness, not very many miles from the latter of them! I believe that no such thing is known to occur anywhere; the two types of what is generally taken to be one great geological system being limited to separate districts, and not occurring together."

There is one other point upon which Mr. Whitaker's views as expressed in the work before us are well worthy of the attentive consideration of geologists. On p. 20 he remarks:—

"It has been said that although, from the cores brought up from some of the deep borings, we can estimate the angle of dip of the rocks, yet for calculations as to the probable extent of any of these rocks, and as to where other rocks may be expected either to come on above or to rise up from beneath them, it is needful to be able also to approximate to the *direction* of dip. I am led to think, however, that this is really of less importance than at first sight seems to be the case; for judging by what we generally see of the older rocks in districts where they are at the surface, they are much subject to disturbances and are thrown into great rolls or folds, so that whilst at one spot dipping north, near by they may turn over and dip south. We find, too, in the coal-fields of Belgium and of the north of France frequent evidence of sharp folding, and indeed of inversion of these older rocks underneath the even and almost undisturbed Cretaceous and Tertiary beds. I think therefore that were we able to find the direction of the dip of the rocks in any of our deep wells it would be unsafe to argue from that alone as to the probable succession of the beds in any direction for a considerable distance."

Mr. Whitaker's suggestions as to the direction in which it might possibly be of use to search for the Coal measures in the south-east of England are offered with a cautious reservation which is highly to be commended; it is evident, however, that he agrees with Mr. Godwin-Austen and Prof. Prestwich in the opinion that the southern suburbs of London and the line of the North Downs afford the most promising fields for future research. It is greatly to be regretted that no attempt has been made to obtain the necessary means, either from public funds or by private subscription, for carrying out this most interesting experiment.

It is not only in connection with his account of the great underground ridge of palæozoic rocks that Mr. Whitaker has been able to make valuable additions to this work. His account of the chalk and the boulder clay have been supplemented by some remarks giving the reader an idea of the latest views which have been published concerning the mode of origin of those formations. To students of Tertiary geology Mr. Whitaker's remarks on the pebble-gravel round London will prove interesting, while archæologists will find a valuable record of the discovery of a canoe (now placed in the British Museum) in the peat cut through in the works of the Victoria-Docks Extension.

This admirable guide to the geology of London is published at the low price of one shilling, and the demand which has already produced the exhaustion of two editions ought surely to convince the authorities of the Geological Survey that it would be wise of them so to curtail the expenses of publication in the memoirs which they issue, as to permit of their being sold at equally reasonable rates.

PROF. A. GRAY'S BOTANICAL TEXT-BOOK

The Botanical Text-Book (Sixth Edition). Part I.—*Structural Botany, or Organography on the Basis of Morphology, to which is added the Principles of Taxonomy and Phytography, and a Glossary of Botanical Terms.* By Asa Gray, LL.D., &c., Fisher Professor of Natural History (Botany) in Harvard University. (New York and Chicago: Ivison, Blakeman, Tayler, and Co., 1879. London: Macmillan and Co.)

THE near prospect of a visit from one who has for upwards of a quarter of a century held the undisputed position of the first botanist in the New World, both as a teacher and a writer, reminds us that his last and in some respects the most important of his many valuable publications, the "Botanical Text-Book," has not yet been noticed in this journal.

Prof. Asa Gray is the author of various elementary works upon the science he has so long cultivated and taught, some adapted for the old and some for the young, unequal in every respect except that of merit and admirable adaptation to their several purposes. Such are his "First Lessons in Botany," which contain just so much as is necessary to obtain such a knowledge of the botany of flowering plants as will enable a student to ascertain their names and affinities by the use of the ordinary descriptive manuals; his "How Plants Grow: a Simple Introduction to Structural Botany," which is the most lucidly written work of the kind known to us; his "Lessons in Botany and Vegetable Physiology;" his "Manual of the Botany of the Northern United States;" and, above all, his "How Plants Behave: an Introduction to a Study of the Habits and Movements of Plants, adapted for the Young," which is a marvel of good arrangement and clear expression, whilst the subject is rendered in the highest degree attractive to both old and young.

These and other elementary works on botany are, though sold by thousands in the United States, comparatively little known on this side of the Atlantic. The same cannot be said of a more comprehensive work by the same author, written for more advanced students, and as a book of reference for the working botanist, namely that which heads this article. The "Botanical Text-Book" appeared so long ago (as a first edition) as 1842, and immediately took rank as a first-class educational work in all English-speaking countries, and from that time to the present, during which the five editions which have appeared, being always brought up to date in point of matter, have been successively recognised by professors in British universities as the best introduction to botany extant in the language, and recommended by many to their pupils as the one they should use.

In all the five editions all the branches of botany have been treated of under the heads of Structure, Physiology, and System; but the twenty-three years that have elapsed since the appearance of the last edition have so greatly enlarged our knowledge of the physiology of vegetables, and of the vast assemblage of plants known as crypto-

gamic, that these subjects can no longer be treated of *pari passu* with the structural, if this latter is to be brought up to the present state of knowledge in a work of the scope and design of the author's "Text-Book." This has determined Dr. Gray to enlarge the scope of his work, to retain the authorship of one volume, which is devoted to Morphology, Taxonomy, and Phytography, re-writing these throughout, to assign another upon Vegetable Histology and Physiology to his colleague, Prof. Goodall; a third, which will be an Introduction to Cryptogamous Plants, to another colleague, Prof. Farlow; and to complete the series by a fourth, from his own pen, on the Morphology and Classification of Flowering Plants, their Distribution, Products, &c.

Thus, when complete, we shall have from the most eminent botanical professors in the New World as comprehensive an introduction to the study of the Vegetable Kingdom as the nineteenth century is likely to produce.

OUR BOOK SHELF

Light and Heat; the Manifestations to our Senses of the Two Opposite Forces of Attraction and Repulsion in Nature. By Capt. W. Sedgwick, R.E. (London: Hodgson and Son, 1880.)

THE reviewer who says what he thinks is sometimes thought unkind. The author's paradoxes require no commentary but themselves to be duly appraised by scientific readers.

"The explanation of the fact that a spot of light is seen alike when pressure is applied to the outside of the eye, and when a single ray of light passes into the eye, is that the ray of light really makes itself manifest to our sense of vision by exerting a pull upon the retina of the eye . . . it follows, of course, that light is a pulling or an attractive force, and is therefore opposed to heat, which, as is well known, is a pushing or repulsive force." (Pp. 14 and 15.)

"Light consists of a large amount of the attractive force, mixed with a small amount of the repulsive force. Heat, on the other hand, consists of a large amount of the repulsive, with a small amount of the attractive force." (P. 28.)

"We have in the growth of plants and trees a beautiful exemplification of the action of heat and light as expansive and attractive forces. The young shoots are extended by the expansive power of heat, and then the attractive power of light comes into play" . . . (P. 38.)

"It may be objected that gravity cannot be the same force as light, because, if it were, it would be greater by day than by night." (P. 42.)

"There is ample evidence all about us to testify to the fact that light is an attractive force. Indeed *we ourselves bear witness to the fact by our fondness for fireworks and illuminations*" . . . (P. 38.)

"Light being the manifestation, in the free state, to our senses of the attractive or cohesive force . . . the fact that the production of light is made the first act in the creation of the world, in the account given us in the Book of Genesis, becomes intelligible." (P. 42.)

"I ask for no other favour, and for no mercy." (P. 3.)

We believe we have sufficiently complied with the gallant captain's request. S. P. T.

The Land and Freshwater Shells of the British Isles. By Richard Rimmer, F.L.S. (London: David Bogue, 1880.)

THIS unpretending and well-written volume is dedicated to the artisans, with many of whom, especially in the North of England, the subject is very popular. The dedication is qualified, viz.: "To those of my countrymen among the working classes who wisely employ their leisure hours in the pursuit of useful and elevating knowledge, with the hope that others among their ranks may be induced to forsake the paths of profitless and degrading dissipation." William Edward, the Banff shoemaker, is (thanks to Mr. Smiles) a celebrated example of the more intelligent workman; and we know of others who, however, "carent vate sacro." The book is very readable; it gives an excellent account of the habits of our land and freshwater mollusks, as well as of their various habitats, and it is not burdened with any synonymy or useless aliases. It is founded on Dr. Gwyn Jeffreys' "British Conchology." But the present work has a drawback. Eight out of the eleven plates give photographs of the shells, which are produced by the "Albertype" process; and the figures, especially of the smaller species, are so blurred or smudgy as to be almost undistinguishable. Plate X. is very good, representing magnified views of the British species of *Vertigo*. There is a useful glossary.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Novel Celestial Object

THE search for planetary nebulæ, described in NATURE, vol. xxii. p. 327, was continued for several evenings without revealing any new object, although it is estimated that the spectra of about 100,000 stars were examined. On the evening of August 28 an object entered the field which presented a faint continuous spectrum with a bright band near each end. Clouds interfered and barely permitted an identification with Oeltzen 17681, or a position in 1880 of R.A. 18h. 1m. 17s., Dec. - 21° 16′.

This object might be mistaken for a temporary star like that in Corona in 1863, and the bands assumed to correspond to the hydrogen lines C and F. This view is contraverted by the permanency of the object which was observed by Argelander in 1849, and at the Washington Observatory in 1848 and 1849. In all these cases its magnitude was estimated as 8, or very nearly its present brightness. No variation of light was detected between August 28 and September 1. The star Oeltzen 17648 precedes it very nearly a minute, and is only four minutes north, so that their light can be easily compared. As they are nearly equal, a slight change would be quickly recognised.

A further examination of the spectrum showed that the less refrangible band is near D, and the other between F and G. The images of both, but particularly of the second, are much elongated by the prism, showing that they are bands, and not lines. The limits of wave-length of the first band are approximately 5,800 and 5,850; those of the second, 4,670 and 4,730. A band at 5,400 and some other fainter bands were also suspected, but their existence is not certain.

The discovery of this object greatly increases the difficulty of distinguishing between a star and a planetary nebula. If the disk is used as a test, the first object described in the paper referred to above might easily be taken for a star. If we define a nebula by its spectrum of bright lines on a faint continuous spectrum, the object now under consideration becomes a nebula. Whether it is a mass of incandescent gas resembling a nebula in character, but not in constitution, or whether it is a star with a vast atmosphere of incandescent gas of a material not as yet known to us, are questions which cannot yet be decided.

Cambridge, U.S., September 2 EDWARD C. PICKERING

Experiments on the States of Matter

THE exploration of the new region which I have lately opened up has led to so many results with both scientific and technical bearings that I have been unable to leave this city for some time to attend any scientific meetings, and I would beg leave, with your kind permission, to make, through the medium of your valuable columns, a few remarks on some recent scientific work.

The quite independent confirmation of my discovery of the limit of the liquid state given in a letter in NATURE, vol. xxii. p. 435, by my old colleague, Dr. Carnelley, helps to dispel the idea of an intermediate state above the critical point, and confirms me in the use of the term "gas" for all fluids above their critical temperatures in speaking of the "solubility of solids in gases." The term vapour should only be applied to an aëriform fluid which by pressure alone can be reduced to the solid or liquid state, and above the critical temperature this cannot be done. As yet I have no evidence that vapours so defined are capable of dissolving solids, and this negative property may help to form a definition of that division of matter. As Dr. Carnelley does not mention the coincidence of our researches, perhaps you will permit me to quote from our respective papers. Dr. Carnelley says:—1. "In order to convert a gas into a liquid, the *temperature* must be *below* a certain point (termed by Andrews the *critical temperature* of the substance), otherwise no amount of pressure is capable of liquefying the gas."

As far back as May 24 I wrote ("On the State of Fluids at their Critical Temperatures," *Proc.* Roy. Soc. No. 205, 1880):—"The same results were obtained as before. When the temperature was below the critical point, the contents of the tube were liquid, and when over that temperature the reaction was always gaseous, notwithstanding the variations of pressure.

"I think we have in these experiments evidence that the liquid state ceases at the critical temperature, and that pressure will not materially alter the temperature at which the cohesion limit occurs." Dr. Carnelley will find the whole of my paper devoted to an experimental demonstration of what he has now deduced from his experiments. The paper was written with the title, "On the Cohesion Limit," but by the advice of Sir William Thomson, to whose great kindness in helping me with advice and information I am much indebted, I altered the title until I had the whole field explored. This I have since done, and have completely established the "cohesion limit" for all liquids—that for homogeneous liquids being an isotherm starting from the critical point. My paper being a very full one has taken much time and work, and the corrections for over a thousand experiments will take me some time yet. Prof. Stokes (whose kindly interest and encouragement have greatly lightened my labours) has been kept informed of my progress, and is cognisant of the work I have done in this direction. Dr. Carnelley's second conclusion is also very interesting, especially when applied to water; but surely we are not to understand that the solid ice was hot throughout, or that, if a thermometer had been imbedded in the ice, it would have risen. Although the vessel be red hot, the ice need never be allowed to melt, but made to pass directly into vapour, and yet its temperature remain 0° till it has been entirely volatilised.

I notice from your report of the British Association that Sir William Thomson calls attention to Cagniard de Latour's method of showing the critical state of a liquid by sealing the requisite proportion of liquid in a stout tube and heating it in a bath. It should not be forgotten that, although to Dr. Andrews undoubtedly belongs the credit of establishing the definite finish of the boiling-line and the apparent continuity of the liquid and gaseous states, to Baron Cagniard de Latour belongs the discovery of "l'état particulier" where the liquid state ends. Latour's method, although often used by Mr. Hogarth and myself, is not convenient for purposes of research. The method, your report goes on to say, was criticised by Prof. W. Ramsay, in what spirit we are not informed, but Dr. Ramsay added that he had found an apparatus in which a screw was employed to produce increase of pressure instead of using the expansion of the liquid itself. Dr. Ramsay, however, did not say whether the apparatus he had found was that invented by Mr. Hogarth and myself, and described by us in *Proc.* Roy. Soc., No. 201, 1880, in which india-rubber in a hollow cap is made by compression to yield a perfectly tight joint and to answer also for a screw when protected by a facing of leather. Dr. Ramsay visited my laboratory, and had the apparatus taken down and fitted up before his eyes, and with my permission had an apparatus made. The use of the compressed india-rubber for obtaining the requisite close fitting constitutes the important feature of my apparatus; the employment of iron for constructing the vessel enabling experimenters to dispense with the use of two liquids as in Andrews' apparatus—mercury being used alone.

I have made some little progress with the construction of vessels to withstand pressure at high temperatures, and I expect in a few weeks (when I have prospect of leisure) to carry my crystallisation experiments to a scientific if not commercial success. J. B. HANNAY

Private Laboratory, Sword Street, Glasgow

Fascination

I EXPECTED some of your readers to refute the explanation of Mr. Stebbing on "Fascination." I see in NATURE, vol. xxii. p. 383 another paragraph which is not more to the purpose. Want of presence of mind and stupefaction are not fascination. In 1859 (twenty-one years ago) I followed in the rocks of Avon, close by the park of Fontainebleau, the fairy paths of Denecourt, when the approach of a storm induced me to leave the blue arrows, indicating the right path, for a short cut. I soon lost my way, and found myself in a maze of brambles and rocks, when I was startled by seeing on my left hand, at a distance of about ten yards, a snake, whose body lifted up from the ground at a height of about a yard, was swinging to and fro. I remained motionless, hesitating whether to advance or to retreat, but soon perceived that the snake did not mind me, but kept on maintaining its swinging motion, and some plaintive shrieks attracted my attention to a greenfinch perched on a branch of a young pine overhanging the snake, with his feathers ruffled, following by a nod of his head on each side of the branch the motions of the snake. He tottered, spread his wings, alighted on a lower branch, and so on until the last branch was reached. I then flung my stick at the snake, but the point of a rock broke it and the snake disappeared with the rapidity of an arrow. On approaching the spot, a real abode of vipers, which I did with the greatest precaution, knowing by observation that death may be the result of the bite of a viper, I saw the greenfinch on the ground agitated by convulsive and spasmodic motion, opening and shutting his eyes. I put him in my bosom to try the effect of heat, and hastened to reach the park of Fontainebleau. The little claws of the bird opening and shutting, perhaps as an effect of heat, made me think that he might perhaps be able to stand on my finger, and he did clutch it, and held on with spasmodic squeezes. In the park I got some water, and made him drink it. In short, he revived and finally flew off in the lime-trees of the park.

Now whilst following the motions of the snake and bird I experienced a singular sensation. I felt giddy; a squeezing like an iron hoop pressed in my temples, and the ground seemed to me to be heaving up and down. In fact the sensation was quite analogous to that experienced on a beginning of sea-sickness.

From these facts would it not seem probable that fascination is nothing more nor less than an extreme fatigue of the optic nerve, produced by a rapid gyratory motion of a shining object and resulting in a nervous attack and a coma? Curiosity rivets at first the attention of the bird, unconscious of any danger, and when giddiness warns him of his peril it is too late. The snake is as well aware of this as the *Lophius piscatorius* is of the effect of his membrane.

In this system the fact of the bird coming down from a higher to a lower branch would be explained by the supposition that, giddiness overtaking him, he opened instinctively his wings and clung to the next support that he found, the motion having partially removed the giddiness so as to enable him to hold fast.

Observe, that nothing hindered the bird from flying away, and that the snake being at most five feet long, could never have reached even the lowest branch.

Besides he could have no nest to protect, for in the rocks of Avon there is no water save rain-water in the hollows of the rocks, and this is not potable on account of microscopic leeches which people it, the instinct of birds teaching them to avoid it.

Jersey, August 29 CHATEL

P.S.—I inquired of Mr. Denecourt, "the sylvan of the forest," if he were aware of the existence of such large snakes in the forest, and he told me that he had only seen, in the "rocher Cuvier Chatillon," a snake about four and a half feet long, which he killed, but that even larger snakes had been seen in this very "rocher d'Avon" and in the "rocher St. Germain," but he thought that they were only "couleuvres" of a large size and quite inoffensive.

Meteor

ON the 19th inst., at 11.34 p.m. (within a minute of G.M.T.), I observed a large meteor in the east, towards which I happened to be looking, the sky being quite free from clouds, and clear.

When first seen it was half way between Capella and α Persei; it passed in a slightly curved direction, which was concave towards Auriga, downwards to a line joining β and α Tauri, disappearing at a point one-third of the distance from β towards α. It was very much brighter than Jupiter, and quite half the diameter of the moon; I made these comparisons immediately after it had passed.

Its passage occupied about eleven and a half seconds, and it left a bright continuous yellow streak in its wake, which did not fade until about two or three seconds after the meteor had disappeared; this enabled me the more readily to fix its position. The whole of its path was not seen, as it emerged from behind a tree with thick foliage, though its light attracted my attention before the meteor appeared.

It was pear-shaped, and its brightness appeared to slightly increase; its colour was a very bright reddish yellow changing to deep purple at its disappearance; it was not followed by any noise. The latitude of place of observation is N. 51° 28′ 20″, the longitude W. 0° 20′ 17″.

C. THWAITES

Isleworth, September 21

EVOLUTION AND FEMALE EDUCATION

ONE of the most remarkable features of the advance of science is perhaps the increasing facility afforded for bringing under the grasp of *physical* treatment questions formerly thought to be within the range of abstract reasoning alone. These two methods, if correct, will of course run parallel to each other, and at the same time tend reciprocally to confirm their truth:—the *physical* method being often the more easily followed, and therefore perhaps considered on that account the more certain of the two. Many instances may no doubt readily present themselves of conclusions formerly reasoned out on abstract grounds (more especially by the ancient philosophers), and subsequently confirmed by physical reasoning. As a modern example of this *double* treatment of the same subject we might mention the very important question of the higher mental training of women, dealt with by the late John Stuart Mill on substantially abstract grounds, and touched on by the theory of evolution on physical grounds. As we propose solely to notice the *physical* side of the question here, perhaps this brief essay may not be thought unsuited to the columns of NATURE. We do not expect to bring forward anything especially new, but we may perhaps exhibit the case in some novel aspects; at the same time we may avoid elements of uncertainty by carefully separating the facts supported by scientific evidence from the question of the desirability or undesirability of the measures to be taken upon these facts as a basis, and thus the paper may hope to attain that degree of reliability or solidity which is usually looked for in a journal of natural science.

Perhaps the most valuable characteristic of the doctrine of evolution (or the history of the past rise of man) is the lesson it gives for future progress. It will be apparent that an inquiry into the conditions affecting the progress of mankind would want one of its primary elements if the conditions bearing on the advancement of woman (as one half the race) were excluded therefrom; and the fact of this point being popularly underrated may be considered as rather in favour of its value and significance than not, inasmuch as all great reforms consist in the conquest of popular prejudice. That the value attached to this reform by Mill, which occupied a great part of his life, was not overestimated by him will, we think, become all the more evident when the subject is brought under the test of the theory of evolution.

Mr. Darwin in his work, "The Descent of Man" (second edition), remarks:—"It is indeed fortunate that the law of the equal transmission of characters to both sexes prevails with mammals, otherwise it is probable that man would have become as superior in mental endowment to woman as the peacock is in ornamental plumage to the peahen" (p. 565).

This therefore puts the question of the education of woman in a somewhat new light: though in a light probably suspected by some (including, it may be said, the writer) beforehand, on abstract grounds. For this would show, on a reliable physical basis, that one of the chief arguments for the intellectual training of woman must be for the direct benefit of *man*. For the above deduction, grounded on the evidence of natural science, would indicate clearly that man, by opposing the intellectual advance of woman for countless generations, has enormously injured his own advance—by inheritance. In other words, while man has been arbitrarily placing restrictions in the way of the mental progress of woman, nature has stepped in, and by the laws of inheritance has (to a large extent) corrected, at his expense, the injury which would otherwise have been inflicted, and which, without this interposition of natural law, would have made itself transparently obvious, centuries ago. Man, by hindering woman from performing her natural share in the work of brain development, has been compelled by nature to do the work for her, and valuable brain tissue (accumulated by mental discipline), which would have been man's own property as the fair reward of intellectual labour, has gone over by the rigorous laws of inheritance[1] to the female side, to fill up the gap artificially created by man through his persistent hindrance of woman from doing her part in the progressive development of the brain. The probable extent of the gap by accumulation (from all causes, including the very important factor of man's obstruction) is apparently roughly indicated by the comparison employed in the above quotation. It would seem, therefore, that it could scarcely be said to be altogether fortunate (in *one* sense at least) that "the law o equal transmission of characters to both sexes prevails with mammals;" for this fact has served to conceal an evil which in reality exists in all its magnitude, and which otherwise it would not have required the intellect of a Mill to detect, but which must have become glaringly apparent long ago. Physical science would therefore appear to show a remarkable confirmation of Mill's magnificent theoretic analysis, and of the reality of those evils, the clear exposure of which by him looked to some like exaggeration. In fact it would result from the scientific evidence that however monstrously women might have been treated, however much idleness might have been enforced, or healthy brain exercise prevented, nature would have infallibly corrected the irregularity *at the expense of man*, entailing of course the partial extinction of the progress of the race (as a whole). Possibly the not uncommon popular ridicule which (at first, at least) accompanied Mill's protests, the conceited independence of some men in ignoring the fact that they are descended from women, and their failure even now to realise so obvious a truth as the desirability of clearing away all obstacles to the intellectual advance of woman (by facilitating education, by removing the bars to healthy exercise of the brain in suitable professions, &c., in place of idleness) may itself be in part a consequence of the deficiency of brain tissue caused by the drain through inheritance which goes to counteract their efforts of obstruction. Some of the reasons urged against the higher mental training of woman are of so superficial a character as themselves to show the extensive magnitude of the evil. One notoriously not uncommon ground adduced

[1] Possibly (and we believe this may have been suggested by others) the less stability, or sometimes almost hysterical character of the female intellect may be naturally due to the brain qualities being gained mainly by *inheritance* instead of by hard practice, as in the case of man's brain attributes. While the faculties of man have acquired the steadiness produced by centuries of healthy intellectual discipline and exercise, the field for this has been closed to woman to a large extent. In fact the scientific evidence would appear to show that the common brain (*i.e.* the brain common to the race) has been built up mainly by man's efforts, while woman has to a great extent *inherited* her share at his expense, though no doubt if left entirely unfettered she would have largely contributed to the common good; and it may be inferred with tolerable safety that the race would then have been elevated far above its present *status*.

is that women already are, as a rule, somewhat inferior in mental power to men, forgetting that they were precisely made inferior by the obstacles thrown for centuries in the way of their advance (some of these specially fixed by legal enactment), and which are sometimes of such a kind as almost to amount to a tax on liberty. It may well be conceivable that the law of inheritance, though it has achieved a vast amount, may not have been able to combat these artificial conditions for producing inferiority with entire success. The above plea of existing inferiority in mental power, therefore, so far from being an argument *against* female education, ought, when justly viewed, to be regarded as the strongest reason the other way. For if obstruction has produced—in spite of the powerful countervailing influence of the law of inheritance—a certain degree of inferiority: so (conversely) by equally reliable casual sequence encouragement would produce an effect in the opposite direction. Moreover, precisely on account of the fact that woman is already somewhat handicapped by nature in the race of progress, would there be all the more reason why every encouragement should be given; *à fortiori*, all artificial hindrances in the way of advancement removed. It would be a great mistake if the idea were for one moment entertained that progress can be accomplished by letting matters generally drift under the influence of prevailing custom. If there is one thing more certain than another it is that man can never hope to progress with satisfactory rapidity without having a sharp eye to the conditions necessary for this object, and examining (by the light of reason and knowledge gradually acquired) all his customs, to see if they are desirable or not. To facilitate this end the history of past progress, unfolded in the theory of evolution, may afford some valuable instruction. The increasing appreciation of the value of co-operating with the weak, instead of domineering over them, may be perhaps regarded as one of the most pleasing accompaniments to the advance of science.

S. TOLVER PRESTON

THE YANG-TSE, THE YELLOW RIVER, AND THE PEI-HO[1]

THESE three rivers form conjointly the great river-system of China. Although at the present day each of them runs its separate course to the sea, there is good reason to believe that several centuries since they were united by a number of connecting branches in a manner somewhat resembling the junction of the Ganges and the Brahmapootra in our own time. Such is the inference to be drawn from an ancient Chinese map copied by Alvarez Semedo, a Portuguese Jesuit, and which must be assigned to a time preceding that of the construction of the Grand Canal by Ghenghis Khan in the beginning of the thirteenth century.[2] Linked together as these rivers were in the past, a brief consideration of their present condition will prove that they are labouring towards the same end in our own day. But before proceeding to examine them in their conjoint character, it will be necessary to consider briefly their leading hydrological features.

1. *The Yang-tse*—the largest and most important of these three rivers—has a course of about 3,000 miles, and drains an area which is variously estimated between 750,000 and 550,000 square miles: for my own calculations I will adopt the mean of these two estimates, namely, 650,000 square miles. Its waters, commencing to rise in February and March, reach their highest level in the month of June or July; and here they remain with occasional fluctuations till the end of August or the beginning of September, finally reaching their lowest level towards the close of January.

With regard to the *discharge of water* of this river, Capt. Blakiston[1] has estimated the average amount carried past I-chang, which is situated at about 960 miles from the sea, at 500,000 cubic feet per second; he founded this estimate on observations made during the months of April and June. When stationed at Hankow in the winter 1877-78, a place distant about 600 miles from the sea, I set to work to make a similar estimate of the water carried past that city for the twelve months included between May 1877 and May 1878. Having taken a line of soundings across the river and having ascertained the river's breadth (1,450 yards, by sextant measurement) at a point below the union of the Han with the main stream, I commenced a series of observations on the rise and fall of the river water and on the force of the current, which, combined with information received from the Custom-house and from other sources, supplied me with the necessary data for my calculation. The results are contained in the following table:—

1877.		Surface current. Knots per hour.	Average depth. Feet.	Water-discharge. Cubic feet per second.
May	31	$2\frac{1}{4}$	64	846,336
June	30	$2\frac{1}{3}$	61	896,293
July	31	3	58	1,022,656
August	31	$3\frac{1}{4}$	62	1,275,381
September	30	$2\frac{3}{4}$	63	1,018,248
October	31	2	53	622,997
November	30	$1\frac{1}{4}$	42	308,560
December	31	1	36	211,584
1878.				
January	31	$\frac{3}{4}$	30	141,085
February	28	$1\frac{1}{3}$	39	412,626
March	31	$1\frac{1}{3}$	45	396,720
April	30	2	57	670,016
				12)7,822,502
				651,875

We may therefore place the average water-discharge for the year at Hankow at *650,000 cubic feet per second.* Now, estimating the area of drainage above Hankow to be about $\frac{11}{13}$ of the whole area, and assuming that the portion of the Yang-tse valley below Hankow drains off its waters at the same rate as the remainder of the river-basin, it follows that the average water-discharge for the whole river may be placed at *770,000 cubic feet per second.*

With reference to the amount of *sediment* carried by the Yang-tse past the same city, I found as much as seven grains in the pint (nearly one drachm in the gallon) in the month of July, when the river was at its height; while in March, when the river was low, I found as little as three-fifths of a grain per pint. The average proportion of sediment during the twelve months in question I estimate at *four grains in the pint* (a little over half a drachm per gallon). This represents a proportion of $\frac{1}{2158}$ by "weight," or (taking the specific gravity of the dried mud at 1·9) of $\frac{1}{4187}$ by "bulk" of the average discharge of water. It is thus easy to obtain the total amount of sediment carried during the twelve months past Hankow, namely, 4,945,280,250 cubic feet: but to allow for the amount of mud a river pushes along its bed, one-tenth must be added according to the principle laid down by Messrs. Humphreys and Abbot in the case of the Mississippi. This will bring the *total annual discharge of sediment* at Hankow up to *5,439,808,275 cubic feet*, or at the rate of 172 cubic feet per second. Now, assuming that the drainage area below Hankow sup-

[1] The author, Surgeon H. B. Guppy, of H.M.S. *Hornet*, writing from Yokohama, February 11, says:—"I forward to you by this mail a paper containing the results of observations I have made during the last two years on the subject of the Yang-tse and the Pei-ho, together with similar information as regards the Yellow River. Looking on these three rivers as in reality one river-system, I have embodied in one paper all the 'data' concerning them; and have treated them both separately and in their conjoint character. I can answer for the accuracy of the various estimations, and have employed the usual methods in obtaining them."

[2] *Vide* a paper by Mr. S. Mossman on the "Double Delta of the Yellow River," published in the *Geographical Magazine* for April, 1878.

[1] "Five Months on the Yang-tse."

plies the same relative amount of sediment as the remainder of the catchment basin, I estimate the *total amount carried down to the sea annually at 6,428,858,255 cubic feet.*

The removal of this amount of sediment from an area of drainage of 650,000 square miles represents a lowering of the surface at the rate of *one foot* (of rock) *in 3,707 years.* This is therefore the rate of "subaërial denudation" of the valley of the Yang-tse as far as concerns the quantity of sediment removed. Of the proportion of solids in solution, I have had no opportunity of judging, but that the soluble matter is in considerable quantity is rendered probable from the extensive limestone districts traversed by this river.

2. *The Yellow River* or *the Hoang-ho* has derived the appellation of "China's Sorrow" from its frequent destructive inundations. It runs a course of about 2,500 miles; but, unlike the Yang-tse, its lower course has frequently shifted in the course of ages, and although it opens at the present day into the Gulf of Pe-chili, only a quarter of a century has passed since it emptied its waters into the Yellow Sea.[1] The mountainous district of the province of Shantung has in truth been the chief means in deflecting the waters of this great river on more than one occasion during the historical era from the Gulf of Pe-chili to the Yellow Sea, and *vice versâ.*

With reference to the *quantity of water discharged* by the Hoang-ho I have had no opportunity of personal observation. We have, however, an estimate not only of the water-discharge, but also of the sediment, which Sir George Staunton supplies us in his account of Lord Macartney's embassy to China in 1792. It was calculated that at the place where the British embassy crossed the Yellow River—its junction with the Grand Canal—the water was carried past at the rate of 418,176,000 cubic feet per hour, or *116,000 cubic feet per second.* The method employed in ascertaining the quantity of sediment was the measurement of the amount of mud deposited from a gallon and three-quarters of water when allowed to stand. From this experiment it was concluded that the sediment was in the proportion of $\frac{1}{200}$ of the original bulk of the water, and the *annual discharge of sediment* was assessed at *17,520,000,000 cubic feet.*

However carefully these observations may have been made, and however near they may approach the actual discharge of water and of sediment at the time in question, it seems to me that one is hardly justified in accepting the result of a single observation as typical of the average state of things throughout the year; and yet Sir George Staunton's estimate has never, as far as I am aware of, been questioned. A single glance at the foregoing table will convince one of the little dependence that can be placed on a solitary estimation; it will be there seen that the Yang-tse discharged nine times as much water when at its highest level in August as it did during the month of January, when its waters occupied their lowest level.[2] Or if the question of sediment is considered, to which the same objection would apply, I have the greatest diffidence in accepting Sir George Staunton's estimate as being of any value except as a trustworthy result of a single experiment; and yet, even considered as the maximum of the whole year, the result is a rather startling one. While the greatest amount of sediment I found in the water of the Yang-tse was seven grains in the pint, and in the case of the Pei-ho—as will subsequently be noticed—fifteen grains in the pint, Sir George Staunton estimates the sediment of the Yellow River at over eighty grains in the same measure of water. Even the muddy waters of the Ganges do not contain more than twenty grains of sediment in the pint of water.

It is therefore not with any surprise that I find the "subaërial denudation" of the Hoang-ho is estimated[3] at less than half that of the Yang-tse, namely, *one foot in 1,464 years.* This estimate only refers to the amount of sediment removed, and yet I cannot but consider it as very liable to correction by some future observer. As this is the only calculation that has ever been made, as far as I am aware, with reference to the quantities of sediment and of water discharged by the Yellow River, I am perforce obliged to accept it *pro tanto.*

3. *The Pei-ho* drains the great plain which constitutes the province of Pe-chili. Its length is said to be about 300 miles, but the lower part of its course below the city of Tientsin is so tortuous that a distance of thirty miles overland is converted into fifty by the river. It is at Tientsin that the Pei-ho proper and the Yu-ho unite together to form the main stream: the latter is generally known by Europeans as the Grand Canal, but as a matter of fact the canal joins the Yu-ho about 150 miles to the southward. During the three winter months—December, January, and February—the Pei-ho is usually frozen over, the ice having a thickness of about eighteen inches; in the same season there is generally a large quantity of ice in the Gulf of Pe-chili, which may completely fill up the head of the gulf.

With reference to the *water-discharge* of this river, I was enabled while wintering at Tientsin during the season 1878-79, to collect some "data" for its estimation during the four months from December to March. Although my estimate strictly applies to but a third of the year, still from the limited rise and fall of the water during the different seasons (it never exceeds six feet) I feel pretty confident that it fairly represents the average rate of discharge during the whole year. The breadth of the river at the place of observation below the city of Tientsin was 280 feet. The following table contains the results of my calculations:—

1878.	Surface current. Knots per hour.	Average depth. Feet.	Water-discharge. Cubic feet per second.
December	$1\frac{1}{5}$	14	6,355
1879.			
January	$\frac{4}{5}$	$14\frac{1}{2}$	4,389
February	$1\frac{3}{5}$	16	9,684
March	2	14	10,592
			4)31,020
			7,755

We may thus place the average discharge of water for the whole year at about *7,700 cubic feet per second.*

Now with regard to the *amount of sediment* carried past the city of Tientsin: I found the average quantity during the four months in question to be about *five grains per pint.* (It varied much at different times, for I found as much as fifteen grains in the middle of March, while in the months of January and February it did not equal a grain in the pint.) This represents a proportion of $\frac{1}{1750}$ by "weight," or $\frac{1}{3528}$ by "bulk" of the average discharge of water: and following the same method of calculation as was employed in the case of the Yang-tse, I estimate the annual discharge of sediment for this river at *80,000,000 cubic feet.*

Now the removal of this bulk of material from an area of drainage, which I estimate at 55,000 square miles, represents a lowering of the surface of *one foot in 25,218 years.* This is the rate of "subaërial denudation" of the Pei-ho basin, omitting of course the question of the solids in solution.

To show the rank that these three rivers hold in the fluvial system of the globe, I have subjoined a list of fourteen other rivers, which gives the quantities of water and sediment discharged by each, as well as the rate of subaërial denudation, as far as I have been able to ascertain.

[1] *Vide* Mr. Morsman's paper, already referred to.
[2] In the case of the Ganges at Ghazepoor the proportion is as 1 to 14.
[3] *Vide* NATURE, vol. xviii. p. 268.

	Water discharged per second.	Sediment per annum.	Subaërial denudation.
	Cubic feet.[1]	Cubic feet.	
Amazon	2,458,026	—	—
Congo	1,800,000 (By Behm and Capt. Tuckey)	—	—
Yang-tse	770,397 (By myself)	6,428,800,000 (By myself)	1 foot in 3,707 years. (By myself)
Plate	700,000 (By Mr. Higgin and Mr. Bateman)	1,543,500,000 (By Mr. Higgin)	1 foot in 29,400 years. (Calculated from Mr. Higgin's estimate)
Mississippi ...	618,000 (By Messrs. Humphreys and Abbot)	7,474,000,000 (By Messrs. Humphreys and Abbot)	1 foot in 6,000 years. (By Mr. Croll)
Danube	300,321	1,255,500,000 (By Mr. Ch. Hartley)	1 foot in 6,846 years.
Shat-el-Arab ...	295,461	—	—
Ganges, at Ghazepoor ...	203,485 (By the Rev. Mr. Everest)	6,368,000,000 (By the Rev. Mr. Everest)	1 foot in 2,358 years.
Indus	190,476	—	—
Atrato	185,274	—	—
Nile	130,032	—	—
Yellow River ...	116,000 (By Sir George Staunton)	17,520,000,000 (By Sir George Staunton)	1 foot in 1,464 years.
Rhone	91,935	594,000,000	1 foot in 1,528 years.
Rhine	69,741	—	—
Po	61,263	405,420,000 (By M. Lombardini)	1 foot in 729 years.
Pei-ho	7,755 (By myself)	80,000,000 (By myself)	1 foot in 25,218 years.
Thames, at Kingston ...	2,300 (By Prof. Prestwich)	1,865,900 (Huxley's "Physiography.")	1 foot in 9,600 years.[2] (Huxley's "Physiography.")

We have now the necessary "data" for considering these three rivers in their conjoint character. Together they drain an area of 1,105,000 square miles; they discharge a body of water equal to *894,000 cubic feet every second;* and they carry down every year to the sea *24,028,800,000*[3] *cubic feet of sediment*, which represents a rate of subaërial denudation equal to the removal of *one foot of solid rock in 1,687 years.*

If we look upon the Yang-tse, the Yellow River, and the Pei-ho as labouring, with the assistance of the gradual elevation of the sea-border which is at present going on, to extend the territory of China seaward towards her ancient coast-line—represented by a line running from Kamtschatka through the Kurile Islands, Japan, the Loo-choo group, Formosa down to the Malay Archipelago;[4] and carry ourselves forward into the future when such task is completed and the waves of the Pacific beat once more against this old sea-border, we shall not have much difficulty in picturing to ourselves what will then be the state of matters. In the place of the gulf of Pe-chili and the Yellow Sea there will be vast alluvial plains traversed by the waters of the Yang-tse, the Yellow River, and the Pei-ho; but before the ancient coast-line is reached they will have joined to form one great river and one united delta. If the Yellow River confines itself mostly in future ages to its course into the gulf of Pe-chili, that gulf will be filled up in process of time; and the Hoang-ho winding along through the bed of this obliterated sea will, after being joined by the Pei-ho, turn its course southward, deflected by the Corean peninsula, until it meets at length its sister stream. On the other hand, should the Yellow River be mostly occupied in future in advancing its southern delta it will join the Yang-tse at a period much less remote from the present; and their united waters will pursue an easterly direction subsequently to be joined by the Pei-ho, which will have been gradually finding its way through the gulf of Pe-chili and the Yellow Sea during the preceding ages. In either event the union of these three rivers would follow.

Such being the case, it may be interesting to speculate on the time required by these rivers to fill up the seas into which they discharge their sediment. Sir George Staunton estimated that at the rate the Hoang-ho was discharging sediment it would fill up the Yellow Sea and the gulfs of Pe-chili and Lian Tung in 24,000 years; but M. Elisée Reclus is of opinion that this estimate ought to be doubled, as the Yellow Sea is much deeper than Sir George Staunton stated it to be (20 fathoms). On carefully examining the latest charts of these seas I am inclined to consider that this estimate cannot be assailed on this point, as my own determination of the average depth is 22 fathoms.

We will now attempt to gauge the time that the three rivers in question would require to fill up by the sediment they deposit the portion of sea which is included by the gulfs of Pe-chili and Lian Tung, the Yellow Sea, and the Eastern Sea north of the 29th parallel and west of the 126th meridian. I have placed the total surface area at 200,000 English square miles, and the average depth at 26 fathoms; and following Sir George Staunton's mode of estimation I find that it would take sixty-six days to form an island a mile square reaching up to the surface of the sea. At this rate it would require 36,000 years to form all the sea in question into dry land, supposing of course that there was no elevation or depression of the sea-bottom during that period. But, the recent formation of several islands and shoals in the Yang-tse estuary, the occurrence of raised beaches and marine remains at Hang-chau, Wusung, and Chefoo, with other similar evidences, demonstrate that there is an elevation of the coast going on at present; and, in that case, it will require considerably less than 36,000 years to form the sea into *terra firma*. Perhaps Sir George Staunton's original estimate for the Yellow River may not be far wrong when applied to the whole sea in question.

[1] Where not otherwise mentioned I have obtained my information of the discharge of water and sediment from the "Earth," by Elisée Reclus.

[2] This estimate also includes the solids held in solution.

[3] In Page's "Advanced Text-book of Geology" Staunton's estimate of the sediment discharged by the Yellow River has been erroneously applied to all "the great Chinese rivers."

[4] *Vide* a paper on this subject, by Mr. A. S. Bickmore, read before the North China branch of the Asiatic Society in November, 1867.

PHYSICS WITHOUT APPARATUS[1]

VI.

ACOUSTICAL experiments require, for the most part, the aid of some good instrument or valuable piece of apparatus. Nevertheless a few instructive illustrations of the principles of the science can be improvised without difficulty. Firstly, there is the familiar experiment brought into fashion, we believe, by Prof. Tyndall, of setting a row of ivory billiard balls or glass solitaire marbles along a groove between two wooden boards, and showing how their elasticity enables them to transmit from one to another a wave of moving energy imparted to the first of the row, thus affording a type of the transmission of sound-waves from particle to particle through elastic media. Then we may show how sounds travel through solid bodies by resting against a music-box or other musical instrument, a broomstick, or any convenient rod of wood, at the other end of which we place our ear. A kindred experiment, illustrative of the transmission of sounds through threads, is depicted in Fig. 20. A large spoon is tied to the middle of a thin silken or hempen thread, the ends of which are thrust into the ears upon the ends of the thumbs. If the spoon be dangled against the edge of the table it will resound, and the tones reach the ear like a loud church bell. The thread telephone or "lover's telegraph," is upon the same principle, the thread transmitting the whispered words to a distance, without that loss by spreading in all directions which takes place in the open air.

[1] Continued from p. 464.

The discovery that a musical tone is the result of regularly recurring vibrations, the number of which determines the pitch of the tone, was made by Galileo without any more formal apparatus than a mill-edged coin, along the rim of which he drew his thumb-nail, and found it to produce a sound. We can show this better by taking a common toy gyroscope-top with a heavy leaden wheel, such as are sold at every toy-shop. With a strong penknife or a file, cut a series of fine notches or grooves across the rim, so that it shall have a milled edge like a coin. Now spin it, and while it spins, gently hold against the revolving wheel the edge of a sheet of stiff writing-paper or of a very thin visiting card. A loud clear note will be heard if the nicks have been evenly cut, which, beginning with a shrill pitch, will gradually fall with a dolorous cadence into the bass end of the scale, and finally die out in separately audible ticks.

Much notice was attracted some years ago by the discovery of singing and sensitive flames. A sensitive

FIG. 20.

flame is not easily made, unless where gas can be burned at a much higher pressure than is to be found in the case of the gas supplied by the companies for house-lighting. To make a singing-flame requires the proper glass tubes and an apparatus for generating hydrogen gas. The roaring-tube, which we are now about to describe, is a good substitute, however, and is also due to the generation of very rapid vibrations, although in this case the way in which the heat sets up the vibrations cannot be very simply explained. Let a common paraffin-lamp chimney be chosen, and let us thrust up loosely into its wider or bulbous portion a piece of iron-wire gauze such as is often employed for window-blinds. If this be not at hand a few scraps of wire twisted together, or even a few hair-pins will suffice. The lamp-chimney must then be held over the flame of a spirit-lamp, or other hot flame, until the wire-gauze glows with a red heat (see Fig. 21). Now remove the lamp or lift the chimney off it, so that the gauze may cool. It will emit a loud note like a powerful (though rather harsh) organ-pipe, lasting for about a quarter of a minute, or until the gauze has cooled. Tubes of different sizes produce different notes.

It is now well known that the quality of different sounds depends upon the form or character of the invisible sound-waves, and that different instruments make sounds that have characters of their own, because their peculiar shapes throw the air into waves of particular kinds. The different vowel-sounds are caused by putting the mouth into particular shapes in order to produce waves of a particular quality. Take a jew's-harp and put it to the mouth as if you were going to play it. Shape the mouth as if you were going to say the vowel O, and on striking the harp you hear that sound. Alter the shape of the mouth to say A, and the harp sounds the vowel accordingly. The special forms of vibration corresponding to the different vowel-sounds can be rendered evident to the eye in a very beautiful way by the simplest conceivable means. A saucerful of soapy water (prepared

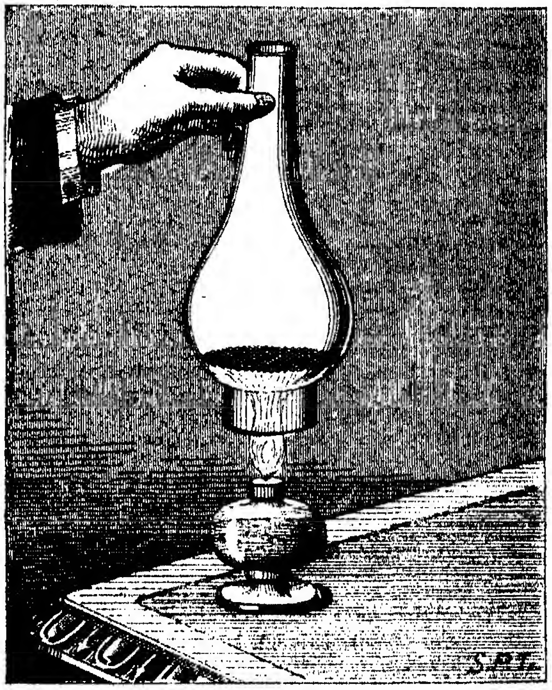

FIG. 21.

from yellow kitchen soap and soft water, or with cold water that has previously been boiled) and a brass curtain-ring, is all that is needed. A film of soapy water shows, as all children know when they blow bubbles, the loveliest rainbow-tints when thin enough. A flat film can be made by dipping a brass curtain-ring into the soapy water, and then lifting it out. When the colours have begun to show on the edge of the film, sing any of the vowels, or the whole of them one after the other, near the film. It will be thrown into beautiful rippling patterns of colour which differ with the different sounds. Instead of a curtain-ring the ring made by closing together the tips of finger and thumb will answer the purpose of providing a frame on which to produce the phoneidoscopic film.

(*To be continued.*)

GENERAL PITT RIVERS' (LANE FOX) ANTHROPOLOGICAL COLLECTION

THE collection which General Pitt Rivers, F.R.S., commenced to form in the year 1851 became well known to all immediately interested in the science of

anthropology during the series of years in which it was exhibited at the Bethnal Green branch of the South Kensington Museum as Col. Lane Fox's collection, and no one visited it without picking up a great deal of interesting and curious information. To those who studied it with care it opened up a new field of exploration, and invested all objects of art and manufacture, from the simplest ornaments, weapons, or implements of savages, to works the product of the highest modern culture, with a certain peculiar interest over and above the gratification derived from the objects themselves without reference to the history of their origin. It is needless to say that the moving power of this peculiar interest was the evolution theory, for the object which General Pitt Rivers set before him was, as he explained, "so to arrange his collection of ethnological and prehistoric specimens as to demonstrate, either actually or hypothetically, the development and continuity of the material arts from the simpler to the more complex forms. To explain the conservatism of savage and barbarous races and the pertinacity with which they retain their ancient types of art. To show the variations by means of which progress has been effected and the application of varieties to distinct uses. To exhibit survivals or the vestiges of ancient forms which have been retained through natural selection in the more advanced stages of the arts, and reversion to ancient types. To illustrate the arts of prehistoric times as far as practicable by those of existing savages in corresponding stages of civilisation. To assist the question of the monogenesis or polygenesis of certain arts; whether they are exotic or indigenous in the countries in which they are found. To this end objects of the same class from different countries have been brought together in the collection, but in each class the varieties from the same localities have been placed side by side, and the geographical distribution of each class has been shown in distribution maps." The gradual growth of the arts has of course been the theme of many writers. But General Pitt Rivers was the first, and up till now has, we believe, remained the only, collector who has investigated the development of arts and manufactures, and brought home their history to students by means of series of the objects themselves arranged in groups so as to illustrate their actual pedigrees.

It is in the arrangement that the collection differs from all others. Very many of the objects of which it is composed are to be found in most ordinary ethnological collections, such as that in the British Museum, and the Christy collection; but in these the specimens are arranged geographically, and though thus serving a purpose of the utmost importance as showing in what matters of culture the various races of man are most clearly distinct and separate, or more or less allied, they do not afford that kind of information which it is the one aim of General Pitt Rivers' collection to convey and develop. In fact in the case of all series of objects of arts or manufactures two collections are absolutely required: the one to illustrate pedigree in accordance with the Darwinian theory, the other to illustrate geographical distribution. A collection arranged on General Pitt Rivers' plan is much needed in natural history galleries. What is specially required for the purposes of general instruction is a series which shall trace the pedigree of man and all the other highest types in the several groups as directly as possible from the lowest forms of life. Such a collection might be arranged in a series of galleries radiating from a central chamber in which should be placed the lowest forms, each gallery leading gradually up to the highest of the group to which it was alloted. Good models should represent in the series those links which are embryonic, or which require reconstruction from fossil remains.

Since the year 1851, when General Pitt Rivers' collection was first commenced, it has been continuously added to, and it has now reached very considerable dimensions. The space allotted to it at present in the South Kensington Museum will not be sufficient to display it sufficiently. General Pitt Rivers has most generously offered to present it to the nation on certain conditions, which will insure its being properly maintained in its present arrangement, and prevent the possibility of its being broken up and distributed amongst other collections by any future authorities who might not thoroughly comprehend its importance in its present condition. It is stipulated that General Pitt Rivers shall have the management of the collection during his lifetime, and that sufficient space shall be allotted to him to allow of his making additions and further developing it in accordance with the plans which he has formed.

A committee consisting of Sir P. Cunliffe Owen, Col. Donelly, Mr. Augustus Franks, Prof. Huxley, Sir John Lubbock, Mr. Poynter, and Prof. Rolleston, was appointed to consider the advisability of the acceptance of the collection by the nation, and it has, we believe, although the conclusions arrived at have of course not been officially announced, reported unanimously in favour of its being accepted. There can be no doubt that it has acted with the best judgment in so doing; indeed the eminent men of science and art of which it was composed could have arrived at no other conclusion. It would be a very serious matter if the country were to miss so excellent an opportunity, and there could be no better place for the collection than in the South Kensington Museum. It is, as it were, the key to the whole of the vast collections there gathered together. On the one hand, in the Pitt Rivers collection is traced the earliest history of inventions, showing plainly how every primitive implement and machine grew slowly from the simplest contrivances, thus leading up to and acting as a preliminary training for the study of the contents of the Patent Museum; whilst on the other is to be learnt the developmental history of all the arts, the gradual development of sculpture and painting, the history of the development of pattern ornaments, the growth of musical instruments, of the art of pottery, of clothes, and the history of the gradual development of ships. All these series and very many others lead directly up to the various large collections of paintings, sculpture, pottery, models of shipping, &c., which it is the main object of the Museum to exhibit, and cannot but greatly enhance their value and interest to the student. They serve to impress upon the observer the curious fact that all arts and inventions, even those apparently of extreme simplicity, have never been arrived at by jumps, but have grown slowly by degrees by means of a series of slight modifications, just as in the case of biological development. The collection, it should be remarked, does not in any way clash with the Christy and British Museum collections, which are arranged on a perfectly different plan, and which do not in any way bring together savage and civilised objects. There is full room for both collections, and indeed a necessity for them.

We will now draw attention briefly to some few of the series of objects exhibited in the collection taken more or less at random as samples of the whole. The collection may be considered as consisting of three parts. Firstly, a collection of photographs of the various races of mankind which is not as yet far advanced, though it contains large and instructive series of portraits of Danes, Scandimavians, the people of Britanny, and Japanese; whilst together with the photographs is a small series of those skulls which show the best marked racial characteristics, and another which is to exhibit the various modifications in the forms of their skulls which are made by different races. Secondly, the very large collection showing the growth of weapons of all kinds. Thirdly, the various series illustrating the development of musical instruments, ornaments, sculpture, painting, and artistic design of all kinds; and fourthly, those which relate to the develop-

ment of implements, utensils, houses, ships, machines, and strictly useful appliances of all kinds. Of course the two latter series run into one another, and it is impossible to draw a distinct line between them in the case of the lower terms of the series. General Pitt Rivers has especially drawn attention to the manner in which primitive implements subserve many uses: how, for example, a spear-head may do duty as a knife, as is the case with the obsidian-headed spears of the Admiralty Islanders. The earliest Palæolithic stone implements made for grasping in the hand were no doubt weapons of offence, diggers, hammers, nut-crackers, choppers, all in one.

We propose to give a slight sketch of some of the series in the collection, taken at random from its several departments, culling freely from the owner's published catalogue, and his papers read before the Anthropological Institute and elsewhere. We may state at the outset that there exists as yet a catalogue of the weapons only. General Pitt Rivers has not been able to complete a catalogue of the remainder of his collection, since it has been continuously in process of augmentation. The catalogue of the weapons contains so much valuable and curious information that the appearance of the remainder may be looked forward to with great interest.

One of the marked features of the collection is that specimens are usually introduced to show what natural objects may have first suggested primitive contrivances to savage man. Thus amongst the series of savage stone hatchets and adzes we find specimens of natural stone axes as it were (Fig. 1, 1), roots of trees which have grown round and attached themselves firmly to stones which have somewhat of an axe-blade shape, so as to appear like natural hatchets. It is quite conceivable that the first idea of the axe, the fixing the stone blade at the end of a lever, may have arisen from the observation by primitive man, and his possible use of such a natural hatchet.

Amongst the series of specimens illustrating the origin of weaving are placed specimens of bark cloth composed of naturally-interlaced fibres, and we may suggest that it would be well if there were added a specimen of a weaver-bird's nest, which may have given the first hint as to basket-work, and thus led to weaving. In this series is placed a collection of spindle-whorls from all parts of the world—Peru, Vancouver Island, Cyprus, Denmark, England, Ireland. It is most remarkable how closely alike are these implements, though from such widely separated localities. The collection of primitive looms is very interesting, though as yet one of the least complete in the collection. In its primitive condition, as at the Caroline Islands and Vancouver's Island, the loom is entirely portable, consisting of a few sticks only, and only narrow bands, to form belts or armlets, are woven with it. Some years ago we saw such a portable loom in use in Britanny, worked by a boy with his hands and feet, to make girth-like bands with. The boy was working by the road-side and playing about every now and then, with the whole apparatus in his hand. In the bark cloth, made of bark strips welded together by means of beating and the action of water, the "tappa" of Polynesia, we probably see the origin of paper, which in Japan is made from the bark of the same tree as tappa.

The collection of weapons commences with weapons of offence, and begins with a series illustrating the development of the shield out of the parrying-stick, such as now used by Australian blacks, the idea of the wide shield covering the whole body having apparently arisen as an improvement on the simple stick held in the centre, which gradually expanded and grew into a shield. The origin of the bow is a very interesting question. General Pitt Rivers, as explained in a learned disquisition on the subject in his catalogue, and also in his published lecture on "Primitive Warfare," believes that the first idea of the bow may have arisen from the use of an elastic throwing-stick, with the spring-trap of the Malay regions possibly as a stepping-stone. In several places in the world, as, for example, in the Admiralty Islands, the bow is a contrivance still unknown; and Mr. Brooke Low, whose fine collection of Bornean manufactures and implements is now on exhibition at the South Kensington Museum, informs us that it is not in use throughout Borneo, though the coast people necessarily know the weapon. The primitive arrow is merely a spear thrown with the bow. It is such in New Guinea, where the arrows are far too long for the bow, and though they fly for a dozen yards or so with great force, soon wobble and turn over. The arrows have no notch and no feather;

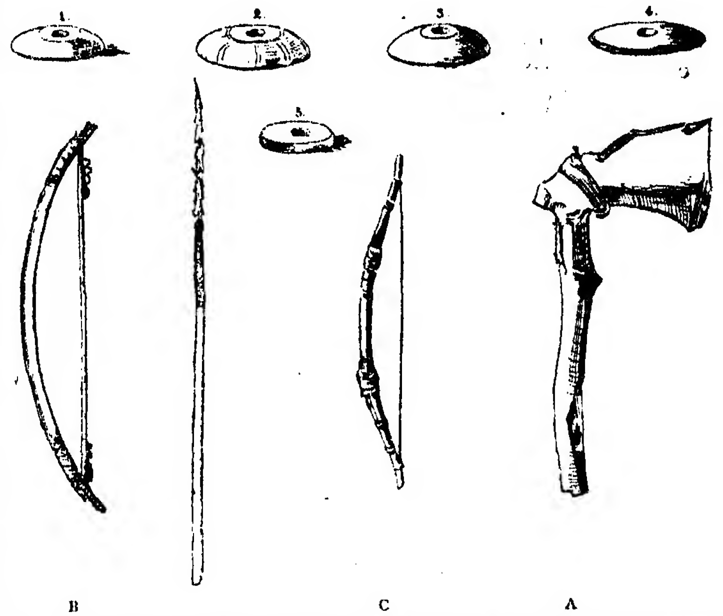

FIG. 1.—A, Natural stone axe formed by the growing of the root of a tree round a blade-shaped stone; B, Papuan bow with broad flat string and long arrow without notch or feather; C, Esquimaux composite bow; 1 to 5, stone spindle whorls. 1, from the Island of Cyprus; 2, from Peru; 3, from Denmark; 4, from Neuchâtel; 5, from Ireland.

the bow-string is wide and flat, made of split rattan cane (Fig. 1, B). The notch and feather are further improvements not yet attained, at all events, in the greater part of New Guinea. At the Aru Islands both notch and feather are in use, but the string is still of rattan narrowed to fit the notch. In some of the New Hebrides the arrows, which are beautifully finished, have the notch, but still no feather. The development of the composite bow made up of several pieces of horn, bamboo, wood, ivory, &c., and usually strengthened by the sinews of animals at the back, is illustrated by a special series (Fig. 1, C). It is concluded to have spread from a common centre in Central or Northern Asia to Turkey, Persia, Greenland, California, and elsewhere.

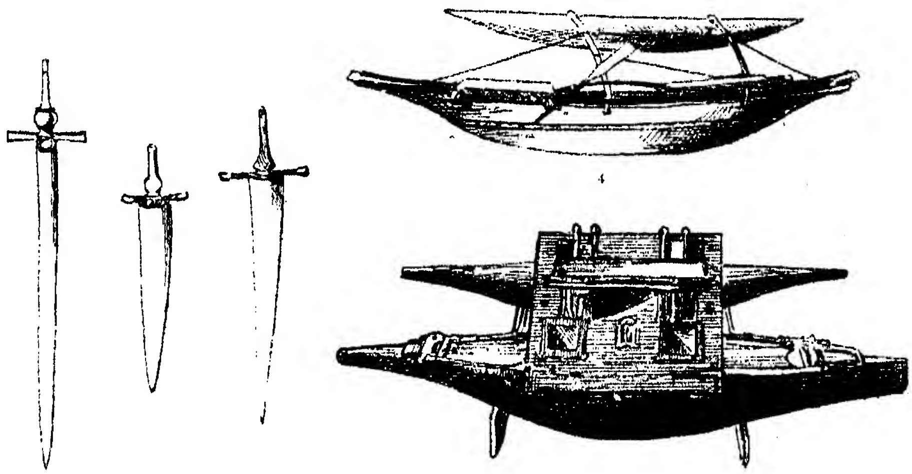
To speak of more civilised weapons, the origin of the bayonet is peculiarly interesting. Its history is set forth in a special small series, and thus explained in the catalogue:—"In the early part of the seventeenth century it was found necessary to retain the use of pikemen in the infantry, on account of the defenceless position of the firelock-men when the enemy approached to close

quarters. To remedy this defect they were accustomed, about the middle of the century, to stick the handles of their daggers into the muzzles of their guns in order to use them as pikes." Implements modified on this principle were called "plug-bayonets" (Fig. 2, 1, 2). One of these in the collection has the date 1647 upon it. The objection to this was that the handles stopped up the muzzle, and the gun could never be fired with the bayonet fixed. Many of the dagger-handles had rings on the guard (Fig. 2, 3), and this suggested the idea of fastening the ring on to the muzzle, and the dagger or plug-bayonet was thus secured on to the outside of a spring, so that the firelock could be loaded and fired with fixed bayonets. The first introduction to this weapon was in one of the campaigns in Flanders, in the time of William III., and greatly were our men astonished at being fired at with fixed bayonets. The series contains all stages leading from the simple dagger with a wooden plug-like handle, through the same with a ring added, to the modern bayonet and its tube and catch.

Another series close by is of classical interest as illustrating the history of the Greek "kopis," the peculiar sword which is to be seen in the hands of combatants represented on Greek vases. It is a curved variety of the straight leaf-shaped bronze sword. It appears to have been brought to Spain by the Romans. It is identical in form with the koohrie of the Goorkas of Nepal, and the Turkish, Albanian, and Persian yataghans are direct descendants of this ancient weapon.

Leaving the series of weapons, we may refer to the collection illustrating the origin and development of boats and ships. Concerning this question General Pitt Rivers has published a valuable memoir, entitled "Early Modes of Navigation," in the *Journal* of the Anthropological Institute. He there divides the subject into five heads, treating of (1) Solid trunks or dug-out canoes; developing into (2) Vessels on which planks are laced or sewn together, and these developing into such as are pinned with plugs of wood, and ultimately nailed with iron or copper; (3) Bark canoes; (4) Vessels of skins and wicker-work; (5) Rafts, developing into outrigger canoes, and ultimately into vessels of broader beam, to which may be added rudders, sails, and contrivances which gave rise to parts of a more advanced description of vessel, such as the oculus, aplustre, forecastle, and poop.

The dug-out canoes probably originated from trunks of trees accidentally burnt hollow in consequence of the common practice of lighting fires at the bases of trees.



3 1 2 5

FIG. 2.—1, Dagger with guard, used also as a plug bayonet: 2, the same, but longer and more bayonet-like; 3, bayonet with simple ring for attachment still retaining its cross hand-guard; 4, Singhalese outrigger canoe, consisting of a dug-out base with planks sewn on above; 5, Fijian double canoe.

Some Australian blacks used to paddle about on logs shaped like canoes, but not hollowed out at all, sitting merely astride with their feet resting on a rail of small sticks driven in. As an improvement to the dug-out, wash-boards, or gunwale-pieces, narrow plank strips are added all round at the edge, to keep the wash of the water out. These wash-boards are gradually increased in height till, when the canoe is loaded, the dug-out trunk is entirely below water, and acts merely as a float to support the vessel of planks resting on it. In such a condition are the Cinghalese canoes which come alongside all the steamers at Point de Galle and take passengers on shore (Fig. 2, 4). There is a model of one of these in the series, and also another of a wide flat-bottomed boat, also from Ceylon, in which two dug-out trunks are fastened to the margins of the bottom, one on each side, so as to form lateral floats and give the boat very great stability, this primitive device being absolutely the same in principle as that adopted in the structure of the Czar's new yacht *Livadia*, lately described in NATURE. In progress of development, the dug-out portion of the canoe becomes proportionately less important, its functions being usurped by the superstructure of planks, and eventually the dug-out disappears, or rather survives as the keel only, and the ordinary boat built of planks is the result. The upper planks long remain laced together, and lashed to the dug-out by means of rattans or sennet, the boats having no ribs, but simply thawts as supports for the planks. In Fiji the ribs seen in the interior of the canoes are not used to bring the planks into shape, but are the last things inserted, and are used for uniting the deck more firmly to the body of the canoe. Wallace has described the boats and boat-builders of the Ké Islands. Here, though the ledges of the planks are pegged together by means of wooden pegs, the planks are still fastened to the ribs by means of rattans. The ribs themselves are an addition, after the boat is otherwise complete, and after the first year the rattan-tied ribs are generally taken out and replaced by new ones, fitted to the planks and nailed.

General Pitt Rivers develops the outrigger canoe from the raft. In all Africa and all America there has never existed an outrigger vessel of any kind. All the canoes are simple; but on the coast of South America rafts are used with sails elsewhere unknown in America. Those termed balzas, used on the Guayaquil, in Ecuador, are described by Ulloa. Some are seventy feet in length, and twelve in breadth. They are made of light wooden logs lashed together, and when they are sailing, planks are pushed down into the water between the logs, and, acting as centre-boards, enable the rafts to luff up or bear

away, according as they are inserted in the fore or hinder part. On the raft theory the outrigger canoe is supposed to have been developed from an improved modification of the sailing raft, in which two logs were made use of instead of many, as opposing less resistance to the water, and were connected by a platform. Such two-log structures, of course without sails, have been described as in use by the Tasmanians. The use of the sailing rafts on the Pacific coast of America seems to lend probability to the theory, since the outrigger canoe is universal in Polynesia. On this theory the double canoe (Fig. 2, 5) is a highly-specialised development of the two-log rafts; and General Pitt Rivers points for additional proof to the fact that in all double canoes one vessel is always smaller than the other. This may however be merely a contrivance for aiding steering.

On the other hand it seems to us very probable that the outrigger canoe is really derived from the double canoes and that the outrigger float represents, not a log in process of development towards a canoe itself, but a degenerate second canoe. On some parts of the coast of New Guinea the Papuans are accustomed to lash side by side firmly several of their large canoes, when about to set out on a trading expedition of 200 or 300 miles and sail along the coast. Such a group of canoes is called a "lakatoi." It is very probable that the fastening of two dug-outs side by side may have early suggested itself, and that the two may have gradually been separated and fastened by longer and longer cross-pieces, as stability was found to be increased thereby. We merely suggest this other view of the matter as worthy of consideration. It is by means of collections such as that now under consideration that such points can be determined. Luckily, for some reason or other, possibly a religious one, savages all over the world make most carefully-constructed models of their canoes. These are not children's toys, but exact models, correct in all details. Even the wretched Fuegians do this, and the models are not made for purposes of barter originally, since they are made by such races as the Admiralty Islanders, who have no opportunity of disposing of them. We seem even ourselves to make more models than necessary, as the quantities of them in museums testify. General Pitt Rivers has collected a most valuable series of native models of boats and ships of all kinds.

(*To be continued.*)

NOTES

JUDGING from the papers and reports that have reached us, through the kindness of the permanent secretary, Mr. F. W. Putnam, the Boston meeting of the American Association has been a great success. The many attractions of Boston drew together a large concourse, including nearly all the great lights of American science. The people of Boston and Cambridge seem to have exerted themselves to the utmost to make the numerous visitors enjoy themselves, and, from the accounts of the many excursions and receptions, these exertions were completely successful. There were something like a thousand names registered on the books of the Association, and at the Cambridge dinner, on August 24, 870 persons were present. The number of papers entered was 280, all of them evidently duly considered before being admitted, and many of them of great scientific importance.

THE address of welcome of Prof. Rogers, of the Massachusetts Institute of Technology, briefly reviewed the origin of the various National Associations, predicting that the American would in time rival that which at the moment was meeting at Swansea. "Let us," Prof. Rogers said, "make it our special work to exclude from our annual reports all detailed publications which are not of a character actually to add to the stock of human knowledge, whether that knowledge be simply the gathering together of facts by careful processes of discernment, or the development of laws by careful mathematical investigation." Mr. Lewis H. Morgan, the president of the Association, in his brief reply to the addresses of welcome, made some remarks which are quite as deserving of attention here as on the other side of the water. "When the meetings of this Association become indifferent to the communities among which they are held, its usefulness will be near its end. There is a direct connection between the work upon which its members are engaged and the material prosperity of the country, in which all alike have an interest. Scientific investigations ascertain and establish principles which inventive genius then utilises for the common benefit. We cannot have a great nation without a great development of the industrial arts, and this, in its turn, depends upon the results of scientific discovery as necessary antecedents. Material development, therefore, is intimately related to progress in science." The address of Prof. A. Agassiz in Section A we gave in a recent number, and that of Prof. Asaph Hall we hope to be able to give next week. Prof. Bell's remarkable lecture will be found on another page.

THE German Association began its sittings at Danzig last Saturday, and continues them during the present week. Judging from the reports that have been sent us, the German *savants* have received a warm welcome in the great Prussian commercial city. The programme of papers, as we have already intimated, is long, and contains several of great importance. Prof. Cohn of Breslau brought forward at one of the public lectures important data, spreading over many years, as to the prevalence of colour-blindness, especially in Germany, Switzerland, and America.

A CORRESPONDENT informs us that at the meeting of the Geological Society of France at Boulogne, to which we have already referred, the French geologists did England the honour of electing Prof. Prestwich president. Besides Professors Prestwich and Seeley, two other English geologists were present at the meeting, the Rev. J. F. Blake and the Rev. T. Wiltshire. There were also present a large number of Belgian geologists. With the French geologists the meeting numbered about fifty members. Daily excursions were made to all the many places of geological interest in the Boulonnais, and in the evenings papers were read by Prof. Gosselet, Dr. E. Sauvage, M. Pellat, and Prof. Prestwich, on the geological features of the places visited. The geologists were most hospitably entertained by the municipality and other public bodies.

AT the Swansea meeting of the British Association Sir William Thomson, as an incidental illustration of a paper by him, gave the following method of "turning the world upside down." Suppose there to be no sea or other water on the earth, and no hills or hollows; and let the earth be a perfectly elastic or perfectly rigid solid, with no moon nor sun, nor other body to disturb it. Commencing anywhere in the northern hemisphere, walk a few miles northwards or southwards. This, by displacing the earth's axis makes a slope. Then walk up hill as long as you can; then walk a few miles southwards; then lie down and rest, and in time the thing is done; that is to say, what was the South Pole is found under Polaris.

THE autumn Congress of the Sanitary Institute was opened at Exeter on Tuesday, under the presidency of Lord Fortescue.

THE death, on August 2, is announced of Karl Ritter von Hauer, the director of the chemical laboratory of the Geological Institute of Vienna.

A CONGRESS on hygiene was held at Hamburg on September 13, 14, 15. The number of members was about 200. At the first sitting the hygiene of hospitals and public buildings was discussed; at the second the hygiene of shipping, after the

delivery of an address by Dr. Reincke; and on the third day the ventilation of private dwellings, and other similar subjects. A resolution, proposed by Dr. Rietschel of Dresden, was passed to induce public authorities to study practically the ventilation of buildings, and another, by Dr. Prath of Dresden, that sanitary inspection should always take place by duly qualified officers. This session is the eighth of the Association.

THE Russian newspapers announce that the jubilee of the zoological museum of the Academy of Sciences, established in 1831 by the Emperor Nicholas, will take place in 1881. Russian and foreign zoologists will meet at St. Petersburg on this occasion.

THE Association Scientifique de France has not continued the observations of meteors which was begun by Leverrier, its founder. No steps have been taken by the Observatory to fill up this important gap in the scientific work of the nation. The interest of observations taken during the last two years in the display of August meteors and the forthcoming inauguration of Leverrier's statue have attracted public attention to this circumstance, and it is hoped these observations will shortly be resumed.

UNIVERSITY COLLEGE, Bristol, has the credit of being the first in England in which the higher education of women has been conducted on a large scale in conjunction with that of men. Its Calendar, which is before us, shows that in the last session, its fourth, the College was attended by more than five hundred students, of whom nearly half were women. A wide range in science and literature is covered by the lectures, of which there are more than forty distinct courses in the day, and more than twenty in the evening. Its engineering department has derived great advantage from the plan under which the students spend the six winter months in the College, and the six summer months as pupils in engineering works in the neighbourhood. The want of space, which has hitherto pressed severely, will be relieved by the opening in October of a part of the new buildings.

THE crayfish is disappearing so rapidly in several French departments that energetic measures have been considered necessary for its protection. The fishing of it has been entirely prohibited in the departments of Meuse and Doubs by prefectorial decrees.

THE freedom of the City of London is to be conferred on Sir Henry Bessemer, F.R.S., on October 6.

M. LORTET gives a brief account in the *Comptes rendus* for September 13, of the results of his dredging in the Lake of Tiberias. The lake is 212 metres above the surface of the Mediterranean, and the greatest depth is 250 metres. M. Lortet finds proofs that the lake was formerly on the same level as the Mediterranean. It is probable, he thinks, that formerly the lake was very salt; and thus a study of the fauna of the lake is full of interest. At least a dozen species of fish were obtained, several of them new forms, which M. Lortet is now investigating. He gives the following list of species which have been determined:—*Clarias macranthus, Capoeta damascena, Barbus Beddomii, Chromis Andræ, C. paterfamilias, C. Simonis, C. nilotica, C. nov. sp., C. nov. sp., C. nov. sp., (un genre nouveau indéterminé), Labrobarbus canis.* Several new species of molluscs have also been obtained; M. Lortet gives the following list:—*Neritina Jordani,* Butt.; *Melania tuberculata,* Müller; *Melanopsis premorsa,* L.; *M. costata,* Olivier; *Cyrena fluminalis,* Müller; *Unio terminalis,* Bourg.; *U. tigridis,* Bourg.; *U. Lorteti,* Locard; *U. Pietri,* Locard.; *U. Maris Galilæi,* Locard. Melanopsis and Melania are of a marine appearance, and seem to M. Lortet to show the transition between salt and fresh water.

IN Vol. xii. of the *Transactions* of the New Zealand Institute Mr. J. W. Stack has some interesting notes on the colour-sense of the Maori. Mr. Stack asks what stage had the colour-sense of the Maori reached before intercourse with Europeans began? This can readily be ascertained by reference to the terms existing in the language at that date for giving expression to the sense of colour. We find, upon examination, that the language possessed very few words that conveyed to the mind an idea of colour, apart from the object with which the particular colour was associated. There are only three colours for which terms exist, namely, white, black, and red. White, *ma* (sometimes *tea*—very limited application). Black, *pouri, pango, mangu.* Red, *whero, kura, ngangana.* If we analyse these words they seem all to relate to the presence or absence of sunlight. *Ma* is doubtless a contraction for *Marama,* light, which is derived from *Ra,* the sun. *Pouri,* black, is derived from *Po,* night. The derivation of *pango* and *mangu* is not so apparent, but I venture to think that both *whero* and *kura* may be traced to *Ra. Ma* is not only the term for whiteness and clearness, but also for all the lighter tints of yellow, grey, and green. Grey hair is called *hina,* but the term was never used to designate anything else but hair; every other grey object was either *ma* or *pango,* as it inclined to a lighter or darker shade. All the words for expressing redness, except *ngangana,* may, Mr. Stack thinks, be traced to *Ra,* and connect the Maori idea of that colour with the brilliant rays of the sun. *Ngangana* is not the word generally used to express the quality of redness, but only certain appearances of it, as in flowers or blood-shot eyes. Yellow and green were recognised, not as abstract conceptions of colour, but only as they are associated with objects. Blue was not formerly recognised, as no word exists to represent it. Anything blue was classed with black, and went under the heading of *pouri,* or *pango,* or *mangu.* The blue depths of ocean and sky were *pouri,* or dark. No words are found in the Maori language to express violet, brown, orange, and pink colours; but there are no less than three words to express pied or speckled objects. *Kopurepure* = reddish speckle; *Kotingotingo* = dark speckle; *tongitongi* = spotted. The limited number of colour-expressions that exist in the Maori language cannot be attributed to the absence of objects presenting those colours for which the terms are wanting. The ornamental scroll-work, and the elaborate patterns employed in tatooing and carving, showed that the Maoris were capable of appreciating the beautiful, both in form and in colouring, and we can only account, Mr. Stack thinks, for their indifference to the more delicate tints of flowers which call forth our admiration by supposing that their colour-sense was not so well educated as our own.

MR. JOHN SCOTT has been appointed Professor of Agriculture and Estate Management to the Royal Agricultural College at Cirencester. Mr. Scott studied agriculture at the University of Edinburgh, and has had many years practical experience in farming, estate management, and land valuing, both at home and in the Colonies. He is the author of two well-known books on farm and estate valuations, and was formerly editor of the *Farm Journal.*

A NEW and revised edition of Bishop Stanley's well-known and deservedly popular "Familiar History of British Birds" has just been published by Messrs. Longmans and Co. It has been revised by "a practical ornithologist of much experience," and has been furnished with numerous additional illustrations.

ANOTHER Lake village, assigned by experts to the age of Bronze, has been discovered at Auvernier, near Neuchâtel. Several millstones quite new, others half made, have been brought to light, from which it is inferred that the place may have been the seat of a manufactory of these articles. Another

conclusion drawn from this find is that Swiss pile buildings served as actual dwellings for the primeval inhabitants of the land, and were not, as has been supposed, used merely as storehouses.

MR. DAVID BOGUE will publish in November a new book by Mr. S. Butler, author of "Erewhon," "Life and Habit," &c., entitled "Unconscious Memory." The work will contain translations from the German of Prosper Ewald Hering of Prague, and of von Hartmann, with a comparison between the views of instinctive and unconscious actions taken by these two writers respectively.

THE British Museum is about to be enriched by a collection of natural history specimens made by the officers of Her Majesty's surveying ship *Alert*, which has been for some months engaged in making a complete survey of the Straits of Magellan.

WITH the view of promoting agricultural improvement in Bengal and encouraging the study of scientific agriculture, the Bengal Government has created two annual special scholarships of 200*l*. each, to be held by science graduates of the Calcutta University at Cirencester College.

A TERRIFIC hurricane passed over the Bermudas on August 29 and 30, stated to have exceeded in violence the historical hurricane of 1839.

Two years ago (NATURE, vol. xviii. pp. 104, 344) we directed attention to the discoveries made in Russia in regard to Fermat's asserted prime-form $2^{2^m} + 1$. We have now to chronicle the fact that to the number of composite integers of this form another addition has just been made. M. Landry has found that $2^{64} + 1$ is divisible by 274177. As at present ascertained therefore the composite members of the form are—

$m = 5$; divisor, $5 \cdot 2^7 + 1$ (Euler),
$m = 6$; ,, $1071 \cdot 2^8 + 1$ (Landry),
$m = 12$; ,, $7 \cdot 2^{14} + 1$ (Pervouchine),
$m = 23$; ,, $5 \cdot 2^{25} + 1$ (Pervouchine).

MM. MARTINET AND LESSON have brought out vol. i. of their work on the origin and migrations of the Polynesians. The next volume is nearly ready, and the remainder will be published in 1881. The aim of this exhaustive work is to demonstrate that the Polynesians are neither Asiatics nor Americans, but Maoris, from the Middle Island.

M. C. DE UFALVY is engaged in editing the narrative of the voyage of M. Panagiotis Potagos in Central Asia; while to M. Henri Duveyrier has been confided, by the Paris Geographical Society, the task of preparing for publication in French that traveller's expedition in Equatorial Africa.

THREE French expeditions are being organised. One, by M. Revoil, to Aden, in the country of the Somalis; another, by M. Moindron, to the northern coasts of New Guinea, which, if practicable, is to advance beyond the points reached by Raffray, Meyer, and Albertis; and the third, by M. Flahant, to the Polar Seas, in conjunction, probably, with Nordenskjöld.

A FRENCH explorer, M. Lecart, who is at present on the banks of the Niger, writes home from "Koundian (Gangaran), July 25," that he has discovered a new vine, which promises to be of great economical value. He says the fruit of the vine is excellent and abundant, its cultivation very easy, its roots tuberose and perennial, while its branches are annual. It can be cultivated as easily as the dahlia. He himself had been eating the large grapes of the vine for eight days, and found them excellent, and he suggests that its culture ought to be attempted in all vine-growing countries as a possible remedy against the phylloxera. He is sending home seeds for experiment, both in France and Algeria, and will bring home specimens of the plant at all stages.

MR. F. J. CAMPBELL of the College for the Blind, Upper Norwood, he himself being blind, gives an interesting account of his successful ascent of Mont Blanc, the first time such a feat was accomplished by a blind man.

THE Report of the Cardiff Naturalists' Society for 1879 has to complain of a considerable falling off in the membership, attributable mainly to bad times. Otherwise the work of the Society has been fairly satisfactory.

AT a recent meeting of the Balloon Society of Great Britain, it was announced that a challenge had been received from M. de Fonvielle, president of the French Académie d'Aërostation, to a balloon contest during the present autumn on English soil. After a discussion it was decided to accept the challenge, the contest to take place between one member of each nationality, and the ascent to be made from the Crystal Palace.

ACCORDING to a table published by the *Statistiche Monatsschrift* of Vienna, the number of volumes in the National Library of Paris is 2,078,000, and in the British Museum only 1,000,000. But it should be noted that the number of volumes does not give an exact idea of the real importance of a library. The Vatican, which is stated to have only 30,000 volumes and 25,000 manuscripts, must be considered as ranking far above its numerical position. According to the provisions of the French law, the deposit is required of each re-impression, even where there is no alteration, and the National Library has not the right of disposing by sale of useless volumes, so that there is an accumulation of popular works of no value at all. There is a room full of Noël and Chapsal's Elements of Grammar, and endless numbers of *Petits Parisiens*. Popular novels are in the same case, and there are more than eighty copies of "Nana."

AN interesting prehistoric sketch of the Spreewald and the Schlossberg of Burg, with special map and illustrations, by Professors Virchow and Schulenburg, has been published by Wiegandt of Berlin.

THE additions to the Zoological Society's Gardens during the past week include a Brown-necked Parrot (*Pæocephalus fusicollis*) from West Africa, presented by Mr. H. Wood; a Jacuraca (*Craspedocephalus brasiliensis*), a —— Tree Snake (*Dryiophis acuminata*), a —— Amphisbœna (*Amphisbæna alba*) from Brazil, presented by Dr. A. Stradling, C.M.Z.S.; a —— Amphisbœna (*Bronia brasiliensis*) from Pernambuco, presented by Mr. W. A. Forbes, F.Z.S.; a Weeper Capuchin (*Cebus capucinus*) from Brazil, a Ring-tailed Coati (*Nasua rufa*), a Spotted Cavy (*Cœlogenys paca*) from South America, a Crab-eating Raccoon (*Procyon cancrivorus*) from West Indies, a Saturnine Mocking-Bird (*Mimus saturninus*), two Silky Hang-nests (*Amblyrhamphus holosericeus*), a Sulphury Tyrant Bird (*Pitangus sulphuratus*) from Monte Video, a Maximilian's Aracari (*Pteroglossus wiedi*) from Pernambuco, deposited; five Ruffs (*Macheles pugnax*), British, purchased; a Reeves's Muntjac (*Cervulus reevesi*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

COLOURS OF SOUTHERN STARS.—In the *Uranometria Argentina*, Dr. Gould has drawn attention to a number of stars presenting marked colour, and to several in which there appears to be change of colour: the following are amongst the more noticeable cases:—

β Hydri is remarkable for its clear yellow light (2·7m.); the Cordoba observations do not support Sir John Herschel's suspicion of variability of brightness. α Indi is also of a bright clear yellow; mag. 3·1. The blue colour of γ Tucanæ is very marked; Gould's magnitude is 4·0. ϕ Eridani (3·5) is remarkable for its blue colour, and ν Puppis (3·5) is decidedly blue; ϵ Pavonis, the estimates of magnitude of which star vary from 3·6 to 4·2, is of a remarkably blue colour. Gould's No. 9 in Dorado, Lacaille

1567, which varies from $5\frac{1}{2}$ to $6\frac{3}{4}$, is excessively red; π^1 Gruis is of a deep crimson, while its neighbour π^2 is conspicuously white; magnitudes respectively 6·7 and 5·9. The star No. 10163 of Oeltzen's Argelander is remarkable for its superb crimson colour; its place for 1875 is in R.A. 9h. 45m. 18s., N.P.D. 112° 25'. μ Muscæ (5·3m.) is intense orange-red.

γ Centauri, varying between 4·5 and 5·1, appears also to vary in colour, having been repeatedly noted as reddish, while at other times it was found without any marked tinge. N Velorum, which has a peculiar yellow colour, contrasting markedly with that of the numerous red stars in its vicinity, is suspected to vary in colour as well as in brightness, the period of the variations appearing to be not far from $4\frac{1}{2}$ days, though the number of observations is not sufficient to give the law of the fluctuations. The positions of these stars for 1875·0 are: γ Centauri, R.A. 13h. 42m. 13s., N.P.D. 123° 49'·5; N Velorum, R.A. 9h. 27m. 25s., N.P.D. 146° 29'·0.

Dr. Gould says that there is "a decidedly greenish tinge to the light of β Libræ, although its colour cannot properly be called conspicuous;" this confirms Smyth's judgment on its tinge—pale emerald.

Telegraphic Determinations of Longitude.—The Hydrographic Office at Washington has published a number of geographical positions determined in 1878 and 1879 by parties under the direction of Lieut.-Commanders F. M. Green and C. H. Davis of the United States Navy. The longitudes were fixed by telegraphic exchanges of time-signals, the initial point of measurement being the meridian of the Royal Observatory at Greenwich. The latitudes (with the exception of Lisbon, determined by the Director of the Royal Observatory, Capt. F. A. Oom) result from numerous zenith-telescope observations of pairs of stars. The details of the observations are in the press, and will shortly appear; meanwhile we extract from No. 59 of the *Notices* of the Hydrographic Office the positions of the more important points—

Lisbon—Centre of dome of the Royal Observatory.
Lat. 38° 42' 31"·3 N. ... Long. 0h. 36m. 44·68s. W.
Funchal (Madeira)—Flagstaff of Fort St. Jago.
Lat. 32° 38' 4"·1 N. ... Long. 1h. 7m. 35·56s. W.
Pernambuco—Lighthouse near Fort Ricão.
Lat. 8° 3' 22"·2 S. ... Long. 2h. 19m. 27·77s. W.
Bahia—San Antonio Lighthouse.
Lat. 13° 0' 37"·4 S. ... Long. 2h. 34m. 8·37s. W.
Rio de Janeiro—Centre of dome of Imperial Observatory.
Lat. 22° 54' 23"·8 S. ... Long. 2h. 52m. 41·41s. W.
Montevideo—Centre of south-east tower of Cathedral.
Lat. 34° 54' 33"·0 S. ... Long. 3h. 44m. 49·02s. W.
Buenos Ayres—Centre of Cupola of Custom-house.

Four-Figure Logarithms and Anti-Logarithms.—Messrs. Layton, Fleet Street, have lately published tables of logarithms of numbers to four places from 1000 to 9999, and anti-logarithms ·0000 to ·9999, arranged by General Hannyngton, similarly to the modern six and seven-figure tables. All the figures are printed, and the value sought is consequently found by mere inspection. The logarithms of numbers 0 to 999 would have required two more pages only, and probably would have been more used than any of the other pages. A complete manual of four-figure logarithms of numbers and trigonometrical functions is much to be desired, and would suffice for eclipses, occultations, star-corrections, and many subordinate astronomical calculations; it is to be regretted that the logarithms of trigonometrical functions are not given in the present publication.

ACTION OF PHOSPHORESCENT LIGHT ON SELENIUM [1]

A FEW weeks ago, when listening to Mr. Heaton's lecture on Balmain's luminous paint at the Society of Arts, it occurred to me to try whether the faint light of phosphorescence would exercise any sensible effect upon the electric conductivity of selenium. I lately made some experiments in this direction, for which I adopted the following arrangement:—One of Dr. Werner Siemens' selenium preparations, of the kind described by me in vol. vi. of the Society of Telegraph Engineers' *Journal*, was placed in the circuit of two Daniell cells, together with a delicate Thomson's reflecting galvanometer. The selenium was put into one end of a blackened brass tube, which was placed inside a dark box provided with a sliding door in front of the open end of the tube. The source of phosphorescence was a *sheet* of glass 20 × 30 centimetres, painted at the back with some phosphorescent material.[1] This *luminous sheet* was placed before the opening of the box, usually at a distance of about 60 centimetres from the selenium plate.

In the first series of experiments the phosphorescence of the *sheet* was excited by exposing it to light from different sources. The results were as follows:—

No. of experiment.	Description of light used for exciting the phosphorescence of the *sheet*.	Increase of conductivity of the selenium by the action of phosphorescent light.
	The sheet was exposed to:—	Per cent.
1	Light reflected from ceiling of semi-dark room for several minutes.	0·7
2	Light reflected from ceiling of moderately light room for fifteen minutes.	2·4
3	Light of the sky at 5 p.m. for several minutes.	4·6
4	Light from a few inches of burning magnesium ribbon.	5·1
5	Sunlight for two minutes exactly.	7·8
6	Sunlight for five minutes exactly.	6·3

During these experiments the phosphorescent light acted on the selenium immediately after the exposure of the sheet to light. After a lapse of some minutes the effect was found considerably lessened; for instance, the third experiment gave only about $\frac{1}{3}$th of the original value five minutes after the exposure. The sheet, exposed to strong light two hours previously, showed no perceptible action on the selenium. The curious fact that the effect is less when the *sheet* is exposed to sunlight for five minutes than when it is exposed for only two minutes, is probably due to the circumstance that the *sheet* becomes sensibly warm during the longer period of exposure.

In the second series of experiments different lengths of magnesium ribbon were burnt in front of the *sheet* and at a distance of about 15 centimetres from it. The intensity of the phosphorescence increased with the time of exposure to light, as the following little table shows:—

Length of magnesium ribbon.	Time the magnesium was burning.	Increase of conductivity of selenium.
Centimetres.	Seconds.	Per cent.
1	2	0·8
3	3	1·8
10	5	2·4
20	12	2·8
30	21	3·4

In the third series of experiments a length of 20 centimetres of magnesium ribbon was burnt in front of the *sheet* at 20 centimetres distance from it. The *sheet* was then, immediately after its exposure to light, placed at distances of 200, 150, 100, and 50 centimetres respectively from the selenium. It was found that the effect upon the selenium varied approximately as the inverse distance of the *sheet* from the selenium plate, or in other words, as the square root of the light intensity. The same relation has been found by Dr. Werner Siemens and others for considerably stronger light intensities.

In the fourth series of experiments the phosphorescent light was made to pass through differently-coloured sheets of glass before acting on the selenium. It was found that colourless glass transmitted all the active rays. Blue glass transmitted $\frac{2}{3}$ths of the total amount; green glass transmitted $\frac{1}{3}$th; red (almost monochromatic); and yellow glass transmitted no perceptible action.

In the fifth series of experiments the action of the *sheet* upon the selenium was compared with that of a spermaceti candle, the phosphorescence of the *sheet* being excited by diffused daylight. Two separate sets of measurements with the standard

[1] This article was sent to us by Dr. Obach in April last.—Ed.

[1] A so-called *Aladdin's lamp* from Messrs. Ihlee and Horne, London.

candle at different distances ($2\frac{1}{4}$ and $3\frac{1}{2}$ metres) from the selenium gave tolerably concordant results when calculated on the supposition that the effect upon the selenium varies as the square root of the light intensity. The influence of about 350 square centimetres of the *luminous sheet* on the selenium was found equal to that of 0·0014 standard candle, or 0·04 standard candle per square metre.

In conclusion I wish to remark that the above must be considered only as preliminary experiments, and the figures given as only approximate. I am now engaged in making further experiments on this subject with the endeavour to obtain more accurate results and to extend these researches, as it seems probable that the sensitive selenium plate may render similar services to the study of phosphorescent light as the thermopile has rendered to the study of radiant heat. EUGEN OBACH

AGRICULTURAL CHEMISTRY[1]

II.

IT has been shown that the plant may receive abundance of nitrogen, may produce abundance of chlorophyll, and may be subject to the influence of sufficient light, and yet not assimilate a due amount of carbon. On the other hand, it has been seen that the mineral constituents may be liberally provided, and yet, in the absence of a sufficient supply of nitrogen in an available condition, the deficiency in the assimilation of carbon will be still greater. In fact, assuming all the other necessary conditions to be provided, it was seen that the amount of carbon assimilated depended on the available supply of nitrogen.

In a certain general sense it may be said that the success of the cultivator may be measured by the amount of carbon he succeeds in accumulating in his crops. And as, other conditions being provided, the amount of carbon assimilated depends on the supply of nitrogen in an available form within the reach of the plants, it is obvious that the question of the sources of the nitrogen of vegetation is one of first importance. Are they the same for all descriptions of plants? Are they to be sought entirely in the soil, or entirely in the atmosphere, or partly in the one and partly in the other?

These are questions which Mr. Lawes and myself have discussed so frequently that it might seem some apology was due for recurring to the subject here, especially as I considered it in some of its aspects before this Section at the Sheffield meeting last year. But the subject still remains one of first importance to agriculture, and it could not be omitted from consideration in such a review as I have undertaken to give. Moreover, there are some points connected with it still unsettled, and some still disputed.

It will be remembered that De Saussure's conclusion was that plants did not assimilate the free or uncombined nitrogen of the atmosphere, and that they derived their nitrogen from the compounds of it existing in the atmosphere, and especially in the soil. Liebig, too, concluded that plants do not assimilate nitrogen from the store of it existing in the free or uncombined state, but that ammonia was their main source, and he assumed the amount of it annually coming down in rain to be much more than we now know to be the case.

Referring to our previous papers for full details respecting most of the points in question, I will state, as briefly as I can, the main facts known—first in regard to the amount of the measurable, or as yet measured, annual deposition of combined nitrogen from the atmosphere; and secondly as to the amount of nitrogen annually assimilated over a given area by different crops—so that some judgment may be formed as to whether the measured atmospheric sources are sufficient for the requirements of agricultural production, or whether, or where we must look for other supplies?

First, as to the amount of combined nitrogen coming down as ammonia and nitric acid in the measured aqueous deposits from the atmosphere.

Judging from the results of determinations made many years ago, partly by Mr. Way, and partly by ourselves, in the rain, &c., collected at Rothamsted; from the results of numerous determinations made much more recently by Prof. Frankland in the deposits collected at Rothamsted, and also in rain collected elsewhere; from the results obtained by Boussingault in Alsace; from those of Marié-Davy at the Meteorological Observatory at Montsouris, Paris; and from those of many others made in France and Germany—we concluded, some years ago, that the amount of combined nitrogen annually so coming down from the atmosphere would not exceed 8 or 10 lbs. per acre per annum in the open country in Western Europe. Subsequent records would lead to the conclusion that this estimate is more probably too high than too low. And here it may be mentioned in passing, that numerous determinations of the nitric acid in the drainage water collected from land at Rothamsted, which had been many years unmanured, indicate that there may be a considerable annual loss by the soil in that way; indeed, probably sometimes much more than the amount estimated to be annually available from the measured aqueous deposits from the atmosphere.

It should be observed, however, that the amount of combined nitrogen, especially of ammonia, is very much greater in a given volume of the minor aqueous deposits than it is in rain; and there can be no doubt that there would be more deposited within the pores of a given area of soil than on an equal area of the non-porous even surface of a rain-gauge. How much, however, might thus be available beyond that determined in the collected and measured aqueous deposits, the existing evidence does not afford the means of estimating with any certainty.

The next point to consider is—What is the amount of nitrogen annually obtained over a given area, in different crops, when they are grown without any supply of it in manure? The field experiments at Rothamsted supply important data relating to this subject.

Thus, over a period of 32 years (up to 1875 inclusive), wheat yielded an average of 20·7 lbs. of nitrogen per acre per annum, without any manure; but the annual yield has declined from an average of more than 25 lbs. over the first 8, to less than 16 lbs. over the last 12, of those 32 years; and the yield (it is true with several bad seasons) has been still less since.

Over a period of 24 years barley yielded 18·3 lbs. of nitrogen per acre per annum, without any manure; with a decline from 22 lbs. over the first twelve, to only 14·6 lbs. over the next 12 years.

With neither wheat nor barley did a complex mineral manure at all materially increase the yield of nitrogen in the crops.

A succession of so-called "root-crops"—common turnips, Swedish turnips, and sugar-beet (with 3 years of barley intervening after the first 8 years)—yielded, with a complex mineral manure, an average of 26·8 lbs. of nitrogen per acre per annum over a period of 31 years. The yield declined from an average of 42 lbs. over the first eight years, to only 13·1 lbs. (in sugar-beet) over the last 5 of the 31 years; but it has risen somewhat during the subsequent 4 years, with a change of crop to mangolds.

With the leguminous crop, beans, there was obtained, over a period of 24 years, 31·3 lbs. of nitrogen per acre per annum without any manure, and 45·5 lbs. with a complex mineral manure, including potass (but without nitrogen). Without manure the yield declined from 48·1 lbs. over the first 12 years to only 14·6 lbs. over the last 12; and with the complex mineral manure it declined from 61·5 lbs. over the first 12, to 29·5 lbs. over the last 12, years of the 24.

Again, an ordinary rotation of crops of turnips, barley, clover, or beans, and wheat, gave, over a period of 28 years, an average of 36·8 lbs. of nitrogen per acre per annum without any manure, and of 45·2 lbs. with superphosphate of lime alone, applied once every four years, that is for the root crop. Both without manure, and with superphosphate of lime alone, there was a considerable decline in the later courses.

A very remarkable instance of nitrogen yield is the following—in which the results obtained when barley succeeds barley that is when one gramineous crop succeeds another, are contrasted with those when a leguminous crop, clover, intervenes between the two cereal crops. Thus, after the growth of six grain crops in succession by artificial manures alone, the field so treated was divided, and, in 1873, on one half barley, and on the other half clover, was grown. The barley yielded 37·3 lbs. of nitrogen per acre, but the three cuttings of clover yielded 151·3 lbs. In the next year, 1874, barley succeeded on both the barley and the clover portions of the field. Where barley had previously been grown, and had yielded 37·3 lbs. of nitrogen per acre, it now yielded 39·1 lbs.; but where the clover had previously been grown, and had yielded 151·3 lbs. of nitrogen, the barley succeeding it gave 69·4 lbs., or 30·3 lbs. more after the removal of 151·3 lbs. in clover, than after the removal of only 37·3 lbs. in barley.

[1] Opening Address in Section B (Chemical Science), at the Swansea meeting of the British Association, by J. H. Gilbert, Ph.D., F.R.S., V.P.C.S., F.L.S., President of the Section. Continued from p. 476.

Nor was this curious result in any way accidental. It is quite consistent with agricultural experience that the growth and removal of a highly nitrogenous leguminous crop should leave the land in high condition for the growth of a gramineous corn crop, which characteristically requires nitrogenous manuring; and the determinations of nitrogen in numerous samples of the soil taken from the two separate portions of the field, after the removal of the barley and the clover respectively, concurred in showing considerably more nitrogen, especially in the first nine inches of depth, in the samples from the portion where the clover had been grown, than in those from the portion whence the barley had been taken. Here then the surface soil at any rate had been considerably enriched in nitrogen by the growth and removal of a very highly nitrogenous crop.

Lastly, clover has now been grown for twenty-seven years in succession, on a small plot of garden ground which had been under ordinary garden cultivation for probably two or three centuries. In the fourth year after the commencement of the experiment, the soil was found to contain, in its upper layers, about four times as much nitrogen as the farm-arable-land surrounding it; and it would doubtless be correspondingly rich in other constituents. It is estimated that an amount of nitrogen has been removed in the clover crops grown, corresponding to an average of not far short of 200*l*. per acre per annum; or about ten times as much as in the cereal crops, and several times as much as in any of the other crops, growing on ordinary arable land; and, although the yield continues to be very large, there has been a marked decline over the second half of the period compared with the first. Of course, calculations of the produce of a few square yards into quantities per acre can only be approximately correct. But there can at any rate be no doubt whatever that the amount of nitrogen annually removed has been very great; and very far beyond what it would be possible to attain on ordinary arable land; where, indeed, we have not succeeded in getting even a moderate growth of clover for more than a very few years in succession.

One other illustration should be given of the amounts of nitrogen removed from a given area of land by different descriptions of crop, namely, of the results obtained when plants of the gramineous, the leguminous, and other families, are growing together, as in the mixed herbage of grass-land.

It is necessary here to remind you that gramineous crops grown separately on arable land, such as wheat, barley, or oats, contain a comparatively small percentage of nitrogen, and assimilate a comparatively small amount of it over a given area. Yet nitrogenous manures have generally a very striking effect in increasing the growth of such crops. The highly nitrogenous leguminous crops (such as beans and clover), on the other hand, yield, as has been seen, very much more nitrogen over a given area, and yet they are by no means characteristically benefited by direct nitrogenous manuring; whilst, as has been shown, their growth is considerably increased, and they yield considerably more nitrogen over a given area under the influence of purely mineral manures, and especially of potass manures. Bearing these facts in mind, the following results, obtained on the mixed herbage of grass land, will be seen to be quite consistent.

A plot of such mixed herbage, left entirely unmanured, gave over twenty years an average of 33 lbs. of nitrogen per acre per annum. Over the same period another plot, which received annually a complex mineral manure, including potass, during the first six years, but excluding it during the last fourteen years, yielded 46·3 lbs. of nitrogen; whilst another, which received the mixed mineral manure, including potass, every year of the twenty, yielded 55·6 lbs. of nitrogen per acre per annum. Without manure there was some decline of yield in the later years; with the partial mineral manuring there was a greater decline; but with the complete mineral manuring throughout the whole period, there was even some increase in the yield of nitrogen in the later years.

Now, the herbage growing without manure comprised about fifty species, representing about twenty natural families; that growing with the limited supply of potass comprised fewer species, but a larger amount of the produce, especially in the earlier years, consisted of leguminous species, and the yield of nitrogen was greater. Lastly, the plot receiving potass every year yielded still more leguminous herbage, and, accordingly, still more nitrogen.

The most striking points brought out by the foregoing illustrations are the following:—

1. Without nitrogenous manure, the gramineous crops annually yielded, for many years in succession, much more nitrogen over a given area than is accounted for by the amount of combined nitrogen annually coming down in the measured aqueous deposits from the atmosphere.

2. The root crops yielded more nitrogen than the cereal crops, and the leguminous crops very much more still.

3. In all cases—whether of cereal crops, root crops, leguminous crops, or a rotation of crops—*the decline in the annual yield of nitrogen, when none was supplied, was very great.*

How are these results to be explained? Whence comes the nitrogen? and especially whence comes the much larger amount taken up by plants of the leguminous and some other families, than by the gramineæ? And lastly, what is the significance of the great decline in the yield of nitrogen in all the crops when none is supplied in the manure?

Many explanations have been offered. It has been assumed that the combined nitrogen annually coming down from the atmosphere is very much larger than we have estimated it, and that it is sufficient for all the requirements of annual growth. It has been supposed that "broad-leaved plants" have the power of taking up nitrogen in some form from the atmosphere, in a degree, or in a manner not possessed by the narrow-leaved gramineæ. It has been argued that, in the last stages of the decomposition of organic matter in the soil, hydrogen is evolved, and that this nascent hydrogen combines with the free nitrogen of the atmosphere, and so forms ammonia. It has been suggested that ozone may be evolved in the oxidation of organic matter in the soil, and that, uniting with free nitrogen, nitric acid would be produced. Lastly, it has by some been concluded that plants assimilate the free nitrogen of the atmosphere, and that some descriptions are able to do this in a greater degree than others.

We have discussed these various points on more than one occasion; and we have given our reasons for concluding that none of the explanations enumerated can be taken as accounting for the facts of growth.

Confining attention here to the question of the assimilation of free nitrogen by plants, it is obvious that, if this were established, most of our difficulties would vanish. This question has been the subject of a great deal of experimental inquiry, from the time that Boussingault entered upon it, about the year 1837, nearly up to the present time. About twenty years ago it was elaborately investigated at Rothamsted. In publishing the results of that inquiry those of others relating to it were fully discussed; and although the recorded evidence is admittedly very conflicting, we then came to the conclusion, and still adhere to it, that the balance of the direct experimental evidence on the point is decidedly against the supposition of the assimilation of free nitrogen by plants. Indeed, the strongest argument we know of in its favour is, that some such explanation is wanted.

Not only is the balance of direct experimental evidence against the assumption that plants assimilate free or uncombined nitrogen, but it seems to us that the balance of existing indirect evidence is also in favour of another explanation of our difficulties.

I have asked what is the significance of the gradual decline of produce of all the different crops when continuously grown without nitrogenous manure? It cannot be that, in growing the same crop year after year on the same land, there is any residue left in the soil that is injurious to the subsequent growth of the same description of crop; for (excepting the beans) more of each description of crop has been grown year after year on the same land than the average yield of the country at large under ordinary rotation, and ordinary treatment—provided only that suitable soil conditions were supplied. Nor can the diminishing produce, and the diminishing yield of nitrogen, be accounted for on the supposition that there was a deficient supply of available mineral constituents in the soil. For, it has been shown that the cereals yielded little more, and declined nearly as much as without manure, when a complex mineral manure was used, such as was proved to be adequate when available nitrogen was also supplied. So far as the root crops are concerned the yield of nitrogen, though it declined very much, was greater at first, and on the average, than in the case of the cereals. As to the leguminosæ, which require so much nitrogen from somewhere, it is to be observed that on ordinary arable land the yield has not been maintained under any conditions of manuring; and the decline was nearly as marked with mineral manures as without any manure. Compared with the growth of the leguminosæ on arable land, the remarkable result with the garden clover would seem clearly to indicate that the question was one of soil, and

not of atmospheric supply. And the fact that all the other crops will yield full agricultural results even on ordinary arable land, when proper manures are applied, is surely very strong evidence that it is with them, too, a question of soil, and not of atmospheric supply.

But we have other evidence leading to the same conclusion. Unfortunately we have not reliable samples of the soil of the different experimental fields taken at the commencement of each series of experiments, and subsequently at stated intervals. We have nevertheless, in some cases, evidence sufficient to show whether or not the nitrogen of the soil has suffered diminution by the continuous growth of the crop without nitrogenous manure.

Thus we have determined the nitrogen in the soil of the continuously unmanured wheat plot at several successive periods, and the results prove that a gradual reduction in the nitrogen of the soil is going on; and, so far as we are able to form a judgment on the point, the diminution is approximately equal to the nitrogen taken out in crops; and the amount estimated to be received in the annual rainfall is approximately balanced by the amount lost by the land as nitrates in the drainage water.

In the case of the continuous root-crop soil, on which the decline in the yield of nitrogen in the crop was so marked, the percentage of nitrogen, after the experiment had been continued for twenty-seven years, was found to be lower where no nitrogen had been applied than in any other arable land on the farm which has been examined.

In the case of the experiments on the mixed herbage of grass land, the soil of the plot which, under the influence of a mixed mineral manure, including potass, had yielded such a large amount of leguminous herbage and such a large amount of nitrogen, showed, after twenty years, a considerably lower percentage of nitrogen than that of any other plot in the series.

Lastly, determinations of nitrogen in the garden soil which has yielded so much nitrogen in clover, made in samples collected in the fourth and the twenty-sixth years of the twenty-seven of the experiments, show a very large diminution in the percentage of nitrogen. The diminution, to the depth of 9 inches, only represents approximately three-fourths as much as the amount estimated to be taken out in the clover during the intervening period; and the indication is that there has been a considerable reduction in the lower depths also. It is to be supposed however that there would be loss in other ways than by the crop alone.

I would ask, Have we not in these facts—that full amounts of the different crops can be grown, provided proper soil conditions are supplied; that without nitrogenous manure the yield of nitrogen in the crop rapidly declines; and that, coincidently with this, there is a decline in the percentage of nitrogen in the soil—have we not in these facts cumulative evidence pointing to the soil, rather than to the atmosphere, as the source of the nitrogen of our crops?

In reference to this point I may mention that the ordinary arable soil at Rothamsted may be estimated to contain about 3,000 lbs. of nitrogen per acre in the first nine inches of depth, about 1,700 lbs. in the second nine inches, and about 1,500 lbs. in the third nine inches—or a total of about 6,200 lbs. per acre to the depth of twenty-seven inches.

In this connection it is of interest to state that a sample of Oxford clay obtained in the sub Wealden exploration boring, at a depth of between 500 and 600 feet (and which was kindly given to me by the President of the Association, Prof. Ramsay, some years ago), showed, on analysis at Rothamsted, approximately the same percentage of nitrogen as the subsoil at Rothamsted taken to the depth of about 4 feet only.

Lastly, in a letter received from Boussingault some years ago, referring to the sources whence the nitrogen of vegetation is derived, he says:—

"From the atmosphere, because it furnishes ammonia in the form of carbonate, nitrates, or nitrites, and various kinds of dust. Theodore de Saussure was the first to demonstrate the presence of ammonia in the air, and consequently in meteoric waters. Liebig exaggerated the influence of this ammonia on vegetation, since he went so far as to deny the utility of the nitrogen which forms a part of farmyard manure. This influence is nevertheless real, and comprised within limits which have quite recently been indicated in the remarkable investigations of M. Schlösing.

"From the soil, which, besides furnishing the crops with mineral alkaline substances, provides them with nitrogen, by ammonia, and by nitrates, which are formed in the soil at the expense of the nitrogenous matters contained in diluvium, which is the basis of vegetable earth; compounds in which nitrogen exists in stable combination, only becoming fertilising by the effect of time. If we take into account their immensity, the deposits of the last geological periods must be considered as an inexhaustible reserve of fertilising agents. Forests, prairies, and some vineyards, have really no other manures than what are furnished by the atmosphere and by the soil. Since the basis of all cultivated land contains materials capable of giving rise to nitrogenous combinations, and to mineral substances, assimilable by plants, it is not necessary to suppose that in a system of cultivation the excess of nitrogen found in the crops is derived from the free nitrogen of the atmosphere. As for the absorption of the gaseous nitrogen of the air by vegetable earth, I am not acquainted with a single irreproachable observation that establishes it; not only does the earth not absorb gaseous nitrogen, but it gives it off, as you have observed in conjunction with Mr. Lawes, as Reiset has shown in the case of dung, as M. Schlösing and I have proved in our researches on nitrification.

"If there is one fact perfectly demonstrated in physiology it is this of the non-assimilation of free nitrogen by plants; and I may add by plants of an inferior order, such as mycoderms and mushrooms (translation)."

If, then, our soils are subject to a continual loss of nitrogen by drainage, probably in many cases more than they receive of combined nitrogen from the atmosphere—if the nitrogen of our crops is derived mainly from the soil, and not from the atmosphere—and if, when due return is not made from without, we are drawing upon what may be termed the store of nitrogen of the soil itself—is there not, in the case of many soils at any rate, as much danger of the exhaustion of their available nitrogen as there has been supposed to be of the exhaustion of their available mineral constituents?

I had hoped to say something more about soils to advance our knowledge respecting which an immense amount of investigation has been devoted of late years, but in regard to which we have yet very much more to learn. I must however now turn to other matters.

(To be continued.)

IMPROVED HELIOGRAPH OR SUN SIGNAL[1]

THE author claims to have contrived a heliograph, or sun telegraph, by which the rays of the sun can be directed on any given point with greater ease and certainty than by those at present in use.

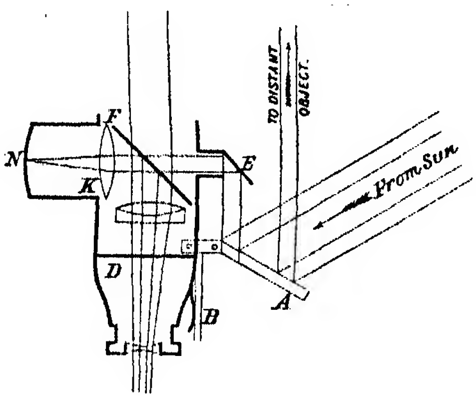
When the sun's rays are reflected at a small plane surface considered as a point, the reflected rays form a cone, whose vertex is at the reflector and whose vertical angle is equal to that subtended by the sun. Adding to the size of the mirror adds other cones of light, whose bounding rays are parallel with those proceeding from other points of the mirror, and only distant from them the same distance as the points on the mirror from which they are reflected. Hence increasing the size of the mirror only adds to the field to which the sun's rays are reflected a diameter equal to the diameter of the mirror, and this at any distance at which the sun signal would be used is quite inappreciable. Adding to the size of the mirror adds to the number of rays sent to each point, and hence to the brightness of the visible flash, but not to the area over which it is visible.

By the author's plan an ordinary field-glass is used to find the position of the object to be signalled to, and to it is attached, in the position of the ordinary sun-shade, a small and light apparatus, so arranged that when the mirror is turned to direct the cone of rays to any object within the field view of the glass, an image of the sun appears in the field, at the same time as the image of the distant object, and magnified to the same degree, and the part of the field covered by this image is exactly that part to which the rays are reflected, and at which some part of the sun's disk is visible in the mirror.

A perfectly plane silvered mirror, *A*, takes up the rays of the sun, and when in proper position reflects them parallel with the axis of *D*, which is one barrel of an ordinary field-glass. The greater part of the light passes away to the distant object, but some is taken up by the small silvered mirror, *E*, which is placed at an angle of 45° to the axis of *D*, and reflected at a right angle through the unsilvered plane mirror, *F*, and the convex lens, *K*, by which it is brought to a focus on the white

[1] Paper read at the British Association by Tempest Anderson, M.D., B.Sc.

screen, H, which is placed in the principal focus of K. The rays from this image diverge in all directions, and some are taken up by the lens K and restored to parallelism; some of these are reflected by the unsilvered mirror, F, down to the field-glass, D, and if this is focussed for parallel rays, as is the case in looking at distant objects, an image of the sun is seen projected on the same field of view as that of the distant object. As the mirrors E and F are adjusted strictly parallel, the rays proceeding from F into the field-glass are parallel and in the opposite direction to those going from the mirror A to E, which form part of the same pencil as those going to the distant object. Hence the image of the sun seen in the field exactly covers the object to which the sun-flash is visible, and in whatever direction the mirror A is moved so as to alter the direction in which rays are reflected to the distant object, and the angle at which part impinge on E and are reflected through the lens K, the image visible in the glass moves in the same direction. Several attempts to produce this result were made by the use of mirrors and prisms, before the lens K was introduced, but they all failed. It was easy to make the image of the sun cover the object when the two occupied the centre of the field of view, but directly the mirror was inclined so as to direct the rays not strictly parallel to the axis of the field-glass, the apparent image diverged generally in the same direction along one co-ordinate, and in the opposite along one at right angles to it, so that nowhere, but in one line across the field, did the image lie in the desired position. The mirrors E and F are adjusted parallel once for all, by noticing the position on a screen of the small



spot of light reflected from the front of F as the light passes from E to K. The mirrors are moved by the adjusting screws till this spot has, to the bright reflection from the mirror A, the same relative position that the centre of mirror F has to the mirror A.

In actual use the field-glass is first fixed in position pointing to the object, either by holding steadily in the hand, or better by a clamp attached, by which it can be screwed into a tree or post, or fixed in the muzzle of a rifle. The instrument is turned on the barrel of the glass till the sun is in the plane passing through the two axes of the instrument, and the mirror A is turned till the bright image of the sun is seen on the screen H, through a hole left for the purpose in the side of the tube. On looking through the glass the sun's image is seen, and by then slightly rotating the instrument or moving the mirror, is made to cover the object. The mirror A is connected not directly to the body of the instrument, but to a lever B, on which it works stiffly, so as to retain any position in which it is placed. Lever B works easily and has a limited range of motion, to one end of which it is pressed by a spring; slight pressure with the finger moves it and its attached mirror, so as to throw the light on and off the object in a succession of long and short flashes by which letters and words may be indicated. Flashes may also be given by moving the instrument if held in the hand.

The above instrument answers well for all positions of the sun except when very low behind the observer's back. For this case another mirror is provided by which the light is reflected on to the mirror A.

The instrument, which is made by Cook and Sons, York, was exhibited. It was favourably criticised by the president, Prof. W. G. Adams, F. Galton, and others.

SELENIUM AND THE PHOTOPHONE[1]

In bringing before you some discoveries made by Mr. Sumner Tainter and myself, which have resulted in the construction of apparatus for the production and reproduction of sound by means of light, it is necessary to explain the state of knowledge which formed the starting point of our experiments. I shall first describe the remarkable substance selenium, and the manipulations devised by various experiments; but the final result of our researches has evidenced the class of substances sensitive to light vibrations, until we can propound the fact of sensitiveness being a general property of all matter. We have found this property in gold, silver, platinum, iron, steel, brass, copper, zinc, lead, antimony, German silver, Jenkin's metal, Babbitt's metal, ivory, celluloid, gutta-percha, hard rubber, soft vulcanised rubber, paper, parchment, wood, mica, and silvered glass; and the only substances from which we have not obtained results are carbon and thin microscopic glass. We find that when a vibratory beam of light falls upon these substances they emit sounds—the pitch of which depends upon the frequency of the vibratory change in the light. We find further that, when we control the form or character of the light-vibration on selenium, and probably on the other substances, we control the quality of the sound and obtain all varieties of articulate speech. We can thus, without a conducting wire as in electric telephony, speak from station to station, wherever we can project a beam of light. We have not had opportunity of testing the limit to which this photophonic influence can be extended, but we have spoken to and from points 213 metres apart; and there seems no reason to doubt that the results will be obtained at whatever distance a beam of light can be flashed from one observatory to another. The necessary privacy of our experiments hitherto has alone prevented any attempts at determining the extreme distance at which this new method of vocal communication will be available. I shall now speak of selenium.

In the year 1817 Berzelius and Gottlieb Gahn made an examination of the method of preparing sulphuric acid in use at Gripsholm. During the course of this examination, they observed in the acid a sediment of a partly reddish, partly clear brown colour, which, under the action of the blowpipe, gave out a peculiar odour, like that attributed by Klaproth to tellurium. As tellurium was a substance of extreme rarity, Berzelius attempted its production from this deposit; but he was unable, after many experiments, to obtain further indications of its presence. He found plentiful signs of sulphur mixed with mercury, copper, zinc, iron, arsenic, and lead, but no trace of tellurium. It was not in the nature of Berzelius to be disheartened by this result. In science every failure advances the boundary of knowledge as well as every success, and Berzelius felt that, if the characteristic odour that had been observed did not proceed from tellurium, it might possibly indicate the presence of some substance then unknown to the chemist. Urged on by this hope he returned with renewed ardour to his work. He collected a great quantity of the material, and submitted the whole mass to various chemical processes. He succeeded in separating successively the sulphur, the mercury, the copper, the tin, and the other known substances whose presence had been indicated by his tests; and, after all these had been eliminated, there still remained a residue which proved upon examination to be what he had been in search of—a new elementary substance. The chemical properties of this new element were found to resemble those of tellurium in so remarkable a degree, that Berzelius gave to the substance the name of "Selenium," from the Greek word *selene*, the moon ("tellurium," as is well known, being derived from *tellus*, the earth).

Although tellurium and selenium are alike in many respects, they differ in their electrical properties, tellurium being a good conductor of electricity, and selenium, as Berzelius showed, a non-conductor. Knox discovered, in 1837, that selenium became a conductor when fused; and Hittorff, in 1852, showed that it conducted, at ordinary temperatures, when in one of its allotropic forms. When selenium is rapidly cooled from a fused condition it is a non-conductor. In this its vitreous form it is of a dark brown colour, almost black by reflected light, having an exceedingly brilliant surface. In thin films it is transparent, and appears of a beautiful ruby red by transmitted light. When selenium is cooled from a fused condition with extreme slowness it presents an entirely different appearance, being of a dull lead

[1] Lecture delivered at the Boston meeting of the American Association by Prof. A. Graham Bell.

colour, and having throughout a granulated or crystalline structure, and looking like a metal. In this form it is perfectly opaque to light, even in very thin films. This variety of selenium has long been known as "granular" or "crystalline" selenium, or, as Regnault called it, "metallic" selenium. It was selenium of this kind that Hittorff found to be a conductor of electricity at ordinary temperatures. He also found that its resistance to the passage of an electrical current diminished continuously by heating up to the point of fusion, and that the resistance suddenly increased in passing from the solid to the liquid condition. It was early discovered that exposure to sunlight hastens the change of selenium from one allotropic form to another; and this observation is significant in the light of recent discoveries.

Although selenium has been known for the last sixty years, it has not yet been utilised to any extent in the arts, and it is still considered simply as a chemical curiosity. It is usually supplied in the form of cylindrical bars. These bars are sometimes found to be in the metallic condition; but more usually they are in the vitreous or non-conducting form. It occurred to Willoughby Smith that, on account of the high resistance of crystalline selenium, it might be usefully employed at the shore end of a submarine cable, in his system of testing and signalling during the process of submersion. Upon experiment, the selenium was found to have all the resistance required—some of the bars employed measuring as much as 1,400 megohms—a resistance equivalent to that which would be offered by a telegraph wire long enough to reach from the earth to the sun! But the resistance was found to be extremely variable. Experiments were made to ascertain the cause of this variability. Mr. May, Mr. Willoughby Smith's assistant, discovered that the resistance was less when the selenium was exposed to light than when it was in the dark.

In order to be certain that temperature had nothing to do with the effect, the selenium was placed in a vessel of water, so that the light had to pass through from 1 in. to 2 in. of water in order to reach the selenium. The approach of a lighted candle was found to be sufficient to cause a marked deflection of the needle of the galvanometer connected with the selenium, and the lighting of a piece of magnesium wire caused the selenium to measure less than half the resistance it did the moment before.

These results were naturally at first received by scientific men with some incredulity, but they were verified by Sale, Draper, Moss, and others. When selenium is exposed to the action of the solar spectrum, the maximum effect is produced, according to Sale, just outside the red end of the spectrum, in a point nearly coincident with the maximum of the heat rays; but, according to Adams, the maximum effect is produced in the greenish-yellow or most luminous part of the spectrum. Lord Rosse exposed selenium to the action of non-luminous radiations from hot bodies, but could produce no effect; whereas a thermopile under similar circumstances gave abundant indications of a current. He also cut off the heat rays from luminous bodies by the interposition of liquid solutions, such as alum, between the selenium and the source of light, without affecting the power of the light to reduce the resistance of the selenium; whereas the interposition of these same substances almost completely neutralized the effect upon the thermopile. Adams found that selenium was sensitive to the cold light of the moon, and Werner Siemens discovered that, in certain extremely sensitive varieties of selenium, heat and light produced opposite effects. In Siemens' experiments, special arrangements were made for the purpose of reducing the resistance of the selenium employed. Two fine platinum wires were coiled together in the shape of a double flat spiral in the zig-zag shape, and were laid upon a plate of mica so that the discs did not touch one another. A drop of melted selenium was then placed upon the platinum wire arrangement, and a second sheet of mica was pressed upon the selenium, so as to cause it to spread out and fill the spaces between the wires. Each cell was about the size of a silver dime. The selenium cells were then placed in a paraffine bath, and exposed for some hours to a temperature of 210 deg. C., after which they were allowed to cool with extreme slowness. The results obtained with these cells were very extraordinary; in some cases the resistance of the cells, when exposed to light, was only one-fifteenth of their resistance in the dark.

Without dwelling farther upon the researches of others, I may say that the chief information concerning the effect of light upon the conductivity of selenium will be found under the names of Willoughby Smith, Lieutenant Sale, Draper and Moss, Professor W. G. Adams, Lord Rosse, Day, Sabini, Dr. Werner Siemens, and Dr. C. W. Siemens. All observations by these various authors had been made by means of galvanometers; but it occurred to me that the telephone, from its extreme sensitiveness to electrical influences, might be substituted with advantage. Upon consideration of the subject, however, I saw that the experiments could not be conducted in the ordinary way for the following reason:—The law of audibility of the telephone is precisely analogous to the law of electric induction. No effect is produced during the passage of a continuous and steady current. It is only at the moment of change from a stronger to a weaker state, or *vice versâ*, that any audible effect is proposed, and the amount of effect is exactly proportional to the amount of variation in the current. It was, therefore, evident that the telephone could only respond to the effect produced in selenium at the moment of change from light to darkness, or *vice versâ*, and that it would be advisable to intermit the light with great rapidity, so as to produce a succession of changes in the conductivity of the selenium, corresponding in frequency to musical vibrations within the limits of the sense of hearing. For I had often noticed that currents of electricity, so feeble as to produce scarcely any audible effects from a telephone when the circuit was simply opened or closed, caused very perceptible musical sounds when the circuit was rapidly interrupted, and that the higher the pitch of sound the more audible was the effect. I was much struck by the idea of producing sound by the action of light in this way. Upon farther consideration it appeared to me that all the audible effects obtained from varieties of electricity could also be produced by variations of light acting upon selenium. I saw that the effect could be produced at the extreme distance at which selenium would respond to the action of a luminous body, but that this distance could be indefinitely increased by the use of a parallel beam of light, so that we could telephone from one place to another without the necessity of a conducting wire between the transmitter and receiver. It was evidently necessary, in order to reduce this idea to practice, to devise an apparatus to be operated by the voice of a speaker, by which variations could be produced in a parallel beam of light, corresponding to the variations in the air produced by the voice.

I proposed to pass light through a large number of small orifices, which might be of any convenient shape, but were preferably in the form of slits. Two similarly perforated plates were to be employed. One was to be fixed and the other attached to the centre of a diaphragm actuated by the voice, so that the vibration of the diaphragm would cause the movable plate to slide to and fro over the surface of the fixed plate, thus alternately enlarging and contracting the free orifices for the passage of light. In this way the voice of a speaker could control the amount of light passed through the perforated plates without completely obstructing its passage. This apparatus was to be placed in the path of a parallel beam of light, and the undulatory beam emerging from the apparatus could be received at some distant place upon a lens, or other apparatus, by means of which it could be condensed upon a sensitive piece of selenium placed in a local circuit with a telephone and galvanic battery. The variations in the light produced by the voice of the speaker should cause corresponding variations in the electrical resistance of the selenium employed; and the telephone in circuit with it should reproduce audibly the tones and articulations of the speaker's voice. I obtained some selenium for the purpose of producing the apparatus shown, but found that its resistance was almost infinitely greater than that of any telephone that had been constructed, and I was unable to obtain any audible effects by the action of light. I believed, however, that the obstacle could be overcome by devising mechanical arrangements for reducing the resistance of the selenium, and by constructing special telephones for the purpose. I felt so much confidence in this that, in a lecture delivered before the Royal Institute of Great Britain, upon May 17, 1878, I announced the possibility of hearing a shadow by interrupting the action of light upon selenium. A few days afterwards my ideas upon this subject received a fresh impetus by the announcement made by Mr. Willoughby Smith before the Society of Telegraph Engineers that he had heard the action of a ray of light falling upon a bar of crystalline selenium, by listening to a telephone in circuit with it.

It is not unlikely that the publicity given to the speaking telephone during the last few years may have suggested to many

minds in different parts of the world somewhat similar ideas to my own.

Although the idea of producing and reproducing sound by the action of light, as described above, was an entirely original and independent conception of my own, I recognise the fact that the knowledge necessary for its conception has been disseminated throughout the civilised world, and that the idea may therefore have occurred to many other minds. *The fundamental idea, on which rests the possibility of producing speech by the action of light, is the conception of what may be termed an undulatory beam of light in contradistinction to a merely intermittent one.* By an undulatory beam of light, I mean a beam that shines continuously upon the selenium receiver, but the intensity of which upon that receiver is subject to rapid changes, corresponding to the changes in the vibratory movement of a particle of air during the transmission of a sound of definite quality through the atmosphere. The curve that would graphically represent the changes of light would be similar in shape to that representing the movement of the air. I do not know whether this conception had been clearly realised by "J. F. W.," of Kew, or by Mr. Sargent, of Philadelphia; but to Mr. David Brown, of London, is undoubtedly due the honour of having distinctly and independently formulated the conception, and of having devised apparatus—though of a crude nature—for carrying it into execution. It is greatly due to the genius and perseverance of my friend, Mr. Summer Tainter, of Watertown, Mass., that the problem of producing and reproducing sound by the agency of light has at last been successfully solved. The first point to which we devoted our attention was the reduction of the resistance of crystalline selenium within manageable limits. The resistance of selenium cells employed by former experimenters was measured in millions of ohms, and we do not know of any record of a selenium cell measuring less than 250,000 ohms in the dark. *We have succeeded in producing sensitive selenium cells measuring only* 300 *ohms in the dark, and* 155 *ohms in the light.* All former experimenters seem to have used platinum for the conducting part of their selenium cells, excepting Werner Siemens, who found that iron and copper might be employed. We have also discovered that brass, although chemically acted upon by selenium, forms an excellent and convenient material; indeed, we are inclined to believe that the chemical action between the brass and selenium has contributed to the low resistance of our cells by forming an intimate bond of union between the selenium and brass. We have observed that melted selenium behaves to the other substances as water to a greasy surface, and we are inclined to think that when selenium is used in connection with metals not chemically acted upon by it, the points of contact between selenium and the metal offer a considerable amount of resistance to the passage of a galvanic current. By using brass we have been enabled to construct a large number of selenium cells of different forms. The mode of applying the selenium is as follows:—The cell is heated, and, when hot enough, a stick of selenium is rubbed over the surface. In order to acquire conductivity and sensitiveness, the selenium must next undergo a process of annealing.

We simply heat the selenium over a gas stove and observe its appearance. When the selenium attains a certain temperature, the beautiful reflecting surface becomes dimmed. A cloudiness gradually extends over it, somewhat like the film of moisture produced by breathing upon a mirror. This appearance gradually increases, and the whole surface is soon seen to be in the metallic, granular, or crystalline condition. The cell may then be taken off the stove, and cooled in any suitable way. When the heating process is carried too far, the crystalline selenium is seen to melt. Our best results have been obtained by heating the selenium until it crystallises, and continuing the heating until signs of melting appear, when the gas is immediately put out. The portions that had melted instantly recrystallise, and the selenium is found upon cooling to be a conductor, and to be sensitive to light. The whole operation occupies only a few minutes. This method has not only the advantage of being expeditious, but it proves that many of the accepted theories on this subject are fallacious. Our new method shows that fusion is unnecessary, that conductivity and sensitiveness can be produced without long heating and slow cooling; and that crystallisation takes place during the heating process. We have found that on removing the source of heat immediately on the appearance of the cloudiness, distinct and separate crystals can be observed under the microscope, which appear like leaden snow-flakes on a ground of ruby red. Upon removing the heat, when crystallisation is further advanced, we perceive under the microscope masses of these crystals arranged like basaltic columns standing detached from one another, and at a still higher point of heating the distinct columns are no longer traceable, but the whole mass resembles metallic pudding-stone, with here and there a separate snow-flake, like a fossil, on the surface. Selenium crystals formed during slow cooling after fusion present an entirely different appearance, showing distinct facets.

We have devised about fifty forms of apparatus for varying a beam of light in the manner required, but only a few typical varieties need be shown. The source of light may be controlled, or a steady beam may be modified at any point in its path. The beam may be controlled in many ways. For instance, it may be polarised, and then affected by electrical or magnetic influences in the manner discovered by Faraday and Dr. Kerr. The beam of polarised light, instead of being passed through a liquid, may be reflected from the polished pole of an electro-magnet. Another method of affecting a beam of light is to pass it through a lens of variable focus. I observe that a lens of this kind has been invented in France by Dr. Cusco, and is fully described in a recent paper in *La Nature*; but Mr. Tainter and I have used such a lens in our experiments for months past. The best and simplest form of apparatus for producing the effect remains to be described. This consists of a plane mirror of flexible material—such as silvered mica or microscope glass. Against the back of this mirror the speaker's voice is directed. The light reflected from this mirror is thus thrown into vibrations corresponding to those of the diaphragm itself.

In arranging the apparatus for the purpose of reproducing sound at a distance any powerful source of light may be used, but we have experimented chiefly with sunlight. For this purpose a large beam is concentrated by means of a lens upon the diaphragm mirror, and, after reflection, is again rendered parallel by means of another lens. The beam is received at a distant station upon a parabolic reflector, in the focus of which is placed a sensitive selenium cell, connected in a local circuit with a battery and telephone. A large number of trials of this apparatus have been made with the transmitting and receiving instruments so far apart that sounds could not be heard directly through the air. In illustration I shall describe one of the most recent of these experiments. Mr. Tainter operated the transmitting instrument, which was placed on the top of the Franklin schoolhouse in Washington, and the sensitive receiver was arranged in one of the windows of my laboratory, 1325 L street, at a distance of 213 metres. Upon placing the telephone to my ear I heard distinctly from the illuminated receiver the words: "Mr. Bell, if you hear what I say come to the window and wave your hat." In laboratory experiments the transmitting and receiving instruments are necessarily within earshot of one another, and we have, therefore, been accustomed to pooling the electric circuit connected with the selenium receiver, so as to place the telephones in another room. By such experiments we have found that articulate speech can be reproduced by the oxyhydrogen light, and even by the light of a kerosene lamp. The loudest effects obtained from light are produced by rapidly interrupting the beam by the perforated disk. The great advantage of this form of apparatus for experimental work is the noiselessness of its rotation, admitting the close approach of the receiver without interfering with the audibility of the effect heard from the latter; for it will be understood that musical tones are emitted from the receiver when no sound is made at the transmitter. A silent motion thus produces a sound. In this way musical tones have been heard even from the light of a candle. When distant effects are sought another apparatus is used. By placing an opaque screen near the rotating disk the beam can be entirely cut off by a slight motion of the hand, and musical signals, like the dots and dashes of the Morse telegraph code, can thus be produced at the distant receiving station.

We have made experiments, with the object of ascertaining the nature of the rays that affect selenium. For this purpose we have placed in the path of an intermittent beam various absorbing substances. Prof. Cross has been kind enough to give me his assistance in conducting these experiments. When a solution of alum or bisulphide of carbon, is employed, the loudness of the sound produced by the intermittent beam is very slightly diminished; but a solution of iodine in bisulphide of carbon cuts off most, but not all, of the audible effect. Even an apparently opaque sheet of hard rubber does not entirely do this. When the sheet of hard rubber was held near the disk interrupter the

rotation of the disk interrupted what was then an invisible beam, which passed over a space of about twelve feet before it reached the lens which finally concentrated it upon the selenium cell. A faint but perfectly perceptible musical tone was heard from the telephone connected with the selenium. This could be interrupted at will by placing the hand in the path of the invisible beam. It would be premature, without further experiments, to speculate too much concerning the nature of these invisible rays; but it is difficult to believe that they can be bent rays, as the effect is produced through two sheets of hard rubber containing between them a saturated solution of alum. Although effects are produced as above shown by forms of radiant energy which are invisible, we have named the apparatus for the production and reproduction of sound in this way "the photophone," because an ordinary beam of light contains the rays which are operative.

It is a well-known fact that the molecular disturbance produced in a mass of iron by the magnetising influence of intermittent electrical current can be observed as sound by placing the ear in close contact with the iron. It occurred to us that the molecular disturbance produced in crystalline selenium by the action of an intermittent beam of light should be audible in a similar manner without the aid of a telephone or battery. Many experiments were made to verify this theory without definite results. The anomalous behaviour of the hard rubber screen suggested the thought of listening to it also. This experiment was tried with extraordinary success. I held the sheet in close contact with my ear, while a beam of intermittent light was focussed upon it by a lens. A distinct musical note was immediately heard. We found the effect intensified by arranging the sheet of hard rubber as a diaphragm, and listening through a hearing-tube. We then tried the crystalline selenium in the form of a thin disk, and obtained a similar, but less intense effect. The other substances which I enumerated at the beginning of my address were now successively tried in the form of thin disks, and sounds were obtained from all but carbon and thin glass. We found hard rubber to produce a louder sound than any other substance we tried, excepting antimony, and paper and mica to produce the weakest sounds. On the whole we feel warranted in announcing as our conclusion that sounds can be produced by the action of a variable light from substances of all kinds, when in the form of thin diaphragms. We have heard from interrupted sunlight very perceptible musical tones through tubes of ordinary vulcanised rubber, of brass, and of wood. These were all the materials at hand in tubular form, and we have had no opportunity since of extending these observations to other substances.

I am extremely glad that I have the opportunity of making the first publication of these researches before a scientific society, for it is from scientific men that my work of the last six years has received its earliest and kindest recognition. I gratefully remember the encouragement which I received from the late Prof. Henry at a time when the speaking telephone existed only in theory. Indeed, it is greatly due to the stimulus of his appreciation that the telephone became an accomplished fact. I cannot state too highly also the advantage I received in preliminary experiments on sound vibrations in this building from Prof. Cross, and near here from my valued friend Dr. Clarence J. Blake. When the public were incredulous of the possibility of electrical speech, the American Academy of Arts and Sciences, the Philosophical Society of Washington, and the Essex Institute of Salem, recognised the reality of the results and honoured me by their congratulations. The public interest, I think, was first awakened by the judgment of the very eminent scientific men before whom the telephone was exhibited in Philadelphia, and by the address of Sir William Thomson before the British Association for the Advancement of Science.

At a later period, when even practical telegraphists considered the telephone as a mere scientific toy, Prof. John Peirce, Prof. Eli W. Blake, Dr. Channing, Mr. Clarke, and Mr. Jones, of Providence, Rhode Island, devoted themselves to a series of experiments for the purpose of assisting me in making the telephone of practical utility; and they communicated to me from time to time the result of their experiments with a kindness and generosity I can never forget. It is not only pleasant to remember these things, and to speak of them, but it is a duty to repeat them, as they give a practical refutation to the often repeated stories of the blindness of scientific men to unaccredited novelties, and of their jealousy of unknown inventors who dare to enter the charmed circle of science. I trust that the scientific favour which was so readily accorded to the telephone may be extended by you to this new claimant—the photophone.

SCIENTIFIC SERIALS

THE *Quarterly Journal of Microscopical Science*, July, contains—F. M. Balfour, on the structure and homologies of the germinal layers of the embryo (with woodcuts).—On Hubrecht's researches on the nervous system of nemertines (with a plate) abstract of.—A. G. Bourne, on the structure of the nephridia of the medicinal leech (with two plates).—Prof. Ray Lankester, on intra-epithelial capillaries in the integument of the medicinal leech (with a plate); and on the connective and vasifactive tissues of the same (with two plates).—Dr. H. Gibbes, on the use of the Wenham binocular with high powers.—On the structure of the spermatozoon.—P. H. Carpenter, on some disputed points in Echinoderm morphology.—Prof. Pouchet, on the origin of the red-blood corpuscles (translated from the *Revue Scientifique*).—Prof. Ray Lankester, on *Limnocodium sowerbii*, a new trachomedusa inhabiting fresh water (with woodcuts and two plates) [for an abstract *vide* NATURE, vol. xxii. p. 147].—Notes and memoranda.—*Proceedings* of the Dublin Microscopical Club for November and December, 1879.

Revue d'Anthropologie, tome iii. fascic. 3 (July).—Prof. J. Delbos, of Nancy, gives a brief report of the discovery, made in 1869, of a number of human skeletons in the loam beds of Bollwiller (Haut-Rhin). His paper, which describes the general geognostic character of the soil in which these remains were found, is followed by a detailed description, by Dr. René Collignow, of each of the seven distinct skeletons that have been recovered. Of these, five were adult males, two females, and one a child of about seven. In general characteristics they resemble the Cannstatt remains.—Dr. Bérenger-Féraud, whose position in Senegal as Médecin-en-chef de la Marine gave him favourable opportunities of studying the habits of the natives, has drawn up an interesting report of all that is known on the spot in regard to the mysterious sect of the Simos, which exercises an important influence on the tribes of the west coasts of Africa, from Cape Vert as far as the Gabon settlements on the equator. The Simo of these regions is the dreaded Mombo-Yombo of other races.—Dr. Gustave Lagneau's paper, "De quelques Dates reculées," is a scholarly dissertation on the community of race traceable in the Belgæ, Galli, and Germani, and on the evidence supplied in reference to the period of their immigration into Keltic lands by the introduction of a dolichocephalic character, in addition to the purely brachycephalic type observable in the skulls of Keltic and Kimmerian races. In discussing the question of the occupation of Western Europe by Iberians, M. Lagneau enters at length into the historical and anthropological grounds for accepting the testimony of Plato and others as to the defeat of those tribes by a powerful race, the Atlantæ, and the existence of a great western continent, or archipelago, the submerged Atlantis, from which the latter peoples made their inroads on West Africa and West Europe.—M. Martinet's enumeration of the prehistoric monuments of Berry deserves special notice for the interesting information it supplies in reference to the so-called "Mardelles," a kind of conically shaped excavations, the purport of which has not been determined, and which, although found elsewhere, as in Normandy, Provence, &c., is of exceptional frequency in Berry, where between 300 and 400 have been explored. In diameter they vary from 20 to 100 metres, in depth from 50 centimetres to 8 metres. Traces of ashes, calcined animal bones, and coarse potsherds, with a few broken flints, have been found at the bottom of these depressions, of which several are generally ranged in a line near natural or artifically constructed caverns.

Journal de Physique, August.—Experimental researches on rotatory polarisation in gases, by M. H. Becquerel.—Magnetic rotatory power of liquids and of their vapours, by M. Bichat.—Experiments on flames, by M. Neyreneuf.

Journal of the Franklin Institute, August.—The limitations of the steam-engine, by W. D. Marks.—Economical cut-off in steam-engines, by S. W. Robinson.—The involute of the circumference of a circle, by J. J. Skinner.—Holman's new compressorium and moist chamber, by J. A. Ryder.

Rivista Scientifico-Industriale, No. 15, August 15.—Periodic spontaneous movement of the stamens of *Ruta bracteosa*, D.C., and of *Smyrnum rotundifolium*, by Dr. Macchiati.—Synthesis of meteorological observations in Modica and Syracuse on the fall of meteoric powders, from the end of 1876 to April 16, 1880, by Prof. Lancetta.

No. 16, August 31.—On types of rocks, by Prof. de Stefani.

—New apparatus for the electric light.—Parallelogram of forces, by Prof. Lancetta.—Further contributions to the Aphides of Sardinia; description of three new species, by Prof. Macchiati.

Atti della R. Accademia dei Lincei, June.—On an apparatus for determining the mechanical equivalent of heat, by Dr. Bartoli.—On the laws of galvanic polarisation, by the same.—On a human skeleton of the age of stone in the Roman province, by Dr. Incoronato.—Liassic limestone of Gozzano, and its fossils, by Dr. Parona.—Works on the Tiber, and varied conditions of the Roman land, by S. Ponzi.—Reply to S. Ferrari's observations (relating to anomalous induction of a magnetic declinometer), by Prof. Keller.—On the mechanism of movements of the iris, by S. Morizzia.—On some derivatives of natural and synthetic thymol, by Professors Paterno and Canzonesi.—Analysis of an augite of Lazio, by Dr. Piccini.—Chemical researches on the lava of Montecompatri, &c., by Dr. Mauro.—On the hæmatopoetic function, by SS. Tizzoni and Fileti.—On the diffusion of the metals of cerite, by S. Cossa.—On tungstate of didymium, by the same.—On a proposition of Jacobi, by S. Siacci.—On a class of differential equations integrable by elliptic functions, by S. Brioschi.—Verification and use of a new formula for calculation of planetary perturbations, by S. De Gasparis.

Rendiconto delle Sessioni dell' Accademia delle Scienze dell' Istituto di Bologna, 1879–80.—We note here the following:—On the placenta of cartilaginous fishes and mammalia, and its applications in zoological taxonomy and anthropogeny, by Prof. Ercolani.—Variations of human temperature resulting from bodily movements, by Prof. Villari.—Dimensions of the electric spark of condensers, by the same.—On variation of length due to magnetism, by Prof. Righi.—On some products of decomposition of albumen at the temperature of the human body, and at slightly lower temperatures, by Prof. Selmi.—On the singular verticillate configuration of laminæ of crystalline snow, &c., by Prof. Bombicci.—On a case of permanent polarity in a magnet opposite to that of the inducing helix, by Prof. Righi.—Laws relative to the dimensions of electric sparks of condensers, by Prof. Villari.—Investigation of phosphorus in the urine in cases of poisoning, and products which may occur, by Prof. Selmi.—A mercury pneumatic machine with double action, by S. Liuzzi.—Verification of ptomaines in most cases of chemico-legal investigation, and formation of some of them, of poisonous nature, in animal substances kept three years in spirits, by Prof. Gianetti.—On the principal changes in the course of the Po, and means of obviating disaster threatened by it, by Dr. Predieri.—On the intimate structure of the eyes of Diptera, and on the eyes of blind Talpa, by Prof. Ciaccio. (This *Rendiconto* contains a considerable number of papers relating to anatomy and local geology.)

Reale Istituto Lombardo di Scienze e Lettere. Rendiconti. Vol. xiii., fasc. xv., July 15.—Outlines of a Government sanitary organisation, by Dr. Zucchi.—On the theory of hallucinations, by Prof. Tamburini.—Triassic fossils of the African Alps, by S. De Stefani.—The learned friends of Alexander Volta, by S. Z. Volta.

SOCIETIES AND ACADEMIES

LONDON

Entomological Society, September 1.—H. T. Stainton, F.R.S., vice-president, in the chair.—Miss Emily A. Smith, Assistant State Entomologist of Illinois, was elected a Foreign Member.—Mr. J. Jenner Weir exhibited specimens of *Odonestis potatoria* and *Smerinthus populi*, which possessed the peculiarities of both sexes.—Sir Sidney Saunders exhibited six winged examples of the Stylopideous genus *Hylecthrus*, and also various other Hymenoptera, and contributed remarks thereon.—Miss E. A. Ormerod exhibited some galls found on *Tanacetum vulgaris*, which she described at length.—Mr. T. R. Billups exhibited a female specimen of *Polyblastus whalbergi*, an ichneumon not previously recorded in Britain.—Mr. E. Boscher exhibited living specimens of the two varieties of the larvæ of *Smerinthus ocellatus*, and contributed a note thereon.—Mr. Meldola exhibited some specimens of *Camptogramma bilineata*, a large number of which had been found by Mr. English near Epping, attached firmly to the leaves of the "tea tree" (*Lycium barbarum*) by the abdomen, in which position they had died, possibly from the effects of a fungoid disease.—Mr. A. H. Swinton communicated a note on *Luciola italica*, an Italian fire-fly.

PARIS

Academy of Sciences, September 13.—M. Edm. Becquerel in the chair.—The following papers were read:—Observations of Faye's comet and of comet *b* 1880 (Schäberle) at Paris Observatory with the equatorial of the western tower, by M. Bigourdan.—On the probable orbital motion of some binary systems of the southern heavens, by M. Cruls. This is from the Imperial Observatory at Rio; and the author's data are compared with those of Sir J. Herschel at the Cape, and Capt. Jacob at Poonah.—Spectroscopic researches on some stars not hitherto studied, by M. Cruls. This relates to stars in the Bee, the Cross, and the Centaur.—On some solar phenomena observed at Nice, by M. Thollon. He gives several sketches of the spectral phenomena of protuberances, &c. He does not hesitate to say that every movement of the solar surface having, along the line of observation, a component which is not *nil*, causes a displacement of the spectral lines. It is also extremely probable, but not certain, that every displacement of a line corresponds to a movement.—On the law of electromagnetic machines (continued), by M. Joubert. With a given intensity of field, whatever the other conditions in which the machine works, from the moment when it gives maximum work, the retardation is equal to $\frac{1}{8}$ of the entire period; the intensity is constant and equal to the quotient by $\sqrt{2}$ of the absolute maximum of intensity; the electromagnetic work is proportional to the velocity; and the velocity is in a constant ratio to the resistance.—On boroduodecitungstic acid and its salts of potassium, by M. Klein.—On the subcutaneous lymphatics of the python of Séba, by M. Jourdain. The arrangement presents an evident similarity to that in Teleosteans (a ventral trunk and two lateral ones, &c.). When the direction of circulation of lymph has been ascertained, it will probably be found the same in both.—Deep dredging in the Lake of Tiberias (Syria), in May, 1880, by M. Lortet. The surface of the lake is 212 m. under that of the Mediterranean, but probably was at one time level with it; the greatest depth met with was about 250 m. at the northern extremity. It was thought that the waters, formerly saline, had probably contained special animal forms, traces of which might still be found at great depths. Some twelve species of fishes were met with, and some new forms. *Chromis* preponderated; indeed, they swarm in the lake. Twelve forms of mollusca were met with, some new species. The *Melanopsis* and *Melania* were of marine character. At the borders of the lake were some shrimps, crabs, and tortoises. Diatoms, foraminifera, &c., were obtained in the fine slime of the bottom, but no algæ or conifera were met with (the water indeed was brackish, and had a temperature of + 24°; that at the bottom was not more brackish than that at the surface).—On the existence in Soudan of wild vines with herbaceous stem, vigorous roots, and eatable fruit, by M. Lécard.—On a thunderstorm observed at Laigle (Orne) on August 6, 1880, by M. Royer. During an hour and a half he counted 4,700 flashes, or about 53 a minute. Sometimes there were 100 a minute. The storm lasted two hours in all. The lightning struck twice, viz., a house and a poplar-tree.

LANDSLIPS

FEW disasters impress the mind so vividly with human helplessness as those that arise from disturbance of the solid ground beneath our feet. The most devastating hurricane can in some measure be foreseen and provided against. Skill and foresight continually do battle with the fury of the waves, and prove on the whole victorious. We are so familiar with the restlessness of air and ocean that the havoc wrought by these elemental powers does not carry with it the sense of aught unusual or against which we may not hope successfully to contend. But to find that the earth beneath us, to which we have, consciously or not, trusted as the only stable feature in our landscape, gives way in a moment of unsuspicious calm, that the everlasting hills are themselves perishable like everything else, that ruin and death may in an instant overwhelm alike scenes of sylvan quiet and of active human industry, brings to the mind that practically experiences the sensation a horror to which there is hardly any parallel in the long list of calamities that thin the ranks of mankind.

Terrestrial commotions of this nature are obviously divisible into two classes. There are first tremors, of which the far-reaching and destructive earthquake is the most signal example. Much has been said and written about the cause of earthquakes, but we are still far from a satisfactory solution of the problem. Probably more causes than one conspire at different times to produce the impulse which sets the earth-wave in motion. But whatever may be their nurture and origin, these operations belong to that large class in which the internal temperature of the planet, with the results of its reactions and its diminution is the chief factor. In the second place come the disturbances arising from the working of the different agents which are set in motion by the direct influence of the sun. Among these the operations of running water are by far the most important.

There can be no doubt that it is in this second class of phenomena that the melancholy catastrophe at Naini Tal must be placed. In various ways the action of running water disturbs the equilibrium of large masses of rock at the surface. The frequent undermining of its banks by a rivulet or river, with the consequent fall of slices of earth or rock into the stream, is a familiar illustration. The dislocation and dislodgment of portions of cliffs by the wedging influence of frozen water is another common example. But the most extensive changes of this kind arise from the influence of water underneath the surface, where the geological structure of the ground happens to be favourable. Trickling through the pores, joints, and fissures of rocks, rain or melted snow makes underground channels for itself. In the course of its progress it sometimes dissolves away large quantities of stone, or loosens and carries away in mechanical suspension the minuter particles of rocks. When this abstraction of materials takes place along a subterranean slope, the lower end of which comes out on the side or bottom of a valley, the effect is to enfeeble the support of the mass of rock resting upon the slope. Eventually this overlying mass may by gravitation break off from its floor and slide down into the valley below. Or should an open porous layer form the platform on which the side of the valley or cliff rests, copious rain may so saturate it as to loosen the cohesion of the superincumbent mass, which, when its weight overcomes that cohesion, is launched forward into the low ground below it. The saturated stratum may be compared to the grease put upon the beams on which a ship is launched from the building-yard. The moisture lubricates the bottom of the overlying rock and allows it to slide down. Such "landslips," as they are termed, are of common occurrence in countries with a copious rainfall, where the ground is uneven and rests on rocks containing easily permeable strata intercalated among others of a more impervious kind. The dislodged mass rushes down with irresistible impetus, breaking up into tumultuous piles of ruin, under which woods, meadows, gardens, fields, houses, and their inhabitants are almost instantly overwhelmed.

Every summer tourist whose wanderings have led him round the coasts of these islands is doubtless familiar with tracts of landslip, some comparatively recent, others so ancient as to go back far beyond the times of tradition or of local history. He will remember how in localities where the scenery would otherwise be of the tamest kind, the ground has been thrown into picturesque knolls and crags, with little glens and valleys winding through them, how the gathered drainage tumbles over miniature falls or collects into diminutive tarns which, in all save size, remind him of mountain lakes, and how over the whole scene the kindly hand of nature has spread her verdure, healing the scars of the original catastrophe by hanging festoons of ferns and mosses over the shattered rock, smoothing and carpeting with velvet turf the once naked floors of loose detritus, and scattering over dingle and den a pleasant shade of copsewood. The under cliffs of the Isle of Wight and other parts of the south coast, the clay cliffs of Sheppey and Yorkshire, the northern sea-front of the Antrim coast, the shores of Skye and adjacent islands of the Inner Hebrides furnish admirable illustrations of every stage in this history, from the raw wound of last year to the fairy-like scenery which conceals the landslips of remote centuries.

Fortunately in Britain we have no harrowing chronicle of human death connected with the story of our landslips. Yet these have not been without occasional loss of life, and sometimes considerable destruction of property. It has been estimated that the coast of Yorkshire between Spurn Point and Flamborough Head loses about 2¼ yards annually, slice after slice of the clay cliff slipping down to the beach, where it is readily attacked and removed by the waves. The clay cliffs of the Isle of Sheppey suffer similar rapid removal, while the chalk cliffs of the Isle of Thanet have had a yearly loss of three feet. From fields that were ploughed and sown with corn in spring segments slip down, so that in these detached portions the crop may be seen ripening half way down the cliff. In the well-known landslip of December, 1839, near Lyme Regis, a strip of chalk cliff three-quarters of a mile long, 240 feet broad, and from 100 to 150 feet high was undermined by the descent of continuous heavy rain and the saturation of a thick deposit of loose sand underneath. It consequently slid

bodily forward on the beach, breaking up into segments in its progress, and carrying fields, trees, and houses along with it. Unquestionably the most appalling disaster of the kind which has happened in recent times was the celebrated Fall of the Rossberg in 1806, a mountain lying behind the Rigi, and composed like it of sandstone and conglomerate. In this case also there had been much previous heavy rain, which, filtering along a porous sandy bed inclined at a steep angle towards the valley, undermined the support of the overlying thick sheet of massive conglomerate. The whole hill-side gave way and several villages and hamlets, with somewhere between 800 and 900 people, were buried under the ruins. To this day the scar on the slope of the mountain is unhealed, and the piles of huge angular blocks, even to the further side of the valley, remain as memorials of the homesteads and villagers that lie buried below.

The recent catastrophe at Naini Tal is another illustration of the same geological process. The locality is situated on the soft Tertiary deposits which flank the sub-metamorphic and more ancient crystalline rocks of the Himalaya range that towers behind. It possesses one of the few known sheets of water on the Himalayan slopes, nestling among irregularly shaped hills. There is every reason to believe that these hills have derived their present contour not only from extensive denudation by the heavy rainfall, but also from the operation of former landslips, and that the lake itself, to which the place has owed so much of its attractiveness, lies in a hollow formed by the same cause. It has been suggested that the late accident arose from the cutting of a roadway along the base of the hill. But this seems an altogether improbable and unnecessary supposition. The structure of the ground is itself sufficient to account for landslips, apart altogether from the mere superficial interference of any road-making. According to the telegraphic reports there had been a particularly heavy rain, no less than twenty-five inches having fallen in forty hours. The annual rainfall at Naini Tal is stated to be ninety inches, so that more than a quarter of the whole yearly rain fell in less than two days. But this year, at least, the rainfall must have been greater, for Mr. Commissioner Taylor, who was charged with the care of the roads in the district and met his death in the recent catastrophe, wrote on August 17 last that eighty inches of rain had fallen in the previous two months. By such a violent downpour the loose soil is swept off the surface, deep gashes are cut down the slopes, and every streamlet and river is converted into a torrent of liquid mud. But the furrowed soils and rocks likewise absorb much moisture. The water launched in such a deluge over the ground soaks at once into the more permeable gravelly layers and saturates them. When these are inclined towards lower ground and covered with heavy masses of earth or rock, the conditions for the production of landslips are supplied to the full. And such seems to have been the case in this melancholy Indian disaster.

The question arises, Can any steps be taken to guard against a repetition of the calamity? We may take it for granted that Naini Tal, in spite of its recent visitation, will continue to be a favourite resort from the arid plains below. The chance of an occasional destructive landslip will not deter men from coming year after year to gain renewed health and rest in the pure air of these uplands. It is obviously impossible to prevent landslips, except such minor falls as could not do any extensive damage. The only resource is to fix the sites of stations and houses on such spots as will either be free from risk of accident or on which the risk will be reduced to a minimum. This is mainly a geological question, but it is evidently one of the utmost social importance. Among the able staff of the Geological Survey of India there is no doubt an officer whose services could be made available to examine and report upon the structure of the ground at Naini Tal with special reference to this question. There ought to be first a careful inquiry into the details of the causes that led to the recent sad event, and with the experience thus gained a further inquiry into the safety of the other parts of the settlement and of other hill-stations similarly placed. Even in a district liable to destructive landslips sites for houses can probably be so chosen and defended as to be practically exempt from liability to such calamitous visitations as that which we now so heartily deplore. The prodigious amount of rain which in a few days or hours deluges the ground in these regions presents an engineering problem which demands actual Indian experience on the part of those who would successfully grapple with it. Neither geologists nor engineers accustomed only to the comparatively mild rain-storms of Europe can probably realise the magnitude of the difficulty which such disasters as that of Naini Tal presents for their consideration.

ARCTIC NEWS

THE past week has been an unusually interesting one so far as Arctic matters are concerned. First of all we have tidings of the return of the Franklin Search Expedition, sent out from the United States about two years ago, to follow up and unearth if possible some important relics of the Franklin expedition, said to exist among the Eskimo. It may be remembered that upwards of two years ago news reached this country that Mr. Barry, the mate of an American whaler, was told by some Nechelli Eskimo whom he met at Whale Point, Hudson's Bay, that some spoons with Franklin's crest upon them, possessed by the Eskimo, were received from a party of white men who passed a winter near their settlement, where they all died; and that these men left a number of books with writing in them, which were buried. The tale seemed very doubtful, and those best acquainted with the history of Franklin search expeditions considered that it was scarcely necessary to act on the gossip of the Eskimo. However, the people of the United States, who have all along manifested a generous enthusiasm in behalf of the Franklin expedition, thought otherwise, and by private enterprise an expedition was sent out in the summer of 1878, under Lieut. Schwatka, to follow up the traces indicated by the Eskimo. This expedition, after an absence of two years, has just returned, and although the success, so far as its immediate object is concerned, has not been great, it has evidently been able to make important additions to a knowledge of the condition of the inhospitable Arctic region traversed, a region rendered classical, if not sacred, by the early and terrible work of Franklin him-

self. The following telegram in the *New York Herald* of September 23, from New Bedford, Massachusetts, was the first announcement of the return of the expedition:—

"The Franklin Search Expedition, under the command of Lieut. Schwatka, have returned here. They have discovered and brought southward relics of the two British ships *Terror* and *Erebus*, which sailed from London, under Sir John Franklin, in May, 1845. The expedition successfully withstood the greatest amount of cold ever encountered by white men. During sixteen days of a sledge journey, extending over a period of eleven months, the average temperature was 100° below freezing point. In the summer and autumn of 1879 the expedition made a complete search of King William's Land and the adjoining mainland, travelling by the route pursued by the crews of the *Erebus* and *Terror* in retreating towards Back's River. They burnt [? buried] the bones of all remaining above ground, and erected monuments in memory of the dead. Their researches have established the fact that the records of the Franklin Expedition are beyond recovery. They have also learnt that one of Sir John Franklin's ships drifted down the Victoria Straits, and was unwittingly scuttled by the Eskimo, who found it off Grant Point in 1849. The expedition have brought away the remains of Irving, the third officer of the *Terror*. From each spot where graves were found a few tokens were selected which may serve to identify those who perished there. They also secured a board which may be of use in identifying the ship which completed the North-West Passage."

A few further details have appeared in the subsequent numbers of the *Herald*, but we must await the arrival of the paper and the publication of Lieut. Schwatka's narrative for full details. Particulars, we are told, are given of the sufferings and hardships endured by Lieut. Schwatka's party, who, however, succeeded in discovering relics of the expedition, and learnt from the natives details of the sufferings it underwent from cold and starvation. The natives related that they saw a small party of officers, believed to be the last survivors of the expedition, black about the mouths and with no flesh on their bones, dragging a boat across the ice. They then disappeared from view, and their skeletons were subsequently found under the boat and in a tent, a prey to wild beasts, and affording evidence that some of them had been eaten by their comrades. Lieut. Schwatka's own party, we are told, made a sledge journey of over 2,819 geographical miles, mostly across unexplored country, and this constitutes the longest sledge journey on record, both as to time and distance; the men it seems lived like the natives.

The sad story of the terrible suffering endured by 105 men who quitted the *Erebus* and *Terror* on April 22, 1848, ten months after the death of Franklin, is too well known from the narrative of the search party in the *Fox* under M'Clintock. Ample evidence was found scattered along the shores of King William's Land and Boothia, by which they endeavoured to reach the Fish River Settlements, of the fate of most of the party, many of whom, the Eskimo told M'Clintock, fell down as they walked, and had to remain unburied. Lieut. Schwatka's party have done what they could to show respect to what remains of the brave and unfortunate band. Unfortunately no written records of the expedition have been found; there was little room to expect that there would. As to the statement about the vessel which completed the North-West Passage, we suppose this must mean that one of the ships had drifted south-westwards so far as to meet with the furthest eastward point reached by Franklin in his earlier expeditions. The records of temperature will be eagerly looked for by meteorologists; the degree of cold seems to have far exceeded any Arctic temperature on record.

An unfortunate set-off to Lieut. Schwatka's successful return is the news that Capt. Howgate has been again compelled to put back in the *Gulnare* to St. John's, Newfoundland, the vessel being so unsuited for her work that the proposed expedition to Lady Franklin Bay has had to be abandoned for this year. Capt. Howgate is certainly very unfortunate in his Arctic scheme, though we trust he will not be daunted, but will next year be able to accomplish the foundation of his Polar colony.

Further sad news comes from San Francisco of the Gordon-Bennett expedition in the *Jeannette*, which set out full of hope not long ago. No tidings can be obtained by the whalers of the expedition, and the relief steamer *Corwin* had to return owing to the severity of the weather. There is however no more reason for giving up hope than there was in the case of the Payer-Weyprecht expedition, which disappeared suddenly off the Novaya Zemlya coast in 1872, and returned about two years later with the tidings of the discovery of a new Arctic land. This land, Franz Josef Land, a telegram from Hammerfest informs us, was visited in August by that most daring of yachtsmen, Mr. Leigh Smith. He explored to the west as far as 45° E. and 80° 20′ N., and sighted land from that point about forty miles north-west. No doubt Mr. Leigh Smith's experience this year and Capt. Markham's in the same direction last year, seem to point out that exploration northwards on the basis of Franz Josef Land is hopeful. So long as such exploration is carried on by private enterprise there can be no objection to it, but if Government has any funds to spare for Arctic work during the next few years, they would be expended to the best advantage in enabling this country to join the European and American concert for the establishment of Polar observing stations, from which England is conspicuously absent.

RODD'S BIRDS OF CORNWALL

The Birds of Cornwall and the Scilly Islands. By the late Edward Hearle Rodd. Edited, with an Introduction, Appendix, and brief Memoir of the Author, by James Edmund Harting. With Portrait and Map. (London: Trübner and Co., 1880.)

THE addition of another volume to the already long series of works upon the local avifaunas of Great Britain is not perhaps an event of any very great importance as regards ornithology in general. Yet the name of the late Mr. Edward Hearle Rodd of Penzance is so well known to British naturalists, and the county in which his observations were made is a land of such special interest, that there can be no doubt of the present volume being acceptable to a wide circle of readers.

At the time of his death it was generally understood that Mr. Rodd had in preparation a general work upon the birds of his native county. This work, however, as we are now informed by Mr. Harting, had only so far advanced as to "consist of a transcript of various notes on the ornithology of Cornwall, communicated by the author to the pages of the *Zoologist* arranged in chrono-

logical sequence." "It was obvious," Mr. Harting remarks, "that in order to render these notes of practical utility it was necessary to re-cast and re-write the whole." This has been ably executed by the editor, and we have now Mr. Rodd's interesting and original observations, which were continued over a period of nearly forty years, reduced into method and order. These observations, thus re-arranged, occupy the first portion of the present volume, and constitute the most important part of it. Appended to it are more or less contracted reprints of the "yearly reports" which Mr. Rodd was for many years accustomed to contribute to the *Journal* of the Royal Institution of Cornwall, containing an account of the principal ornithological rarities which had come under his notice in each year, and of the additions thus made to the list of the Cornish avifauna. The editor has also considerably increased the value of the volume, especially to Cornish naturalists, by his Introduction. In this is given an account of the previously existing literature on Cornish ornithology, beginning in 1478 with the *Itinerary* of William of Worcester and continued down to the present period, and constituting a most useful summary of information on the subject. Mr. Harting has likewise appended a list of Cornish and provincial names, which will further increase the interest of his work.

The extreme southern and western situation of Cornwall renders it one of the first resting-places in spring and one of the last in autumn of those birds which visit us during the summer migration, whilst several well-known Continental species, which are scarcely ever found in the more eastern parts of Great Britain, occur more or less regularly in this remote county. The black redstart, for example, so little known to the majority of English observers, except in its native haunts in Rhineland and Switzerland, is "not uncommon" in Cornwall in the winter months, though usually met with in immature dress. An adult male, however, in very beautiful plumage was captured in December, 1856, in the immediate neighbourhood of Penzance. Another much less-known European passerine bird, which has been met with in no other part of the United Kingdom, straggles occasionally into Cornwall—curiously enough, as it is essentially an eastern species, and might be rather expected to occur on the coasts of Norfolk and Suffolk. This is the little red-breasted flycatcher (*Muscicapa parva* of Bechstein), of which a single example in immature plumage was obtained near Falmouth in 1863. Two other specimens of the same species were subsequently captured in the Scilly Islands. Eastern Europe, as we have already observed, is the true home of this little bird, which will be well known to such of our readers as have visited Constantinople, where it is very common in autumn among the old walls and ruins.

Another very interesting visitant to the coasts of Devon and Cornwall is the Greater Shearwater (*Puffinus major* of Faber). This species is also well known on the Scilly Islands, where it goes by the singular name of "Hack-bolt." Its congener, the Manx Shearwater (*Puffinus anglorum*), is still more common on the Cornish coast, and breeds in some of the Scilly Islands. But for details on these and other peculiarly western birds we must refer our readers to Mr. Rodd's volume, which no student of the British Ornis should fail to add to his library.

DEEP-SEA SOUNDING AND DREDGING

United States Coast and Geodetic Survey, Carlile P. Patterson, Superintendent. A Description and Discussion of the Methods and Appliances used on Board the U.S. Coast and Geodetic Survey Steamer "Blake." By Charles D. Sigsbee, Lieut.-Commander, U.S.N. Pp. 192, xli. Plates. (Washington: Government Printing Office, 1880.)

THE publication of the "Depths of the Sea" and of the "Voyage of the *Challenger*" by Sir Wyville Thomson has made the public familiar with the work of the English in the exploration of the depths of the ocean. But little is known, even in America, of the important part which the United States Coast Survey has taken in the solution of the problems of the physical geography of the sea. The Coast Survey during the superintendence of Prof. Bache instituted a series of investigations on the physical problems of the deep sea, connected with the Gulf Stream, which have little by little been expanded by his successors, Prof. B. Peirce and the Hon. Carlile P. Patterson, into the most important hydrographic exploration yet undertaken by any government. With a wise liberality secondary hydrographic scientific problems, mainly of interest to the biologist and geologist, have been made a part of the work of the Coast Survey. Thus since 1866 the use of the dredge, the trawl, the tangles, and of all the apparatus necessary for a thorough exploration of the fauna of the depths of the sea has become as familiar to some of the navy officers attached to the Coast Survey as the use of the sextant or of the lead.

The Coast Survey steamers, *Bibb*, *Hassler*, and the *Blake*, have acquired a special reputation as deep-sea dredgers. The work of the *Bibb* and *Hassler* is known to naturalists mainly from the memoirs of Pourtales. Of the results of the *Blake* only a part has as yet been published under the direction of Mr. Alexander Agassiz.

Not only all naturalists but also hydrographers must be interested in the volume just published respecting the equipment of the *Blake*, a small steamer of only 350 tons burthen, which, under the skilful commands of Lieut.-Commander C. D. Sigsbee and Commander J. R. Bartlett, has not only done more rapid but also far more accurate work than has been accomplished with the old methods and appliances of the large men-of-war usually detailed for similar work by European governments.

Lieut.-Commander Sigsbee gives in this Report full descriptions of the thermometers, the water-cups, the salinometers, and of the methods of observing the currents in use on the *Blake*. The most important part of the Report is that devoted to deep-sea sounding. The sounding-machine, called a modification of Sir William Thomson's machine for sounding with wire, is known on the *Blake* as the "Sigsbee machine," and Sir William Thomson would find it difficult to recognise in the sounding machine of the *Blake* the apparatus he first suggested for sounding with piano wire. Throughout the Report the results of Lieut.-Commander Sigsbee's inventive genius are evident, from the water-cup to the shot detacher, the dredges, the trawls, the reels, the accumulator, there is nothing which he has not rendered more useful. His enthusiasm was shared by his officers, and their names

appear as his co-inventors on the Plates illustrating these different appliances.

The accuracy attained with Sigsbee's sounding-machine is very great, the probable error of sounding with piano wire at great depths not exceeding one quarter of one per cent. What the error may be if soundings taken by the old methods will only be known when all the former rope soundings have been repeated with wire soundings.

The last chapters are taken up with descriptions of the double trawls, the dredges, and other apparatus for collecting the animals found at great depths. An account is also given of making a haul at great depth and of the management of the steel wire rope, first introduced by Mr. Agassiz for deep-sea dredging on the *Blake*, and which has done so much to facilitate this class of work on vessels of the small tonnage of the *Blake*.

The Report is fully illustrated with heliotype plates as well as with tables showing the manner of recording the observations made.

It is pleasant to notice that the harmony between the civilians and the officers was not for an instant disturbed, during the three dredging cruises made by the *Blake*, extending from the Windward Isles to the Eastern extremity of George's Shoal.

The naturalists on board the *Blake* were indeed fortunate to have as their associates officers whose industry, energy, and interest in the work never flagged, and who have now attained a proficiency in deep-sea work hardly deemed possible three years ago.

OUR BOOK SHELF

i. *Elements of the Differential Calculus, with Examples and Applications: a Text-book.* By W. E. Byerly, Ph.D. (Boston: Ginn and Heath, 1879.)

ii. *An Elementary Treatise on the Differential Calculus, founded on the Method of Rates or Fluxions.* By John Minot Rice and W. Woolsey Johnson. Revised Edition. (New York: J. Wiley and Sons, 1879.)

NEARLY five years have passed since we noticed a small pamphlet by the authors of (ii.), together with treatises on the calculus of Messrs. Buckingham (Chicago) and Clark (Cincinnati), and we then remarked upon the growing interest taken in mathematics by American students. A further outcome of the same interest is the two works now before us. As it is not to be expected that such works will take the place in our colleges of the text-books already in use amongst English mathematicians, seeing that, like our own books, these are greatly indebted to the classic works by Duhanel and Bertrand, we shall not dwell at any length upon their merits or demerits. Each work under notice is well done to the extent to which it goes, and will furnish the young student with a good introduction to the admittedly difficult subject of which it treats.

(i.) takes as its foundation the "rigorous use of the doctrine of limits," introducing easy integration at a very early stage, and has frequent recourse to geometrical and mechanical illustration with a view to making the subject of interest.

(ii.) is the elaboration, in an excellent work, of the paper (subsequently a pamphlet) referred to above, which was introduced to the notice of English readers by a *résumé* of its contents in the *Messenger of Mathematics* (August, 1874) by Mr. Glaisher.

Both books are effectively got up, and (ii.) is exceedingly well printed.

Spirit-Gravities with Tables. By Thomas Stevenson, M.D., &c. (London: John Van Voorst, 1880.)

DR. STEVENSON has published a series of Tables in which the specific gravity of alcohol from 100 to 0·05 per cent. is given for each difference of 0·05 per cent. The percentages of alcohol by weight and volume, and of proof spirit are contained in the Tables. The specific gravities are given to four places of decimals. The Tables are founded on those of Gilpin and Drinkwater, and for spirits of less specific gravity than 0·8250—*i.e.* containing more than 89·05 per cent. by weight of alcohol—on that of Fownes.

In an introduction the various Tables hitherto in use are discussed; and various useful data are noted. The Tables are clearly printed, and will be of much service to those who are required to analyse alcoholic liquids.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Supposed New Island in the Azores

A REPORT was current in the English and American newspapers some weeks ago that a new island had made its appearance among the Azores, similar in character to that which came up near the extreme western end of St. Michael's in the early part of the century. As I had determined to spend my long vacation among these islands, I was curious to witness a phenomenon so interesting and so rare as the birth of a new volcanic island. I learn that the report has its foundation in the occurrence of a landslip on the north-east end of St. George. A large portion (about 82 alqueiros in extent) of the land at Lapa, near the village marked Topo on Vidal's Chart, launched itself bodily into the sea—that is, in an almost unbroken mass, to a distance of about 300 metres from the mainland. There were a number of cattle grazing on the land at the time; these apparently were so little affected by the occurrence that when found they were feeding unconcernedly on "the new island," as if it had been associated with their whole existence. A little survey of the spot has been made, and the Director of the Public Works at Vellas, the chief town of St. George, was kind enough to give me a map of this, the most recent addition to—or perhaps one ought to say subtraction from—the Azores.

T. E. THORPE

Parthenogenesis in the Coleoptera

IN the "concluding remarks" in his treatise on "Wahre Parthenogenesis" (1856), von Siebold says, "Es ist daher jetzt Aufgabe der Entomologen, nach weiteren Beispielen von Parthenogenesis in der Insektenwelt zu forschen"; and on the last page (237) of his "Beiträge zur Parthenogenesis," published fifteen years later, he expresses the conviction that many facts relating to this phenomenon are still to be discovered. The instances of *true* parthenogenesis discussed or referred to in these two works relate to insects of the orders Hymenoptera and Lepidoptera, and to some crustaceans. Including viviparous agamogenesis, however, as parthenogenetic, the orders Hemiptera and Diptera also furnish examples of this mode of reproduction; and for its occurrence in at least one genus of the Trichoptera I have the authority of Mr. R. McLachlan, F.R.S. The possibility of parthenogenetic reproduction in the Coleoptera rests only, so far as I am aware—see "Comparative Embryology," by F. M. Balfour, vol. i. p. 64—on the single instance communicated by me to this journal last year (Nature, vol. xx. p. 430), and this being so, it seemed desirable to make sure of this point by further research during the season now almost past. Accordingly I have this year kept a considerable number of females of *Gastrophysa raphani*, laying unimpregnated eggs, and with results which have not only confirmed the previous experience, but much extended it, as I am at present in possession of a living

beetle reared from a parthenogenetic ovum. With your permission I shall now endeavour as briefly as possible to give those circumstantial details without which a bald statement of results would not carry with it a rational conviction of the accuracy of my observations.

From beetles gathered in the beginning of last April I had a batch of eggs on the 7th, which hatched out on the 21st of the same month, and on May 13–15 yielded about thirty pupæ, which were immediately put into separate vessels. On the 20th–22nd appeared the imagines, of which ten subsequently turned out to be females, and were placed together in pots, but not before the greatly enlarged abdomen had given unmistakable evidence of their sex. The first eggs, three batches, were laid on June 2 (so completing the cycle, from egg to egg, in fifty-six days). On the 12th of the month I found in one of these batches, consisting of forty-two eggs, thirteen developed, of which two hatched out, the larvæ dying shortly afterwards. Others seemed to have partly hatched, but most eventually perished in the shell. At this time fertilised eggs were hatching in nine days. It appeared to me that several of the thirteen were imperfectly or monstrously developed; one, for example, having only one misshapen (?) mandible; another, excess in number and irregularity in grouping of the eye-spots; &c., &c. Again, on June 17 I found in a parcel of (twenty-five) eggs, laid June 6–7, six which had developed up to the hatching. In the usual course, at the time of hatching, the young larva comes out of the shell clear like barley-sugar, but blackens afterwards; in the case of these parthenogenetic larvæ which do not hatch out, this blackening takes place within the shell. In a third batch, of over twenty eggs, laid June 8, I found three eggs similarly developed. In the meantime, and afterwards, many dozen batches had been laid, in which, however, I did not detect any development.

A second experiment miscarried; but I was more successful with a third and fourth. From a batch of eggs laid June 5–6 I derived pupæ which on July 8 following I placed separately in pots, and obtained from them thirteen beetles, of which seven turned out to be females. About the same time I brought in from the fields some well-grown larvæ, the beetles from which were isolated immediately after their exclusion, and subsequently yielded eight females. These (seven and eight) were all kept in separate pots during the course of the experiment. Of the seven no less than five laid eggs which afterwards developed parthenogenetically. They laid as many as ten parthenogenetic batches among them, but while some of them laid three such batches, others laid only one. These were invariably the first batches laid, and none of the batches laid subsequently contained any viable eggs while the experiment lasted, which was in some cases up to the tenth batch. Of the eight beetles of the fourth group, only one laid one parthenogenetic egg in its first batch. The number of parthenogenetic eggs in a batch varied from one to seven. In four batches there was only one such egg; in three batches five, and in the other four batches two, three, six, and seven respectively. The total eggs in a batch averaged 41·7, and as there were thirty-six parthenogenetic, the proportion over all was 1 in 12½. However, as may be supposed, the proportion in the individual batches varied very much, one small parcel of only eleven eggs having as many as five developed.

In most of these cases also the larvæ perished in the shell. A few hatched out more or less completely, and died. Two, however (of the seven in one batch), were more fortunate. These came out on July 29, and for some hours seemed very feeble and barely alive. Next morning I found that one, which subsequently took the lead of its fellow in all respects, had crawled away under cover, and the other was soon able to follow its example. I could not find that they had eaten anything till the evening of the 31st. After that, however, they throve apace. The larger one passed its first and second moults on the 3rd and 7th of August, the smaller following it on the 4th and 8th. The former pupated on the 14th, and the imago was excluded on the 19th. The latter, having pupated, August 15–16, appeared to go on well till the time for the exclusion of the beetle, when its further development became arrested, and it died. The survivor was weakly at first, and rather imperfect always as regards the elytra, which are somewhat small, and do not close in the middle line. It has, however, thriven well, and developed that enlargement of the abdomen peculiar to the female. But up to the present (September 22) it has laid no eggs, nor shown any inclination towards males placed in the pot with it.

When it became obvious that no more parthenogenetic eggs were to be obtained from these beetles, I placed the survivors of them in succession in a pot with a (the same) male beetle, with the result that most afterwards laid fruitful eggs in the ordinary way. I mention this because it seems to be in contradiction, as far as these insects are concerned, with the statement of von Siebold ("Beiträge," p. 89): "Es ist nun eine bekannte Sache, dass, wenn Insecten-Weibchen vor der Begattung erst einmal Eier zu legen angefangen haben, ihre Männchen alsdann mit ihren verspäteten Liebesbezeigungen bei ihnen nichts mehr auszurichten im Stande sind."

If now I may be permitted to make a few general observations on some of the points indicated for further inquiry, rather than established, by the foregoing experiments, I would say: (1) that parthenogenesis seems to occur chiefly in the first-laid batches; (2) that it is peculiar to some females, while others appear to be exempt from it; (3) that confinement and domestication, as it were, acting hereditarily, which we already know so profoundly to affect the generative system in the higher animals, appear to favour this mode of reproduction in *Gastrophysa raphani*; (4) that there are degrees of viability in parthenogenetic embryos, so that the development seems to be arrested chiefly at certain points, as at the hatching of the egg and the exclusion of the imago. In this respect the Gastrophysa egg behaves very much as the ovum of *Bombyx mori* is reported to do (*v.* "Beiträge," pp. 230–232). (5) Another point in which *G. raphani* agrees with other parthenogetically reproductive arthropods is its many-broodedness in a season. There may be three or four generations in direct succession in the year, and there is a constant succession of eggs all the time. In this it appears to differ from any of its allies with which I am acquainted. (6) Finally, the case of *G. raphani* would seem to be one of true parthenogenesis in its most restricted sense—the same beetle which in the unimpregnated state lays sterile eggs, with here and there one capable of development, after receiving the male element, laying eggs which are fertile and develop in the ordinary way. That is to say, the ova are true ova, and not pseud-ova or buds, the parent a perfect female and not an "Amme" like the summer Aphis. J. A. OSBORNE

Milford, Letterkenny, Ireland, September 22

Observations of Auroræ on August 12 and 13

THE finest display was between 10 and 11 o'clock on the evening of the 12th, when a magnificent corona was formed almost exactly on γ Cygni. At this time the bases of the columns on the eastern horizon were distinctly red. Unfortunately the spectroscope could not be brought to bear until the aurora had faded to a small fraction of its greatest brightness. With a very small dispersion (Vogel spectroscope) the spectrum was continuous from W.L. 557 mm. to W.L. 473, with strong traces of a finely banded spectrum, terminating abruptly at the great line 557. Towards the violet an isolated line was seen and measured.

On the 13th the great line was seen and also traces of the others. The measures may be summarised as follows:—

Wave-length.	Spectroscope.	No. of measures.
557·16 ± 0·20	Grubb	8
527·5	,,	1
{ 469·6	,,	1
{ 473·2	Vogel	1
{ 430	Grubb	In middle of field
{ 434	Vogel	1

The Grubb spectroscope has a dispersion of 5° 40′ from C to *h*. The first line was measured with an illuminated micrometer wire, the others with the edge of an opaque screen. The Vogel spectroscope has a scale of bright lines with sixty divisions to the whole visible spectrum. RALPH COPELAND

Ice at High Temperatures

FROM Mr. Hannay's letter (NATURE, vol. xxii. p. 483) and from private communications I have received it appears there has been a little misconception as to the manner in which I judged of the temperature of the ice in the experiment referred to in NATURE, *ibid.*, 435. Mr. Hannay's theory, that the ice was protected from the hot glass by an intervening layer of vapour, at first occurred to myself and to others as the true explanation of the phenomenon, but that this explanation will not serve in the present case is, I think, proved by the fact that a thermometer *was* imbedded in the ice and rose to temperatures varying in different experiments between 120° and 180° C., at

which points the ice had either all volatilised or had become detached from the bulb. This appears improbable from our present ideas concerning latent heat, but it is nevertheless a fact. If I can make the necessary arrangements it is my intention to show the experiment at an early meeting of the Chemical Society, when it will be open to criticism.

In regard to the remarks contained in the former part of Mr. Hannay's letter, I of course did not bring forward the *first* proposition in my letter as anything new, but merely to show that my experiments confirmed the previous conclusions of others on the critical temperature. THOS. CARNELLEY

Firth College, Sheffield, September 27

A Peat Bed in the Drift of Oldham

IN NATURE, vol. xxii. p. 460, there is a description of a bed, or rather beds, of peat in the drift at Oldham. A few days ago I had an opportunity of examining the section described by Mr. Jas. Nield, and under his guidance, but I differ from him in opinion as to the age of the peat. The section occurs on the steep sloping side of a valley, and just above it there is an exposure of sand covered by boulder clay. In my opinion some of the latter has simply slipped down, off the sand, on to the surface of the peat at a lower level; or it may have been excavated and thrown down for the purpose of obtaining the underlying sand. Besides, the principal bed of peat rests on blue silt, which again rests on boulder clay. The upper bed of peat occurs at one end of the section, and both ends present the appearance of a talus of *débris* from a higher level. Still the section is somewhat obscure, though a few hours' digging at a right-angle to its present exposure would probably prove the blue silt and peat to be more recent than the boulder clay, although the latter is certainly the highest bed in the section as at present exposed. However, geologists are indebted to Mr. Nield for calling attention to the section, and no doubt he and others will take means to prove the true position of the peat, which is sure to attract considerable attention.

122, London Road, Liverpool, September 18

Hardening of Steel

I SHOULD have, had circumstances permitted, thanked Mr. Walter R. Brown for his kind response to my letter, "Iron and Hydrogen" (NATURE, vol. xxii. p. 220), and for the reference to Mr. Anderson's report, with which I was unacquainted.

The points mentioned by Mr. T. W. Giltay certainly seem somewhat to controvert the theory of alloyed hydrogen; but thinking over the facts some time ago it struck me that the aqueous vapour in the air would be a source for the gas as in chilling beneath water. It would be interesting to know whether mercury, as commonly used, is not also faintly alloyed with hydrogen.

For my own part, I am inclined to the carbon theory, but the facts were brought forward with the idea of seeing them discussed, and a somewhat obscure but important subject brought to light. H. J. JOHNSTON-LAVIS

Mosquitos

SEEING in NATURE, vol. xxii. p. 11, the use of infusion of quassia recommended, and being a great martyr to mosquitos, I immediately set to work to brew two or three gallons with all the energy with which I had already tried many remedies and nostrums.

The basements of nearly all the good houses here in Naples are used as stables, and consequently form a great attraction for these insect pests.

This large quantity of very concentrated infusion was disposed of as follows:—The whole of the bed-room walls, ceiling, carpet, and furniture were gone over with a Lister's vapour carboliser containing the solution; sheets and night-dresses wrung out and dried before use, body sponged all over, and bed clothes re-sprayed with the solution each night.

This certainly was a fair trial, but the results after all this expense, trouble, bitter lips and mouth was a complete failure.

It really seems that the only true protection against mosquitos is the curtain with all its inconveniences.

September 21 H. J. JOHNSTON-LAVIS

GENERAL PITT RIVERS' (LANE FOX) ANTHROPOLOGICAL COLLECTION[1]

II.

OUTRIGGERS are very varied in their structure. In some canoes there are two opposite one another, one of which does not touch the water; it is merely a balance platform; in some both outriggers only occasionally touch the water. It is not improbable that the side-galleries of some junks are developed out of balance platforms, and that the ledges known as the "chains" of modern European vessels are of similar origin. The rudder is merely a development of the steering paddle. It is still merely a fixed paddle, being worked by an operator with his face in the direction in which the boat is moving, whilst oars have taken the place of all the other paddles of the boat.

Another series illustrates the origin of clothing. Clothing was derived, no doubt, partly from the development of ornaments, being originally entirely ornamental, as a large proportion of it still is, even amongst ourselves, and partly from gradual modifications of belts and such accoutrements, which served a useful purpose when put round the body as convenient appliances for hanging things to for carriage. A pocket is a luxury which a savage does not possess. He has to sling his little necessaries to his belt, or secure them in the lobe of his ear, or carry them, to his embarrassment, in his hand. Even in Japan the men are obliged to sling their tobacco-pouches and pipes from their belts by means of silken cords and the beautifully-carved ivory buttons or netsukes so well known in European collections. They have pockets only in their sleeves, and these are insufficient. The simple cincture is the sole clothing of the Andaman Islander. A bunch of pandanus slips is added in front in a further stage, and eventually a complete encircling fringe is reached. When paper cloth (tappa) has been invented, or woven material, this is substituted for the fringe, and a kilt is the result. In some parts of Great Britain dress has not advanced beyond this stage, or rather the primitive form of dress has been adopted as a curiosity. The sporran probably represents the original dress, the bunch of grass of the Andaman Islander, now worn over the kilt instead of as originally next the skin. At a further stage, the kilt being found uncomfortable, it was fastened together at one spot between the legs, and hence arose the idea of trousers, which, through the baggy Turkish inexpressibles, gradually developed into their present form.

The simple cloak of skin or tappa developed gradually into coats and various more convenient tight-fitting garments, but in all robes of ceremony the savage cloak form is still retained by the most highly civilised races. One of the latest additions made to his collection by General Pitt Rivers is a series of Britanny caps, showing the gradual development of all the strange forms in vogue in different districts, by means of the abnormal growth of the strings, crown, or front, of one simple type.

Another series shows the development of drinking-vessels of all kinds, starting from the natural vessels found ready to hand, such as human skulls, cocoanut-shells, gourds, and horns. From the cocoanut with a handle comes the ladle, and hence the spoon, and so on.

Another series is devoted to the development of musical instruments. Wind instruments are modifications derived from the horns of animals, spiral shells, reeds, bamboos, and bones. From these by gradual steps are attained the trumpet and spiral brass instruments, the curl of which probably came from the spiral shell; also pan-pipes, and hence organs, and flutes. As bearing on the origin of the bagpipes is exhibited a bag and whistle carried by Indians of the north-west coast of America to imitate the call of ducks and decoy them.

[1] Continued from p. 493.

Drums were derived from bamboos, being at first simple pieces of bamboo open at both ends and beat on the ground as now at Fiji. Wooden logs are then hollowed out to imitate them, and hence the large erect wooden drums of New Guinea and Melanesia generally, and the horizontal canoe-like drums, "lali," of Fiji. But these hollow wooden drums without a tense membrane are more justly classed with bells, and metal

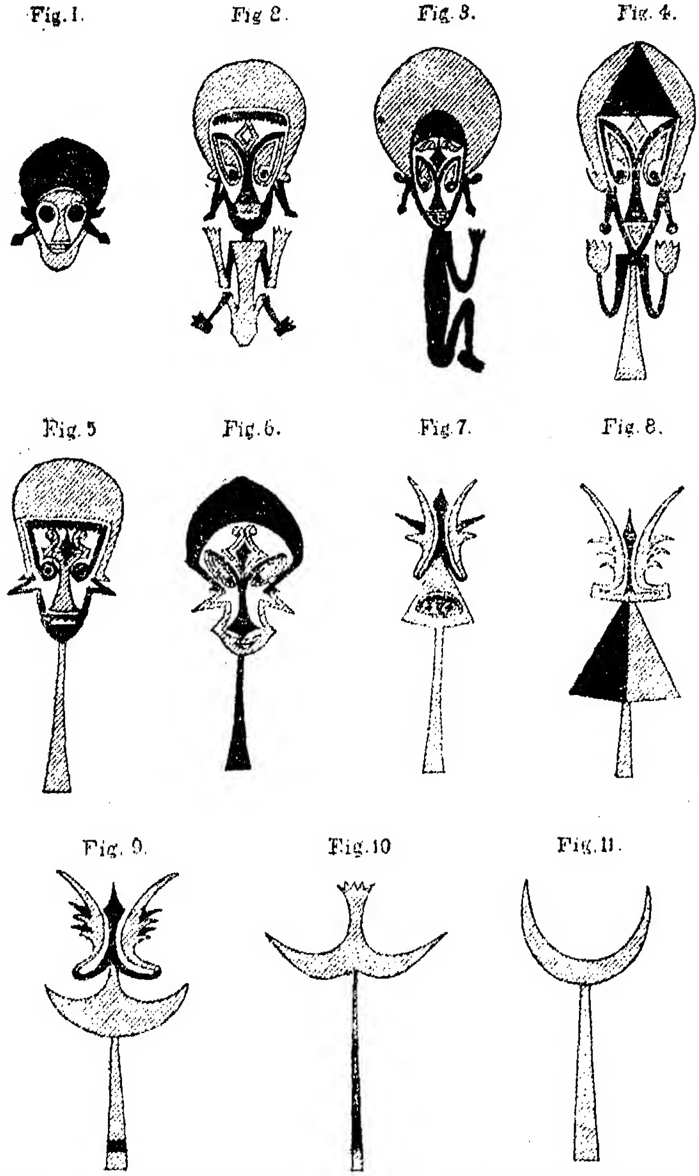

PLATE 3.—Ornamentations copied from a series of canoe paddles from New Ireland, showing the gradual degeneration of the representation of the human form into a crescent-shaped ornament.

bells were probably derived from them through the wooden bells such as those used in Japan. The clapper is a late addition to the bell, which does not exist in Japan or China. It is worthy of note that the large wooden drums of Fiji and Papua are used for the same purpose as bells, to summon large meetings and communicate general warnings or similar intelligence. Dr. Michlucho Maclay has given a full account of their use in New Guinea.

A tense membrane having been added to one end of a bamboo, the real drum was reached, and from this is derived the Papuan drum, which is long and pipe-like in form, and has a membrane of lizard skin (Hydrosaurus) at one end. It is often shaped like a crocodile's head at the open end, is somewhat dice-box-shaped, and is used in dancing.

Another series is devoted to the growth of the art of pottery. Amongst savages the Fijians are pre-eminent for the excellence of their pottery and for the variety and grace of the forms of the vessels which they manufacture. The common simpler flask-shaped form made by them is said to have been suggested by that of the nest of a wasp (*Polistes*, sp.) common in the islands. They glaze their pottery, and make vessels in the shapes of animals such as turtles, in all kinds of forms, even in double and triple clusters, recalling to mind the pottery of ancient Peru.

Yet another series exhibits the extent to which various races of mankind have succeeded in representing the human figure in wood, stone, or ivory carving, or models, or in pottery. It is interesting to trace here the steps by which the art of sculpture has grown. Sculpture grew by the most gradual steps to its civilised excellence. When savages produce the excessively rude representations of men which commonly do duty as gods, the faults in the work are not due to an absence of power to execute better carvings, but simply to an absence of accumulated experience as to how the human figure should be represented. It is remarkable how extremely well some savages copy European carvings when once they get the chance of a little teaching. As an example of this sort of work General Pitt Rivers displays a carving of the Virgin and Child executed by the Qua Qua Indians of the North-west American coast. The piece might pass muster as an example of modern Swiss work. Besides this specimen are three sitting figures in the old unassisted native style, carved by the Vancouver Islanders. They are very different indeed in execution, and rude, but they still show a certain amount of artistic feeling. Indeed, the whole of the Indians of the Upper North-West Pacific coast, and especially the Haidahs, are conspicuous for very advanced artistic powers as savages. Savages vary immensely in their artistic development. Many, such as the Hottentots and South African races generally, appear never to have made any representations of the human figure. Those who do make such figures always adopt a conventional form for them, which is so well marked that an experienced eye can detect at once by what race any particular figure has been made. Perhaps the most curious figures are those of Easter Island, with shrunken abdomens and prominent ribs. The figures seem copied from half dried-up corpses, and were perhaps copied from the dead originally. Some Peruvian human faces are extremely good; but the Japanese and Chinese seem never to have idealised the human countenance, except perhaps in their representations of Buddhist gods, the faces of which are however more or less Indian in type, so that the idea was probably derived, with the religion, from extraneous sources.

A considerable series is devoted to the development of religious properties of various kinds from different parts of

the world. Side by side are placed the coarse wax models of breasts, hands, feet, eyes, and other parts of the human body offered up at the present time in Roman Catholic shrines in France and elsewhere by persons who have been cured of diseases in those parts, and the exactly similar earthenware models of the same parts which were used for the same purpose in ancient Cyprus, and have been found there in excavations. It is most curious how exactly the two series correspond. A small collection comprehends the representations of the Mother and Child of various races. Side by side may be seen and compared the Peruvian, Cyprian, Egyptian, Indian, Chinese, and Christian embodiments of this idea.

Several series are devoted to the curious question of the development of pattern ornament. The development of patterns appears to have arisen in two ways: either drawings of various natural objects have been made upon weapons, implements, and utensils, and these drawings, having become more and more conventionalised by successive copyings, have degenerated into patterns which have in many instances been subsequently elaborated as such; or various patterns have been from the first suggested by various articles often used in connection with the objects ornamented, by coils of string, or by wire, or by nets, or accidental markings on the objects themselves. Patterns thus once commenced have been gradually modified, and have run through a series of changes which can be traced step by step. A particular elaborate pattern is a thing which has probably arisen only once in the progress of evolution, and in tracing its history we trace at the same time the history of the race which makes use of it. It may yield as important evidence as even language itself.

The earliest known ornamentations are those of primitive man found in the caves of Europe. They are all representations of animals, figures of the mammoth, cave-bear, or reindeer scratched on ivory or bone. Some of the most interesting of General Pitt Rivers' series are those which show how such rude figures gradually de-

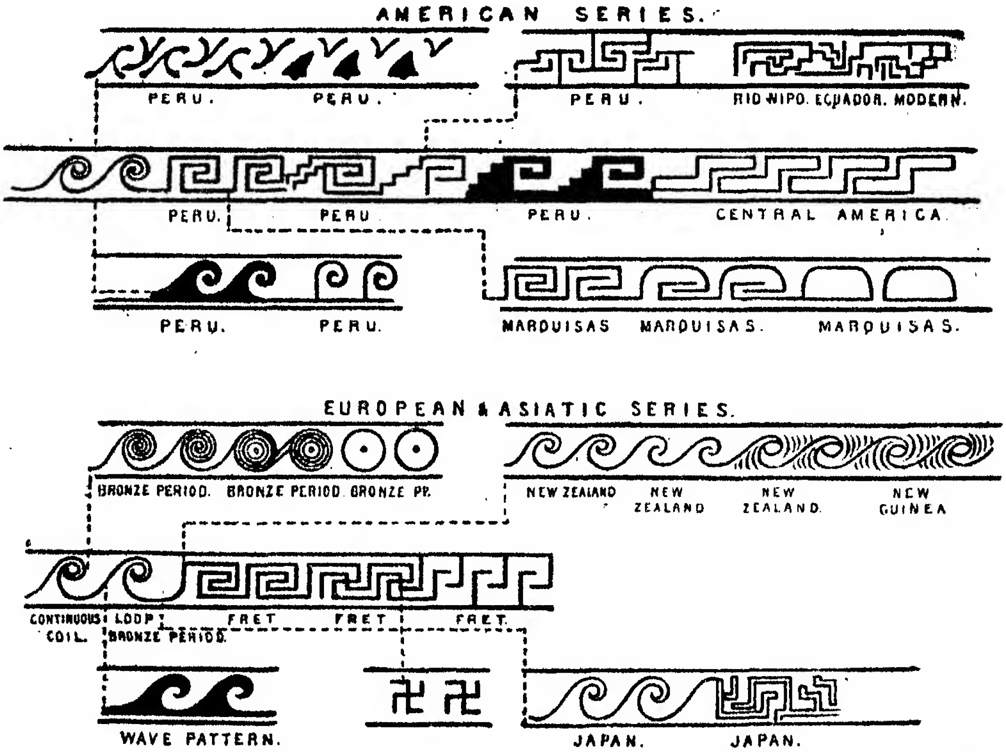

PLATE 4.—Series of diagrams to illustrate the various modifications of the double loop coil ornament in the Old and New Worlds.

generate into mere conventional pattern ornaments. One of the most striking examples is one described by him in his address to the Department of Anthropology at the meeting of the British Association at Brighton in 1872. It is the series of transformations which are undergone by a figure of a human head represented on their paddles by the natives of New Ireland. The series is shown in the annexed woodcut (Plate 3), taken from the specimens exhibited in the collection. The human figure gradually loses its limbs and body, then the sides of the face, leaving only the nose and ears, and ultimately the nose only, which finally expands at the base, and is converted into the representation of a half moon. In this sequence we have an exact parallel to the transformations observed upon ancient British coins by Mr. John Evans, by which the representation of the chariot and horses of Victory on a coin of Philip of Macedon becomes converted into a single horse, and ultimately into fragments of a horse.

Amongst the natives of the North-West coast of America a curious intricate conventional ornament represented on all their paddles and many other objects, is derived from an albatross head, as shown in a series in the collection. A series of curved wooden sharp-edged clubs or glaives show how the form of a fish, to represent which the curved head of the club is carved, degenerates into a single W ornament, the remains of the fish's mouth. Mr. Brooke Low has in his Bornean collection already referred to a series of native fabrics ornamented with elaborate patterns, each of which pattern has a name, usually the name of an animal. One pattern is evidently a representation of a crocodile, it is so named, and others are derived from it. He finds it impossible to determine in many instances by examination from what form the other patterns have been derived, but believes that the history of their origin survives in their names. One name given to them was, for example, "cat," referring to the animal, from a drawing of which the pattern was originally developed. No doubt all the curious patterns in vogue

in Polynesia, New Guinea, and elsewhere, have a definite history and meaning yet to be traced. Modern European patterns have also interesting histories to disclose. One of the series in the collection explains the origin of the lozenge- and leaf-pattern common on oak carvings from the intersections of the Gothic arch and ogee arch.

Of the development of ornament from chance marks upon objects, the most interesting example exhibited is probably an Australian boomerang, which happens to have three small round black knots on one side of it placed at equal intervals. The savage owner, struck by the appearance of the knots, burnt a series of similar black marks at equal distances all along the one face of the boomerang, to complete the natural pattern, and then, pleased with his work, put a series of lozenge-shaped marks to correspond on the other side of the weapon. At the Sandwich Islands a most beautiful ornament of the gourds used for water is derived from the net-bag in which the gourds were slung. No doubt the pattern at first became accidentally printed on the gourds, and were afterwards elaborated.

The last series to which we shall draw attention relates to the transformations of the curious ornament which General Pitt Rivers calls the double-loop coil, and which is characteristic of all New Zealand weapons and implements, canoes and houses. The ornament was probably originally copied from coils of string or wire. The distribution of the ornament is very interesting. It is found abundantly in New Guinea, so exactly corresponding to the New Zealand form that it seems certainly to point to some connection between the islanders or partial migration from New Guinea to New Zealand at some time or other, unless some floating object may have conveyed the pattern. A similar ornament occurs in the far-off Marquesas Islands, the natives of which in several other matters of culture show affinity with the Melanesians. It is also very common on Mexican and Peruvian works of art, and especially on gold figures, where it is represented in its former live form by spiral coils of fine wire. From the double-loop coil, as General Pitt Rivers has shown, many other patterns are derived. The fret or key pattern is merely a continuous loop-coil squared. Other patterns, such as the wave pattern, are derived from the coil by slight degeneration. Some of the most marked patterns derived from it are shown in the accompanying figure (Plate 4), which explains itself. It is most curious how nearly parallel the series of modifications attained in the Old and the New World run to one another.

In conclusion we can only express a hope that the Pitt Rivers collection will be accepted by the nation on its generous donor's conditions, and we strongly recommend any of our readers who have not studied it to pay it a long visit at once, and profit by the varied fund of instruction and entertainment which it cannot fail to impart.

THE MASON COLLEGE, BIRMINGHAM

THE Josiah Mason Science College, which is to be opened by an interesting address from Prof. Huxley to-morrow, was begun about five years ago by the venerable and generous donor, Sir Josiah Mason. It is intended to cover ground not occupied by any other of the numerous educational institutions of Birmingham, to which it promises to be an addition of the highest value. The building itself is described as a lofty and spacious Gothic pile, covering about an acre in extent in the very heart of Birmingham.

By its foundation deed the College is established to provide instruction, as far as possible, in mathematics, abstract and applied; physics, both mathematical and experimental; chemistry, theoretical, practical, and applied; the natural sciences, especially geology and mineralogy, with their application to mines and metallurgy; botany and zoology, with special application to manufactures; physiology, with special reference to the laws of health; the English, French, and German languages; and the scheme may, in the discretion of the trustees, include all such other branches of instruction as will conduce to a sound practical knowledge of scientific subjects, excluding mere literary education. The trustees have also power to make provision for instruction in art as well as in science; and, by a supplemental deed, they are authorised to include in the course of study certain subjects requisite for the training of medical students. There is no restriction of the advantages of the college as to sex, creed, or birthplace; but, other things being equal, preference is to be given to candidates who have been educated in Sir Josiah Mason's Orphanage at Erdington, and after these to persons born in Birmingham or Kidderminster, the latter being the founder's birthplace. One wise provision of the deed empowers the trustees, with certain reservations, to alter the course of teaching and the arrangements of the instruction when a change is considered desirable, and at stated intervals the trustees are required to take the arrangements into consideration with a view to revision. At present the branches for which provision is made are confined to mathematics, physics, chemistry, and biology. The mathematical professor is Mr. J. M. Hill, M.A., London, B.A., Cantab, Fellow of University College, London. Physics are taught by Prof. J. H. Poynting, M.A., B.Sc., London, Fellow of Trinity College, Cambridge. The chemistry professor is Mr. W. A. Tilden, D.Sc., London, F.R.S.; and biology is represented by Prof. T. W. Bridge, M.A., F.Z.S. According to present arrangements instruction is provided in the elementary as well as the higher branches of the sciences taught, with a special view to their application to the industries of the Midland district. The course is also designed to prepare students for the degrees of B.Sc. and D.Sc. in the University of London.

The internal arrangements seem to be altogether admirable. The main corridor abuts on two noble apartments, each 48 feet by 30 feet—one intended for the library and reading-room, the other for the physical laboratory—both rooms being provided with ante-rooms. On the first floor, the chief and central room, situated in the front of the building, is the chemical lecture theatre, 50 feet by 33 feet, fitted with seats, tier above tier, for the accommodation of 155 students. The male students will occupy the lower half and the female students the seats above and behind them, a separate entrance being provided for each sex. The mechanical arrangements and apparatus for the use of the lecturer and the carrying away of noxious fumes are of the most complete and ingenious character, and the assistants' ante-room, for the preparation of chemical experiments, is on an equally satisfactory scale. Class-rooms for electricity, magnetism, biology, physics, and models, and a couple of spacious lecture theatres, each 47 feet by 30 feet, one for biology and mathematics, the other for physics, occupy the remaining space on the first floor. The second floor is devoted principally to the chemical departments, for which the arrangements are of the most complete and elaborate character. A large room, 52 feet by 33 feet, in the front of the building, over the chemical lecture theatre, will be used as a general assembly or examination room, and will be available for the meetings of scientific societies. The two laboratories situated at the back of the building, and lit both by windows and skylights, measure together about 104 feet long by 32 feet wide. In the larger laboratory, intended for qualitative analysis, there are four double operating-tables fitted with sinks, gas and water for forty students, in addition to a large unencumbered table in the middle of the apartment for long trains of chemical apparatus. The laboratory for quantitative analysis contains similar fittings and appliances

for thirty-two students. On the third floor a large and lofty central room, with open limber roof, partially lit from the roof, is intended for a museum. The basement story, extending under the whole of the ground floor, is lofty and well lighted, and contains store-rooms, rooms for special operations in physics and chemistry, a large room for mineralogy, rooms for living animals, boilers, &c. Altogether the building contains at present about 100 rooms. The heating and ventilating arrangements are upon a somewhat novel plan. Near the centre of the area rises a huge chimney-stack to the height of 160 feet, containing three flues divided by thin partitions. The smoke from the boiler passes off by the central flue and heats the air in the adjoining flues, which are used for ventilating the lecture theatres. The warming is effected by a coil of pipes containing 4,475 superficial feet, and fed with water from the large boiler in a vault in the sub-basement. The arrangements in fact are throughout of the most modern and approved types, having been adopted by the architect after mature consideration of all the best features of the principal scientific colleges in this country and on the Continent, which he visited at the request of the trustees.

The generous founder, who has taken a most active interest in the progress of the work, has built the college and furnished its various departments entirely at his own cost, so that the large endowments previously conveyed to the trustees remain untouched. Sir Josiah Mason has stated that his ambition was to afford all classes in the Midland district, where he had been born and bred, the means of carrying on those scientific studies of which he had felt the want as completely and thoroughly as they can be prosecuted in any of the great science schools of Europe.

We earnestly trust that the noble and benevolent intention of the founder will continue to be carried out, and that in time the institution will become as important and comprehensive a centre of higher education as Owens College is now.

THE PROPOSED LICK OBSERVATORY

Mr. S. W. BURNHAM has printed his Report to the Trustees of the "James Lick Trust" of observations made on Mount Hamilton, California, with reference to the location of the observatory, for the erection and endowment of which funds are thereby provided. His object being to test the adaptation of the site for astronomical purposes by observations of double-stars mainly, Mr. Burnham took with him his 6-inch refractor, by Alvan Clark and Sons, which he has used in nearly all his astronomical work, and the excellence of which has been sufficiently proved by the number of difficult double-stars discovered with it during the last six or eight years. He remained on Mount Hamilton from August 17 to October 16, and in this interval was in the observatory on every clear night, with three exceptions. During the first thirty-seven nights he states vision was first-class on all occasions with these exceptions; on two nights the ocean fogs from the valley below reached the summit of the mountain and remained all night, and on two other nights there was only medium steadiness. The kind of weather for astronomical observations during the whole period of sixty days that Mr. Burnham remained at the summit, was forty-two first-class nights, seven medium nights, and eleven cloudy and foggy ones. In the whole interval there was not a single poor night when it was clear. By first-class seeing Mr. Burnham explains that he means "such a night as will allow of the use of the highest powers to advantage, giving sharp, well-defined images, and where the closest and most difficult double-stars within the grasp of the instrument can be satisfactorily measured." The conditions were generally very permanent for the whole night, which is not often the case in ordinary localities. On many nights Mr. Burnham remained at the telescope until daylight, and so had abundant opportunities of noting this important fact.

Having provided himself with a series of cardboard disks, with apertures increasing from one inch up to the full aperture of the object-glass, Mr. Burnham observed a large number of familiar objects, contracting the light until the smaller star was just distinctly visible; many of these objects had been used elsewhere for a similar purpose. He considers some of the observations are remarkable, allowing for the difficulty of the objects with much larger apertures in other localities: μ^2 Herculis (the close pair) was very fairly seen with the full aperture, and the companion of α^2 Capricorni was plain with the aperture contracted to 4 inches, and was seen double with the whole six; these objects Mr. Burnham says he is confident have "never been seen before with so small an object-glass." The fifth and sixth stars of θ^1 Orionis were very plain at an hour-angle of $4\frac{1}{2}$ hours; ζ Herculis was well seen with $3\frac{1}{2}$ in.; and η Cassiopeæ was easy when the aperture was reduced to $1\frac{1}{2}$ inch. Forty-two new double stars were detected, and micrometrical measures of ninety of these objects previously named were put upon record. A great many were examined by daylight, but the air, during the greater part of the day at least, was not found to be steadier than is ordinarily the case elsewhere. It is mentioned, however, that the fifth and sixth stars of the trapezium of Orion were beautifully seen in broad daylight just before sunrise. At the epoch 1879·684 the first measure was made fifteen minutes before sunrise, and "both stars were readily seen for some time after this." Venus was very readily seen with the naked eye at any hour of the day, and easily found without any instrumental indication of its place. Mr. Burnham urges that the new double stars brought to light evidence better than anything else can, what may be done at Mount Hamilton, and remarking that these discoveries were effected with an instrument which in these days of great refractors would be regarded as a comparatively inferior telescope, he considers that it is impossible to overestimate the great discoveries which might be made at this station with a first-class object-glass, such for instance as the Naval Observatory, Washington, already possesses, or the proposed Pulkowa glass of twenty-five times the light-power of the one employed; and according to the terms of the Trust the telescope for Mount Hamilton is required to be "superior to and more powerful than any telescope ever yet made;" a condition, however, which perhaps may not be so easily fulfilled as laid down. Mr. Burnham concludes from his experiences on Mount Hamilton that it "offers advantages superior to those found at any point where a permanent observatory has been established." The station is about fifty miles south of San Francisco and twenty-six miles nearly east of San José, the nearest point of railway connection. The ocean fogs, which might have been feared, were not found to reach the elevation, except rarely. Nearly every night this fog, commencing soon after sunset, comes in from the Pacific between the Golden Gate on the north and the Bay of Monterey on the south, and covers the whole valley, but is ordinarily perhaps 2,000 feet below the summit of the mountain, which has an elevation of 4,250 feet above the level of the sea, and has no sensible effect at such altitude.

It will be seen that Mr. Burnham's knowledge of the locality is confined to the space of two months, but a letter from Prof. Davidson of the U.S. Coast Survey, who has had long experience at other seasons, is appended to the report, which is of a very favourable nature, and Mr. Burnham appears to have no hesitation in advising the adoption of Mount Hamilton as the site of the Lick Observatory, which we may hope will be successful in procuring an instrument worthy of the other great astronomical

advantages which it is likely to possess. The geographical position of the observatory peak is in longitude 121° 36′ 40″ W., latitude 37° 21′ 3″ N.

THE UNITED STATES WEATHER MAPS FOR OCTOBER AND NOVEMBER 1878

THE WEATHER MAP for OCTOBER 1878, which appeared in our issue of August 19, showed an area of barometric depression overspreading the whole of the United States except a narrow patch extending from Great Salt Lake northwards. The depression was deepest in the region of Minnesota, where it was 0·150 inch under the average, stretching thence in a west-south-west direction toward San Diego, where it was 0·077 inch below the mean. On the Atlantic sea-board of the States, pressure was 0·014 inch in the south and 0·033 inch in the north below the average, and continued relatively low right across the Atlantic, the depression deepening to another minimum over the region including the north-west of Ireland and Scotland, where the greatest defect from the average reached 0·220 inch. This wide-spread depression stretched still further to eastward over the whole of Europe, except the extreme north of Scandinavia, the southern half of Italy, and all Russia, except its north-western provinces; and to southward at least as far as the equator. Another extensive region of low pressure covered the whole of Asia to the south of a line drawn from Shanghai round by Lake Balkash to the Persian Gulf, and extended south-eastward over the whole of the East India Islands and Australasia as far as the east coast of New Zealand, where atmospheric pressure rose to the average of the month. Pressure was also much under the average in Cape Colony and Mauritius.

On the other hand pressure was above the average over the head waters of the Platte and Missouri rivers, and from Vancouver Island northward over the north-west of America, rising to an excess of 0·180 inch in Alaska. But the most important area of high pressure covered Greenland, where it rose in the south to 0·244 inch above the mean, and spread to the south-westward over Labrador, Newfoundland, and the Dominion of Canada as far as Montreal, and to the eastward over Iceland and the north of Scandinavia. A third area of extensive high pressure embraced the southern half of Italy, Greece, Egypt, Syria, nearly the whole of European Russia, and all Asia to the north of the area of low pressure already pointed out.

The distribution of the temperature anomalies of the month were of the simplest character in their relations to this anomalous distribution of the pressure. In the States to westward of the line of greatest barometric depression a reference to the map will show an extraordinary prevalence of strong north-west winds, where, consequently, temperatures were low, the defect from the average being 4°·8 at Winnipeg, 4°·0 on the Platte, 3°·6 on the Lower Columbia, and 2°·6 at San Diego. On the other hand, temperatures were everywhere above the average to the east of the Mississippi, the excess being nearly 5°·0 in the New England States, but only about the third of a degree in Florida in the south, and in Newfoundland in the north.

Turning now to the great depression north-west of the British Islands, winds were northerly in Iceland and South Greenland, and there the temperature was respectively 2°·3 and 1°·1 below the average. Pressure rose higher from west to east over Europe as far as the Ural River, and into Asia as far as the Tobol, where it was fully 0·100 inch above the mean pressure of October. Westerly and southerly winds accordingly ruled, and temperatures were everywhere above the average over this large tract of the earth's surface, the greatest excess being in the basin of the Dnieper, the maximum 7°·6 being recorded at Kiev. Pressure was 0·012 inch in excess of the average in Syria and Egypt, but the northerly winds in Syria indicate a lower pressure southward, and in accordance therewith temperature was 2°·0 at Beyrout and 0°·7 at Alexandria below the mean. From the rivers Ural and Tobol eastward through Siberia to the Sea of Okhotsk, temperatures were at all places below the average, the defect being from 2°·0 to 3°·0 in the basins of the Obi, Yenisei, Amoor, and Peiho.

It has been stated that pressure was 0·244 inch above the average in South Greenland. At the two more northern stations however the excess was only 0·205 inch and 0·112 inch; and in accordance with this diminution of the pressure northwards over Greenland it is to be noted that whilst in the extreme south of Greenland the temperature was below the average, it rose above it at the stations further north successively to 0°·5, 3°·1, and 4°·0.

NOVEMBER, 1878, the U.S. Weather Map for which accompanies this notice, is memorable as the commencement of a period of unprecedentedly cold weather in the British Isles, which was protracted with scarcely even a temporary interruption to the middle of December, 1879.

In the United States pressure was above the mean to westward of the Mississippi and Missouri, the greatest excess, 0·090 inch, being near the sources of the latter river. Over the rest of the States and Canada pressure was under the average, there being at least three distinct centres of greater depression formed in this extensive region, one over Minnesota and Lake Winnipeg; a second along the St. Lawrence valley, and thence northward probably away towards the head of Baffin Bay, the greatest observed defect from the average being 0·131 inch near Anticosti; and a third along the north of the Gulf of Mexico. In Alaska pressure was fully half an inch below the mean of November.

But the most marked feature of the month was the development of a region of high pressure in mid-Atlantic and thence northward over Iceland and Greenland; the greatest excess, 0·362 inch above the average, occurring in the north-west of Iceland. Immediately to eastward an area of low pressure overspread the whole of Europe, rising however to the average on the southern, eastern, and northern, as well as on the western, limits of the continent. Within this extensive depression, just as in the American depression, were developed several centres of still greater depression, viz., in the Baltic, North Sea, north-west of France, and Corsica. Another area of low pressure extended over India, the Philippine Islands, the East Indian Archipelago, Eastern Australia, Tasmania, and New Zealand. Over the whole of the rest of Asia, the north and east of Africa, and the south and west of Australia atmospheric pressure was above the average.

The temperature anomalies in the United States were quite extraordinary. Within and immediately to eastward of the western barometric depression temperatures were from 12°·4 to 13°·7 above the normal for the month, and over this region southerly winds prevailed; whereas immediately to westward, winds were westerly and northerly, and temperature fell to 3°·4 above the normal, and on the Pacific coast to the normal. On the South Atlantic and Gulf States winds were northerly and the temperature only about half a degree above the normal. In connection with the St. Lawrence valley depression, the temperature anomalies were 6°·0 in the Upper Lake region, 4°·0 in Ohio valley, 3°·6 in the Lower Lake region, and 1°·0 in the St. Lawrence valley above the normal.

In the west of Greenland, the pressure anomalies of the three stations proceeding northward were 0·130 inch, 0·048 inch above, and 0·016 inch below the mean, and from the strong southerly winds resulting therefrom the temperature anomalies were respectively 6°·8, 9°·0, and 9°·5, almost rivalling the relative excesses of temperature which made the weather of this month so memorable over large portions of the States. As higher pressures

ruled to westward from the North Cape to the Straits of Gibraltar, strong northerly winds swept over the whole of Western Europe, and the temperature everywhere fell below the average of the season, the defect being 4°·3 in the north of Norway, 4°·0 in Farö, 4°·4 in Islay, 2°·8 in Jersey, and 5°·6 in Portugal. This area of low temperature stretched eastward into Europe as far as Vienna, Trieste, and Mentone.

To the east of the line of lowest pressure within the great barometric depression which covered all Europe except its extreme outskirts, temperatures were above the average, and greatly so as far east as the head waters of Yenisei, and thence round by Taschkend, Syria, and the north of Africa. Over the greater portion of this broad region the excess was not less than 5°·0, and in the north of the Black Sea it reached as high as 9°·4 above the normal. In Eastern Siberia, Mantchooria, and Northern China very low temperatures prevailed, a deficiency of 8°·1 being recorded on the Upper Amoor.

The chief features of the meteorology of the northern hemisphere for November, 1878, and they are very striking, were these:—(1) The almost unprecedently high temperature, amounting to from 6°·0 to 13°·7 above the average over a large part of the United States, from 6°·8 to 9°·5 above the average over West Greenland; an excess of from 5°·0 to 9°·5 over nearly the whole of European Russia and Western Siberia; (2) large and extensive barometric depressions formed in conjunction with these most anomalous temperatures; and (3) the formation of an area of high pressure—inclosed within remarkably steep gradients of mean monthly pressure—over mid-Atlantic, extending thence in a north-easterly direction over Iceland toward Spitzbergen. To this it may be added that, whilst the high temperature anomaly of the surrounding low pressure regions rose to 13°·7 in the United States, 9°·5 in Greenland, and 9°·4 in Europe, the low temperature anomaly of the included region of high pressure fell only to 5°·6 below the normal at Coimbra, but over no great extent did it fall lower than 4°·0 below the normal.

The U.S. Weather Maps for December, 1878, and subsequent months, when low temperature anomalies were their out-standing features, will be looked forward to with the greatest interest as likely to throw light on the development of the meteorological conditions which impressed so arctic a character on our British weather during 1878–79. In connection with this large problem it is impossible to overestimate the vital importance of a serious and searching inquiry into the causes which brought about the high temperature anomalies of the United States, Greenland, and Russia. It is to these anomalies in all likelihood we must look for an explanation of the origin of the high pressure in the included region of the North Atlantic, which was undoubtedly the immediate cause of the strong northerly winds and low temperatures which then prevailed over Western Europe.

NOTES

PROF. W. CHANDLER ROBERTS, F.R.S., will deliver the introductory lecture to his course of Metallurgy, on Monday next, October 4, at three o'clock, at the Science Schools, South Kensington Museum.

MR. A. C. HADDON, Demonstrator of Comparative Anatomy in the University of Cambridge, with the sanction of the authorities, instead of conducting his class as usual during the Long Vacation at Cambridge, made the novel experiment last summer of taking it to the shores of Torbay, where he established a temporary zoological station on the principle of that at Naples, whither he himself had formerly been sent by the University to study. The attempt was very successful, and will doubtless be repeated another year. It was found that in addition to the ordinary class-fee of one guinea, a fee of four guineas covered the expenses of the extemporised laboratory, which was sufficiently provided with the instruments and appliances requisite in the present state of zoological study, as well as those of boat-hire for the dredging and surface-skimming excursions that formed the chief outdoor-work of the class, throughout the seven weeks of its stay; while embryological and histological dissections, together with the preparation and preservation of marine specimens for the University Museum, afforded constant occupation at home. The books, mostly monographs, needed for the determination and proper examination of the animals captured, were supplied by the superintendent of the museum, Mr. J. W. Clark, and the class received much valuable assistance from Mr. A. R. Hunt, whose intimate knowledge of the fauna of Torbay was freely placed at its disposal.

MR. MCGIBBON, the Superintendent of the Botanic Gardens, Cape Town, South Africa, a position which he has filled for thirty years, retires on a pension of 150*l.* a year. A movement is on foot to remove the Gardens from their present contracted site in Cape Town itself, and to create in the neighbourhood of the city a botanical establishment more worthy of the seat of South African Government. As a first step the appointment of Director has been offered to the well-known Cape botanist Prof. MacOwan, of Gill College, Somerset East. It is, however, doubtful whether the state of his health will allow of his undertaking it.

ON the 21st inst. there died at his residence in Camberwell, at the advanced age of 89, Charles Johnson, who for more than forty-four years held the post of Professor of Botany at Guy's Hospital. He was editor of Sowerby's "English Botany," author of "Grasses of Great Britain," "British Poisonous Plants," "Ferns of Great Britain," and other valuable contributions to natural history. In early life he took up the study of natural science, being one of the first members of the City Philosophical Society, of which Dr. Faraday and other eminent men were fellow-members. He was a high authority on agriculture and all subjects connected with economic botany.

THE death is announced of Prof. Samuel Stehman Haldeman, Professor of Comparative Philology in the Pennsylvania University, at the age of sixty-eight years. In 1836 he was employed in the geological survey of New Jersey, and in the following year in that of his native State, Pennsylvania. Dr. Haldeman filled the chair of Natural History in the University of Philadelphia and in a Delaware college, and was Professor of Geology and Chemistry to the State Agricultural Society of Pennsylvania prior to accepting the post which he held at his death. Other deaths announced are, on August 27, Dr. Hanstein, Professor of Botany and director of the Botanic Garden at Bonn; and on August 21, Prof. E. B. Andrews, of the Geological Survey of Ohio, the author of several important contributions to the geology of that State.

MR. DARWIN has forwarded to us an article contributed to an American medical journal by Dr. B. G. Wilder, Professor of Physiology in Cornell University, on "The Two Kinds of Vivisection—Sentisection and Callisection;" as he thinks the suggestion therein contained deserves consideration in this country. "All well-informed persons," Dr. Wilder writes, "are aware that the vast majority of vivisections, in this country at least, are performed under the influence of anaesthetics; but the enthusiastic zoölaters, who desire to abolish the objective method of teaching physiology, practically ignore this fact, and dwell chiefly upon the comparatively infrequent operations which are attended with pain. Having read the

arguments upon both sides and had some correspondence with leaders of the anti-vivisection movement, I have been led to think that the discussion may be simplified, and a right conclusion sooner reached, if we adopt new terms corresponding to the two kinds of experimentation. Having waited long in the hope that some candid discussion of the whole subject might contain the needed terms, I venture to suggest that painful vivisection be known as *sentisection*, and painless vivisection as *callisection*. The etymology of the former word is obvious; the distinctive element of the latter is the Latin *callus*, which, in a derived sense, may denote a nervous condition unrecognised, strictly speaking, by the ancients. Some idea of the relative numbers of callisectionists and sentisectionists may be gained from the fact that I have been teaching physiology in a university for twelve years, and for half that time in a medical school; yet I have never performed a sentisection, unless under that head should be included the drowning of cats, and the application of water at the temperature of 60° C. (140° F.), with the view to ascertain whether such treatment would be likely to succeed with human beings. I think that even elementary physiological instruction is incomplete without callisection, but that sentisection should be the unwelcome prerogative of the very few whose natural and acquired powers of body and mind qualify them above others to determine what experiments should be done to perform them properly, and to wisely interpret the results. Such men, deserving alike of the highest honour and the deepest pity, should exercise their solemn office not only unrestrained by law, but upheld by the general sentiment of the profession and the public."

AMERICAN papers speak of remarkable clouds of flies that have visited various districts. At East Pictou, Nova Scotia (about 44° 50′ N., 63° W.), such a cloud was seen on August 21. "They passed Lismore about six o'clock in the evening close to the shore. They went with the wind, which was blowing lightly from the west, occupying about twenty minutes passing a given point. They made a loud buzzing noise, which was heard by many who missed seeing them. They flew so low that some of them appeared to fall into the water. About two miles below Lismore they slightly changed their flight, heading more to the north. After their passage numbers of strange flies were observed in some of the houses near the shore. They were about half an inch in length, with wings proportionately longer than those of the common house-fly, but whether they belonged to the swarm is uncertain." At Halifax, Nova Scotia, immense swarms passed over Guysboro' (lat. 44° 40′ N., long. 61° 30′ W.), on September 5. They came from the east and resembled a dark cloud. A communication from Poughkeepsie, New York (lat. 41° 50′ N., long. 74° W.) states that a storm of flies was encountered on the Hudson River on the afternoon of September 4. The steamer *Martin*, bound south, encountered the fly storm between New Hamburgh and Newburgh. It seemed like a great drift of black snow, and it reached southward from shore to shore as far as the eye could reach. There were millions upon millions of the flies, and they hurried northward as thick as snow-flakes driven by a strong wind. They were long and black and had light wings, and the cloud must have been miles in length. Our readers may remember that some weeks ago we recorded a somewhat similar phenomenon as having been seen in various parts of France.

A VERY successful attempt has been made to measure a base-line, near Aarberg, for the triangulation of Switzerland. The first measurement gave 2400·087 metres; the second, made independently of the first, gave 2400·085 metres as the result, the difference between the two being thus only two millimetres. The measurement was made under the direction of the Spanish General Ibanez, who invented the instrument by which the work was done. The place selected for the line is on the Sisselen road, which presents here an almost straight and level line of three kilometres.

A CONGRESS is to be held from October 1 to 10 at Saragossa, to discuss matters relating to the phylloxera.

THE "Elephant Sugar Cane" of Cochin China, which is said, though this requires confirmation, to reach a height of eleven feet and a diameter of seven inches in six months, has been successfully introduced by the Royal Gardens, Kew, from Saigon, into Jamaica. The rather sensational reputation of this variety has excited a good deal of interest in it amongst the West Indian planters.

MR. ROLAND TRIMEN, the Curator of the South African Museum, has arrived in this country.

THE Annual Report of the Smithsonian Institute for 1878 shows that it continues to be as active as ever in the advancement of scientific knowledge. In all its departments a vast amount of work has been done during the year, much of this work being really of an international character. Many valuable additions were made to the National Museum during the year, and several monographs of the first importance published. One of the principal papers in the volume is a memoir of the late Prof. Joseph Henry, by Prof. Asa Gray. About 100 pages are devoted to a paper by Mr. W. B. Tayler on "Henry and the Telegraph," and another long paper describes Henry's researches on sound, with special reference to fog-signalling. Other papers are a translation of Arago's biography of Condorcet; Ernest Favre's biographical notice of Louis Agassiz; "The Effect of Irritation of a Polarised Nerve;" "Pflüger's Electrotonus," by Dr. B. F. Lautenbach; "Researches on Fever," by Dr. H. C. Wood; "Constants of Nature," by Prof. John LeConte; list of apparatus relating to heat, light, electricity, magnetism, and sound, available for scientific researches involving accurate measurements, in various institutions in the United States; "Ornithological Exploration of the Caribbee Islands," by Mr. F. A. Ober; "Report of Explorations in Greenland," by L. Kumlein.

VOL. XVI. of the *Transactions and Proceedings* of the Royal Society of Victoria contains the results of a very satisfactory year's work. The following are among the papers in this volume:—"On the Relation between Forest Lands and Climate in Victoria," by R. L. J. Ellery, F.R.S.; "Experiments on the Tensile Strength of a few of the Colonial Timbers," by Fred. A. Campbell, C.E.; "The Diorites and Granites of Swift's Creek and their Contact Zones, with Notes on the Auriferous Deposits," by A. W. Howitt, F.G.S.; "On the Genus Amathia of Lamaroux, with a Description of a New Species," by the Rev. J. E. Tenison-Woods, F.G.S., &c.; "Notes on the Customs of Mota, Banks Islands," by the Rev. R. H. Codrington, M.A., Oxford, with Remarks by the Rev. Lorimer Fison, Fiji; "Some New Localities for Minerals in Victoria," by J. Cosmo Newberry; "The Tidal Datum of Hobson's Bay," by R. L. J. Ellery, F.R.S.; "Notes on the Geology of the West Tamar District, Tasmania," by Norman Taylor; "Observations of the Outer Satellite of Mars in 1879," by E. J. White, F.R.A.S. Williams and Norgate are the London agents of this Society.

THE Government of India has offered the prize of 100*l*. for the best "Manual of Hygiene," to serve as a text-book for the use of the British soldiers in that country. Works submitted in competition for this prize must be sent in by their authors to the Secretary to the Government of India in the Military Department at Calcutta, so as to reach his hands not later than the last day of next March. The work is "to be written in clear and simple English, and thoroughly practical, showing the ordinary causes

affecting health, and the special dangers to which British soldiers are exposed in India, more particularly during their first year in the country, and the best means by which those dangers may be averted." The work, if accepted, will be printed at the public expense, and become the property of the State; and it is not to exceed in bulk "more than fifty or sixty pages of print, of small pica, octavo size."

AN ingenious method for obviating the frequent stoppage of trains at stations, and yet accommodating the passengers from these stations, has been devised by M. Hanrez. A "waiting carriage," comprising a steam-engine with special gear, and space for passengers and luggage, is placed on a siding at the station, and picked up by the train as it goes past. The latter, by means of a hook on its last carriage, catches a ring supported on a post, and connected with a cable wound on a drum in the waiting carriage. Thereupon the drum begins to unwind, and in doing so compresses a system of springs, while the carriage is moved at a rate gradually increasing to that of the train. The engine of the carriage then winds in the cable, the train and carriages are connected, passengers are transferred (the carriages being of the American type) from the joined carriage to the train, and *vice versa*, then the two are disconnected, and the engine of the carriage, working on the wheels, brings it back to the station whence it was taken.

MR. R. TUCKER writes:—A verification of M. Landry's statement (NATURE, vol. xxii. p. 495) may be acceptable:—

$$2^{2^6} + 1 = 2^{64} + 1 = 18446744073709551617$$
$$= 274177 \times 67280421310721.$$

THOSE of our readers who have girls to educate we recommend to consult the Queen's College Calendar for 1880-81, published by Macmillan and Co.

THE Sanitary Institute seems to have had a very successful meeting last week, all the usual topics embraced in its programme coming on for discussion. Dr. B. W. Richardson gave a very interesting and instructive lecture on "Woman as a Sanitary Reformer," one of the first conditions being her education in physiology and such other sciences and arts as bear on every-day household life. Dr. Richardson made it clear that if women were educated as they ought to be they would be an immense power in keeping houses and households in a healthy condition.

WE have received the new calendar of the Newcastle College of Science. The classes in this institution now include mathematics, experimental physics with laboratory, chemistry with laboratory, geology, including geological surveying, natural history, land surveying, mining, modern history, French, German, mechanical drawing.

ABOUT 88,000*l*. has now been subscribed towards the cost of the projected new University College at Liverpool, and little more will be needed to make up the amount required. It was originally intended to raise 80,000*l*. for the endowment of seven professorships and two lectureships; but part of the money subscribed (about 7,000*l*.) has been contributed towards the foundation of a Roscoe chair of art—a professorship not originally contemplated; Lord Derby gives 10,000*l*. to found a chair of natural history; Messrs. William, S. G., and P. H. Rathbone give a like sum to found a King Alfred chair of modern history and literature; Mr. A. H. Brown, M.P., and Messrs. Cressfield and Barrow also give 10,000*l*. to found a chair of ancient history; Mrs. Grant subscribes a similar amount to found a chair in some branch of science; and 10,000*l*. is given by the trustees of the late Mr. Roger Lyon Jones to the Royal Infirmary School of Medicine, to found a chair of experimental physics, with which mathematics will be for the time associated. Between 7,000*l*. and 8,000*l*. has been subscribed towards founding a chair of philosophy, logic, and political economy. Though the endowment funds are nearly complete, there remains the cost of a building to be provided.

WE have received from Madras Dr. Oppert's work "On the Weapons, Army Organisation, and Political Maxims of the Ancient Hindus, with special reference to Gunpowder and Firearms."

THE Aristotelian Society, which was founded last spring for the systematic study of philosophy, has just completed its work for this session, having studied philosophy from Thales to Proclus. The session for 1880-81 will open on October 11 at 20, John Street, Adelphi, at 8 p.m., when an introductory address will be delivered by the President, Mr. Shadworth H. Hodgson, LL.D., on "Philosophy in Relation to its History." During the session the Society intends to study mediæval philosophy, and the whole of modern philosophy, from Bacon to Comte and Spencer.

A SOCIETY for the Promotion of Agricultural Science has been formed in the United States, which will meet annually for the reading of papers, and which will in other ways endeavour to encourage scientific research in connection with agriculture. Such papers as are likely to be of permanent value will be published. Prof. W. J. Beal of Lansing, Michigan, is president of the society.

AT the last meeting of the Balloon Society a letter was read from M. de Fonvielle offering to bring over a balloon with a gas capacity of 42,000 feet, and compete with Mr. Wright in his balloon, both balloons to start simultaneously from the Crystal Palace in a contest for the longest aërial distance travelled in some particular direction. The proposal was referred to a committee.

WE have received a handsome quarto publication, "Contributions to the Archæology of Missouri, by the Archæological Section of the St. Louis Academy of Science." This first part is devoted to Pottery; it will be followed by others, the object being to furnish to those interested in the archæology of the country, a reliable statement of facts connected with the occurrence of prehistoric remains in this important region. The present volume contains a general description of the south-eastern Missouri district and of the pottery which has been found in such abundance in the burial mounds of that region. Several charts and plans and figures of characteristic specimens of the pottery, beautifully drawn and lithographed, have been selected for illustration. The authors of the two papers in the volume are Mr. W. B. Potter and Dr. E. Evans. Should the present venture meet with encouragement other volumes may soon be expected treating of "Implements," "The Construction and Grouping of Earthworks," and "Osteological Remains." We trust the enterprise will meet with the encouragement it well deserves. The volume is published by George A. Bates, Naturalists' Bureau, Salem, Mass.

AN unusually severe shock of earthquake was felt at Fribourg on Sunday, the 19th inst., about 11 a.m. A smart earthquake shock was felt at Morat at 8 o'clock, a.m., on the 21st, and another twelve hours later at Fribourg, which, though of shorter duration than that of Sunday, caused considerable alarm. An earthquake took place at Wellington, New Zealand, on July 28.

A SILESIAN Botanical Exchange Club has been established, evidently intended for the exchange of specimens among botanists of all countries. A copy of the rules may be obtained by applying to Herr Adolph Toepffer, Bandenburg an der Havel, Prussia.

DR. HECTOR, of the New Zealand Geological Survey, expresses his opinion that in Westland and Otago vast auriferous racts remain as yet untouched.

"The Monthly Index to Current Periodical Literature, Proceedings of Learned Societies, and Government Publications," published at the office of the *American Bookseller*, New York, seems to us a very useful publication.

The passage of the meteor referred to in Mr. Thwaites' letter last week, occupied one and a half, not eleven and a half seconds.

The additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Major Gape; an Egyptian Jerboa (*Dipus ægyptius*) from Egypt, presented by Dr. Hastings; a Cape Bucephalus (*Bucephalus capensis*) from South Africa, presented by Mr. C. B. Pillans; two Black-faced Spider Monkeys (*Ateles ater*) from East Peru, a Southern River Hog (*Potamochœrus africanus*) from South Africa, a Razor-billed Curassow (*Mitua tuberosa*) from Guiana, a Yarrell's Curassow (*Crax carunculata*) from South-East Brazil, a Blue and Yellow Macaw (*Ara ararauna*), two Orinoco Geese (*Chenalopex jubata*) from South America, two Rufous Tinamous (*Rhynchotus rufescens*) from Brazil, deposited; a Common Rhea (*Rhea americana*) from South America, a Spotted-billed Toucanet (*Selenidera maculirostris*) from Brazil, an Electric Silurus (*Malapterurus beninensis*) from West Africa, purchased.

BIOLOGICAL NOTES

Transverse Commissure in Arthropods.—From a recent memoir laid before the Belgian Academy by M. Lienard (*Archives de Biologie*, tom. i. fasc. 2), it would appear that an arrangement of the cephalic nerve-centres, hitherto thought to have been peculiar to Crustacea, is really to be found in nearly the whole of the Arthropoda. It has been long known that in Crustaceans, *e.g.*, Decapoda, besides the super and sub-œsophagean ganglionic masses and their lateral connections, there is a well-marked transverse commissure, situated in front of the sub-œsophagean mass, and immediately behind the œsophagus. This commissure in other Arthropoda seems, from quite technical causes, to have escaped notice. M. Lienard finds it nearly everywhere among the Myriapoda, Coleoptera, Odonata, Lepidoptera, Hemiptera, Diptera (nymphs and larvæ). He has dissected the complete ring in nearly 100 forms, belonging to 70 genera. He is trying to ascertain the origin of the fibres which form the transverse commissure.

The Hæmatopœtic Function.—In a recent paper to *R. Accademia dei Lincei*, Sig. Fleti describes the effects of splenotomy as observed by him in dogs. Some of these are as follows:—Immediately after the operation (the previous *régime* of life being maintained) the quantity of hœmoglobin increases for a short time, and more in old than in young animals. Next it diminishes much and progressively in old animals, but without reaching half the normal quantity. In a third phase there is a slow progressive increase, which by degrees brings the quantity up to and above the normal. In young animals the diminution is much less, and the quantity of hæmoglobin sooner reaches and surpasses the normal. In all cases the weight of the animal does not diminish, but may even considerably increase (under good hygienic and alimentary conditions). Sig. Fileti adds some chemical observations as to colorations obtained with hydrochloric acid and yellow prussiate of potash. It clearly appears (he concludes) that, the spleen being removed, the marrow of the bones does not compensate for its function. As the quantity of hæmoglobin first increases—and we cannot admit a real increase in production as resulting from splenotomy—we must suppose that in this brief period the failure of the spleen makes itself felt more in destruction than in production. The former of these functions comes to be compensated more quickly, and there is then a gradual diminution in production of hæmoglobin as a direct consequence of the spleen being absent, and this diminution is greater the less able the marrow is to act, *i.e.* the older the animal. When, finally, the hæmatopœtic function of the spleen has been completely compensated by the marrow of the bones, the quantity of hæmoglobin returns to the normal figure, and may even surpass it. Sig. Fileti is studying the influence of light on the production of hæmoglobin.

Development of Lepidosteus.—In an interesting memoir read at the last meeting of the British Association (Swansea) Prof. F. M. Balfour and Mr. W. N. Parker gave the results of their investigations of some larval forms of Lepidosteus which had been most liberally supplied to them by Prof. Alexander Agassiz. Some of the more important of these were:—1. That the segmentation was, as in the sturgeon, complete, but the larger segments of the lower pole very early fused together to form a yolk sac. 2. That the epiblast was divided into nervous and epidermic layers, and that the nervous system was formed by a solid thickening of the epiblast, as in Teleostei, and not by the closure of a groove, as in the sturgeon. 3. That the lens of the eye and auditory vesicle were developed from the nervous layer of the epidermis. 4. That the general relation of the embryo to the yolk, and the general characters of the germinal layers are precisely like those in Teleostei. 5. That there is present a suctorial disk in front of the mouth, with numerous papillæ, as was first noticed by Agassiz; this disappears in the adult, and is probably a persisting rudiment of a primitive vertebrate organ, remains of which are also found in the adhesive papillæ of larval ascidians, the adhesive disks of larval amphibians, &c.

Visceral Anatomy of Herring.—Mr. F. W. Bennett calls attention to the following, it would seem new, fact in the visceral anatomy of this common fish (*Journ. Anat. and Physiol.*, July, 1880). It possesses an extremely long air-bladder, which stretches towards to the head, terminating near the labyrinth of the auditory organs. About the middle of its length it is connected by a duct with the stomach. The latter is capacious and elongated; while the commencement of the mid-gut is near the gullet the posterior portion of the stomach continues on into the ductus pneumaticus. This communication will be found most usually closed with mucus; but Mr. Bennett points out that there is another and a more important communication between the air-bladder and the cloaca. Till within one half-inch of this latter the air-bladder retains its well-known and beautiful silvery appearance; this then suddenly ceases, and the remainder of the bladder is muscular. This will account perhaps for its having been overlooked so long; what the exact uses of this passage may be are not yet known, but it is certain that it affords freer passage for gas than the duct leading into the stomach. Bristles may be readily passed through it, and gas may be made to bubble out if slight pressure be carefully applied under water. The usual arrangement of the apertures of the cloaca is as follows:—In front lies the anus, then the generative aperture, and hindmost of all, the urinary duct opens; the opening of the duct now described by Mr. Bennett lies between the anus and the urinary aperture, and usually to the left of the genital aperture.

Monstrous Beetles.—Mr. Horace F. Jayne has recently published, in the *Trans.* American Entom. Soc., vol. viii. (pp. 155–62, Pl. IV., descriptions of some monstrosities observed in North American Coleoptera, all of which belong to that class to which the terms "Monstra per excessum" and "Monstres polyméliens" have been applied. They belong to the genera *Calosoma*, *Cychrus*, *Metrius*, *Pasimachus*, *Scarites*, *Dyschirius*, *Chlænius*, *Lichnanthe*, *Polyphylla*, *Strategus*, *Telephorus*, *Prionus*, *Eleodes*, and *Helops*, and form an interesting addition to the already numerous recorded instances of this kind of monstrosity in beetles. All show a tendency to reduplication in some of the cephalic or thoracic appendages. In some it is the antennæ, in others the palpi, in others the legs, that are thus affected, and in some cases the tendency is exhibited in more than one of these appendages in the same individual. Beetles appear to be particularly liable to the production of such monstrosities, but it is probable that no parallel instance like that here recorded and illustrated by Mr. Jayne in an example of a longicorn beetle (*Prionus californicus*) has been noticed. In it each maxillary palpus has two terminal joints, and each femur has two perfectly-formed tibiæ and tarsi, with the claws, &c., the whole monstrous development being remarkably symmetrical; the labial palpi and the antennæ are normal, as is all the rest of the insect. Mr. Jayne contents himself by describing and figuring these interesting monsters, and does not venture upon any suggestions as to causes, in which he is perhaps wise, considering the uncertainty that exists as to the origin of parallel monstrosities in animals far higher in the scale. Reduplication of cephalic, thoracic, and probably abdominal appendages in the Arthropoda is by no means rare, but it is possible that a distinct combination of two individuals more or less united in one, such as is sometimes found in vertebrates, does not exist.

DIGESTION IN PLANTS.—Dr. Lawson Tait has recently investigated afresh the Digestive Principle of Plants. While he has obtained complete proof of a digestive process in *Cephalotus*, *Nepenthes*, *Dionæa*, and the *Droseraceæ*, he entirely failed with *Sarracenia* and *Darlingtonia*. The fluid separated from *Drosera binata* he found to contain two substances, to which he gives the names "droserin" and "azerin." Dr. Tait confirms Sir J. D. Hooker's statement that the fluid removed from the living pitcher of *Nepenthes* into a glass vessel does not digest. A series of experiments led him to the conclusion that the acid must resemble lactic acid, at least in its properties. The glands in the pitchers of *Nepenthes* he states to be quite analogous to the peptic follicles of the human stomach; and when the process of digestion is conducted with albumen, the products are exactly the same as when pepsine is engaged. The results give the same reactions with reagents, especially the characteristic violet with oxide of copper and potash, and there can be no doubt that they are peptones.

STIPULES IN ONAGRACIÆ.—Prof. Baillon says (*Bull. mensuel. Soc. Lin. de Paris*, No. 33) that in the majority of works on descriptive botany, this family is mentioned as characterised by the constant absence of stipules, and in justification of this quotes the classical works of Decaisne, Duchartre, Endlicher, and Hooker; nevertheless he states that the existence of these organs in this family admits of easy proof, not indeed that they ever occur of large dimensions, for then they could not have escaped detection, but still they are present, more commonly as little subulate tongue-like bodies, acute, often red-coloured at the base of the petioles in both opposite and alternate-leaved plants. In Hauya they soon turn black and wither off early. In the fuchsia of our gardens little stipules are often present. In Circea they can also be detected. In the Lopezia of our gardens all the leaves have two very distinct stipules, which indeed have been often referred to in botanical works, and it is the same with Haloragis, though Bentham and Hooker describe them as here absent.

A NEW GREEN CILIATED PLANT.—Under the title of "A New Ciliated Organism furnished with Chlorophyll," Prof. van Tieghem has published (*Bull. Soc. Bot. France*, 1880, p. 130) a memoir of a strange new form. The organism in question was found by Prof. Perrier twice: once at Roscoff, in sea-water containing algæ and some of the lower animals; and again at the Museum (Paris), in a little aquarium in the laboratory. It presents the appearance of a gelatinous tremulous mass of a pure green colour; in outline well defined, spherical or oval in shape, attaining more than a centimetre in diameter, and attached by a portion of its periphery to a large marine alga. At first sight it would be called a Nostoc. Exposed to sunlight it gave out oxygen, so one concludes its colouring-matter to be chlorophyll. On a closer inspection it is seen that the mass is composed of a colourless jelly, scattered throughout which are isolated green points, visible to the unassisted eye, and sufficiently numerous as to give to the whole mass the green coloration distinguishing it, so one would not now refer it to Nostoc. Each little green body is spherical, and measures from three to four-tenths of a millimetre. It is formed of a very finely granular and somewhat dark protoplasm, very uniformly permeated with an amorphous chlorophyll; neither nuclei nor vacuoles, nor red spot were detected, and the surrounding membrane was very thin. At one place (called the pole) the cell bore a tuft of vibratile cilia which were attached side by side, so as to cover a space more or less large according to age and to allow of independent movements. On the equator at two diametrically opposite points a small hollow in the green mass is seen, and by these passes a band of homogeneous protoplasm which traverses the membrane, turning towards the pole, and in the superior hemisphere dividing on its outer border into fine fringes with vibratile cilia. These cilia are confluent at their base, and are not independent in their movements. In process of development the polar cilia become detached (absolutely fall off), next the lateral moustaches disappear (these seem to be retracted), a continuous membrane covers over all, but the general aspect and dimensions remain unchanged. Later on the cell divides into two (equatorially), next it divides again (perpendicularly), and the segmentation continues until there is a family of sixteen rounded-off cells, and the organism has passed through a phase of encystment. Lastly each daughter cell increases in size, separates more and more from its neighbour, gets closed in a fine membrane, and then appears all covered over with cilia. It now escapes into the water and secretes in abundance a gelatinous material. The clothing of cilia drops off as the form approaches its adult size: soon appear the polar cilia, next the lateral moustaches; and so far its life-history is complete. At no phase in its development was either cellulose detected in its cell-membrane, nor starch in its protoplasm. Prof. van Tieghem concludes:—"Is this organism an animal or a plant? I am not well able to say, and I must add besides that this question, to which formerly so much importance attached, in the actual condition of science, appears to me to be destitute of interest." It is called *Dimystax perrieri*. With every respect to the dictum of so distinguished a botanist as Prof. Tieghem, we venture to call our readers' attention to this strange form, which M. Roze seems disposed to regard as an animal, in the hopes that some of them may assist in determining its proper position in nature.

PHYSICAL NOTES

A FRESH measurement has been made by Mr. T. C. Mendenhall of the acceleration of gravity at Tokio, an account of which appears in the *American Journal of Science*. The experiments were made after the accepted methods with Kater's and Borda's pendulums, the only novelty introduced being that of employing a chronograph in connection with a reliable chronometer to determine the time of vibration of the pendulum. At every sixtieth or hundredth vibration of the pendulum a light break-circuit apparatus placed beneath it was raised to just such a height as to be "thrown" by the pendulum at its lowest point of swing, thus enabling its rate to be calculated to the ten-thousandth of a second. Mr. Mendenhall considers his determinations to be more reliable than those of Professors Ayrton and Perry, which were made with a long wire pendulum; he revises their calculations, altering their value of "g" from 9·7974 to 9·7979, and asserts that their calculation of the theoretical value by Clairaut's formula is wrong, and should be 9·7980, not 9·797 (metres). His own determinations give a mean result of 9·7984.

A SECONDARY battery, the electrodes of which consist of porous fragments of gas-carbon, has been devised by M. Henri Sauvage. Though inferior in power and durability to a perfectly "formed" Planté cell with lead electrodes, this cell would be cheaper, more readily and rapidly constructed, and would yield a current of longer duration. The action is probably due to the occlusion of the hydrogen and oxygen gases respectively in the pores of the carbon. The inventor recommends that the two plates used as electrodes be kept apart with a simple thin wooden frame.

PROF. O. N. ROOD calls attention to the fact that when the colour of ultramarine blue is mixed with white by the method of rotating disks the tint appears to verge towards violet. Brücke advanced the explanation that what we call white is really a reddish colour. Aubert, on the contrary, regarded it as showing that violet is only a pale shade of ultramarine blue. A series of experiments made with other colours showed that when mixed thus with white green-yellow becomes greenish, and green green-bluish, that full yellow and orange incline to red, and red becomes purplish. These observations accord with neither theory, and Prof. Rood advances none himself. He thinks that the fact as it stands explains why it is impossible in the polariscope to produce a red free from purplish tint, there always being white light mingled with the red rays.

PROF. J. TROWBRIDGE, in investigating with telephones connected to earth-plates the flow of return-currents through "earth," found that at a mile from the Harvard College Observatory the time-signals of the observatory clock could be heard by merely tapping the earth at points fifty feet apart.

FROM his recent researches on dilatation and compressibility of gases under strong pressures, M. Amagat derives (*Comptes rendus*, August 30) the following laws:—1. The coefficient of dilatation of gases (for temperatures not too much above the critical) increases with the pressure to a maximum, then decreasing indefinitely. 2. This maximum occurs under the pressure with which the product $p\,v$ is minimum, where the gas accidentally follows Mariotte's law. 3. It diminishes for higher and higher temperatures, and at length disappears. 4. At a sufficiently high temperature the compressibility of fluids is represented by the formula $p\,(v - \alpha) = \text{const.}$; α being the smallest volume the mass of fluid can occupy; this is the limiting law. For each gas α has a special value. 5. For pressures

below the critical the deviation (from Mariotte's law), first positive for a temperature sufficiently low, becomes *nil*, then negative, with increasing temperature; but beyond a certain negative value it diminishes indefinitely without changing sign. 6. For pressures between the critical pressures and a superior limit, special for each gas, the period during which the deviation is positive is preceded at a lower temperature by a period in which it is negative; so that the deviation twice changes sign. 7. Beyond the upper limit of pressure indicated in the preceding law the deviation is always negative, whatever the temperature; it diminishes, in general, when the temperature increases, except for pressures near the limit, where its variation is more complicated.

It is known that rain and other meteoric waters contain a quantity of gas and saline matters which they find in the atmosphere and carry with them. The amount varies with the seasons, but may be estimated, on an average, at about 8 cc. of oxygen, and 0·50 to 0·60 cc. carbonic anhydride per litre, along with small quantities of ammonia, nitrite, nitrate, and carbonate of ammonium, organic matters, and chloride of sodium. In a recent paper to the Belgian Academy M. de Koninck holds that in the alteration and metamorphism of rocks by infiltration of those waters may be found the solutions of many questions in geology hitherto unsolved. The facts he cites relate to tertiary and quaternary deposits which in many parts of Belgium are so transformed by the waters in question that it is impossible to recognise them if account be taken only of petrographic characters.

From observing how different persons gave different estimates of the apparent size of blood-corpuscles seen in the microscope, M. Montigny was led to make a series of further experiments on the subject (which are described in the *Bulletin* of the Belgian Academy, No. 6). He comes to the conclusion that even for good observers an estimation of the kind referred to is principally affected by the length of distinct vision, but that often this appreciation is subject to the influence of occult causes which affect the relation between sensation and judgment. The examination of microscopic objects may be influenced, like astronomical observations, by a kind of *personal error*, by reason of which individuals have a tendency to see microscopic images, some larger, others smaller, than they should appear, abstraction being made of the influence of the length of distinct vision on our appreciations. These conclusions, it is pointed out, do not at all affect the exactness of measurements determined by *savants* with the microscope, but they tend to show that each observer should measure for himself the different magnifying powers of the instrument he uses, obtained by changes of eye-pieces and objectives.

With the view of demonstrating the mechanical action of electrolysis, all action of heat being excluded, Signor Basso has lately experimented thus (*Il Nuovo Cim.*, ser. 3, tom. vii.). A thin square glass plate is covered with collodion, and on this when dry is put a thin layer of good gelatine, mixed with about $\frac{1}{20}$ of its weight of a saturated solution of bichromate of potash. The bare side of the plate is exposed to light, to attach the gelatine layer. Then the plate is put in an aqueous solution of chloride of gold till the upper layer is impregnated with the gold salt, and it is exposed to diffused daylight. Next the covered side is strewed with fine graphite, and the glass connected by means of four fine wires running along its sides to the negative pole of a battery. The plate is then placed in an ordinary bath of sulphate of copper. The copper is deposited regularly on the whole of it. In a few days wrinkles and bubbles appear; and if the copper have been deposited as far as the borders, the plate may at length even break, thus proving the mechanical force, which is a direct consequence of electrostriction.

ON THE PRESENT STATE OF SPECTRUM ANALYSIS[1]

At the Sheffield meeting of the British Association a committee was appointed to report on the present state of spectrum analysis. The committee has this year presented its first report. The report is divided into four parts:—

1. On the spectra of metalloids, drawn up by Dr. A. Schuster.
2. On the influence of temperature and pressure on the spectra of gases, drawn up by Dr. A. Schuster.
3. On the emission spectra of the rays of high refrangibility, drawn up by Prof. W. N. Hartley.
4. On the absorption spectra of the rays of high refrangibility, drawn up by Prof. A. K. Huntington.

In the report on the spectra of metalloids, we have for each element a full account of the literature on the subject with all necessary references. The various spectra of each metalloid and its compounds are enumerated, and special stress is laid on the discussion which nearly always has taken place on the chemical origin of these spectra. It will be found that often more work is needed to clear up doubtful points, but there is no special controversy at issue at the present moment except in the case of the carbon spectra. A discussion of very long standing is still occupying the minds of many spectroscopists as to whether the spectrum which is seen at the base of every candle flame is due to carbon or to a hydrocarbon. The arguments and experiments on either side are given in detail and are finally summed up as follows:—"Those who believe the spectrum to be due to the element carbon rely chiefly on the brilliancy with which these bands are developed when cyanogen is burnt in oxygen, also when the spark is taken in cyanogen, carbon tetrachloride, and carbonic oxide at high pressure; all the gases being dried with the greatest care. Those who oppose this view and who hold that the spectrum is due to a hydrocarbon refer to the impossibility of excluding all traces of moisture, and to the fact that this spectrum is well developed under circumstances where we know hydrocarbons to be present."

When cyanogen is burnt a series of bands appears in the blue violet and ultra-violet, and another controversy has taken place whether these bands are due to carbon or to a compound of carbon and nitrogen. Two papers have lately appeared on the subject. One by Mr. Lockyer, in which he describes an experiment in which the bands were seen in a spark taken in carbon tetrachloride, although the nitrogen lines were not visible in the jar discharge; and another by Professors Liveing and Dewar, in which these bands were traced to impurities of nitrogen in all cases in which they were seen. A spark in carbonic oxide showed the bands when the gas was prepared from ferrocyanide of potassium, but not when it was made by heating a mixture of quicklime with pure and dry potassium oxalate. When all the air had been properly expelled a tube containing carbon tetrachloride did not show the bands.

The following quotation will give an idea of the points which are discussed in the second report:—

"We shall endeavour for clearness' sake to arrange our material under five different heads. We shall first discuss what changes we have a right to expect in the appearance of a spectrum, if the quantity of luminous matter is increased or if the temperature is raised, the absorbing properties of the gas remaining unaltered. We shall next speak of the widening of lines, which, as we shall see, often accompanies an increase of pressure. Then we shall treat of the different spectra given by one and the same body at different temperatures; and we shall see how far satisfactory explanations have been offered for their existence.

"So far our road will be clear; but we shall see that these spectra of different orders, as they have been called, are only extreme cases of continuous changes which are nearly always going on. Very often we can refer these continuous changes to a gradual displacement of one spectrum by another; but often we shall not be able to prove the existence of a second spectrum. There is *à priori* nothing impossible or even improbable in the view that the relative intensity of different lines may be different at different temperatures, and often when we observe a variation we may equally well explain it by assuming the gradual appearance of a new spectrum or an alteration only in the relative intensities of the lines. It becomes then a matter of extreme difficulty to decide which of the two suppositions is correct. In doubtful cases we may often be able to obtain important information by means of a method which is little understood even by spectroscopists. It is the method which has first been extensively used and investigated by Mr. Lockyer of projecting an image of the luminous source, spark, arc, or flame on the slit of the spectroscope and thus localising the spectra, which are thrown and confused together if the luminous source is examined directly without the interposition of a lens. We shall see how by means of this method we shall often at a single glance be able to tell how the body will behave at different temperatures and under different pressures. Many facts which have been quoted as remarkable might have been foretold by means of this method. Our fourth chapter will be devoted to it. In our last chapter we

[1] Abstract of Report read at the Swansea meeting of the British Association.

shall have to give an account of some changes which have not found a place under the previous heads."

Space will only permit us to quote a few of the questions raised. It is now generally admitted that pressure is the principal cause which determines the widening of lines, but it is not generally known that a different appearance of the lines may be presented according as the pressure is due to the impact of similar or dissimilar molecules; thus a molecule of sodium will widen its lines more easily in an atmosphere of sodium than in another atmosphere. Mr. Lockyer has observed that the lines of oxygen or nitrogen may be obtained sharp at atmospheric pressure by mixing a small quantity of one gas with the other. The gas which is present in small quantities has its lines sharp.

The curious fact is mentioned that when a line widens unsymmetrically it widens in nearly all cases more towards the red, and then towards the violet end.

In that part of the report which relates to multiple spectra an account is given of the gradual spreading of the opinion that these spectra are due to different molecular groupings. The question of long and short lines is next discussed, and great stress is laid on the fact that the longest lines are by no means always the strongest. An abstract of Mr. Lockyer's work on the subject is given, and of the confirmation which his results have found in later work. Thus Mr. Lockyer found that the longest lines were always the first to be reversed. Professors Liveing and Dewar have since examined the absorption-spectra of many metallic vapours. The lines which they have seen reversed were nearly in all cases those which are longest in the spark, though not always those which are strongest. Results obtained by M. Lecoq de Boisbaudran with sparks, the temperature of which was lower than in the ordinary jar-discharge, also confirm Mr. Lockyer's results. Discussing the attempts which have been made to explain these and other facts, it is again mentioned that we must assume the impacts of a similar molecule to produce a greater effect than the impacts of a dissimilar one. The last part of the report treats of some other changes in the relative intensities of lines. We only mention the experiments in which Mr. Lockyer found sometimes the green sodium line to be present without the well-known yellow double line. The report concludes as follows:—

"We have here again two hypotheses, that of molecular shocks and that of molecular combinations. Both explain the facts satisfactorily, and I do not think that one of them necessarily excludes the other. I believe, on the contrary, that a line can be drawn, and that while the regular changes observed chiefly in band-spectra may be due to one cause, the often irregular changes in metallic spectra, where one set of lines disappears and another appears often on the violet side, but sometimes towards the red, may be due to another cause.

"It is often said that we must not ascribe the same phenomenon to two different causes, when one of them is sufficient to explain it; but the point at issue is whether the phenomena are the same in all cases. An advance of science has constantly led to the separation of phenomena which were formerly considered to be connected together, and we believe that the further development of the different points we have attempted to discuss, in which different observers have strongly taken up opposite opinions, will lead to the blending together of different views rather than the entire elimination of one of them."

Prof. Hartley, in his part of the report, gives us an account of our knowledge on emission spectra in the ultra-violet region. He treats especially of the researches on the solar spectrum by Mascart, Draper, and Cornu.

Prof. A. K. Huntington reports on the absorption spectra in the ultra-violet region. The results obtained by Prof. Stokes and Dr. Miller are given in detail. Amongst the results obtained by Dr. Miller, it seems especially interesting to notice the connection which apparently exists between the absorbing properties of a liquid and that of its vapour. When one of them is transparent to the ultra-violet rays the other is also, and *vice versâ*.

Prof. Soret, it is well known, constructed a few years ago a spectroscope with a fluorescent eyepiece, and has by means of it carried researches in the ultra-violet parts of the spectrum. We notice especially the examination of absorption-spectra of the bases of gadolinite, and the conclusions drawn from it on the existence of new elementary bodies. Prof. Cornu has given much attention to the absorption power of our atmosphere, and we find a full account of his experiments in Prof. Huntington's report. In conclusion we have a short abstract of the work done by Professors Hartley and Huntington on absorption-spectra in the ultra-violet region. They obtained the following results:—

1. The normal alcohols of the series $C_4H_{2n-1}OH$ are remarkable for transparency to the ultra-violet rays of the spectrum, pure methylic alcohol being nearly as much so as water.

2. The normal fatty acids exhibit a greater absorption of the more refrangible rays of the ultra-violet spectrum than the normal alcohols containing the same number of carbon atoms.

3. There is an increased absorption of the more refrangible rays corresponding to each increment of CH_2 in the molecule of the alcohols and acids.

4. Like the alcohols and acids, the ethereal salts derived from them are highly transparent to the ultra-violet rays, and do not exhibit absorption-bands.

Interesting results were also obtained by the examination of substances containing the benzene nucleus, and in a separate paper the absorption-spectra of essential oils were examined and discussed. Prof. Hartley has still further extended the researches jointly begun with Prof. Huntington, and has arrived at the conclusion that no molecular arrangement of carbon atoms causes selective absorption, unless three pairs are doubly linked together in a closed chain.

It will be seen that a few only of the branches of spectrum analysis have been discussed in the present report, and next year no doubt will bring us a further instalment of a work which we hope will prove useful to those who are interested in spectroscopic investigations.

AGRICULTURAL CHEMISTRY [1]

III.

I HAVE thus far directed attention to some points of importance in connection with the sources of the constituents of our crops, and I must now briefly refer to some in connection with the composition, and to some relating to the uses, of the crops themselves.

As to composition, I must confine myself to indicating something of what is known of the condition of the nitrogen in our various crops; though I had intended to say something respecting the carbohydrates, and especially respecting the various members of the cellulose group.

As to the nitrogen—in our first experiments on the feeding of animals, made in 1847, 1848, and 1849, the results of which were published in the last-mentioned year—we found that, in the case of succulent roots used as food, not only were they not of value as food in proportion to their richness in nitrogen, but when the percentage of it was higher than a certain normal amount, indicating relative succulence and immaturity, they were positively injurious to the animals. So marked was the variation of result according to the condition of maturity or otherwise of of the foods employed, that, when reviewing the results of the experiments which had up to that time been conducted, in a paper read before this Section of the British Association at the Belfast meeting in 1852 (and which was published in full in the annual volume [2]), we stated that the mode of estimating the amount of proteine compounds by multiplying the percentage of nitrogen by 6·3 was far from accurate, especially when applied to succulent vegetable foods, and that the individual compounds ought to be determined. The Rothamsted laboratory staff was however much smaller then than it is now, and with the pressure of many other subjects upon us, it was at that time quite impossible to follow up the inquiry in that direction.

It is indeed only within the last ten years or so that the question has been taken up at all systematically; but we are already indebted to E. Schulze, A. Urick, Church, Sachsse, Maercker, Kellner, Vines, Emmerling, and others, for important results relating to it.

Our knowledge in regard to the subject is however still very imperfect. But it is in progress of investigation from two distinctly different points of view—from that of the vegetable physiologist and that of the agricultural chemist. The vegetable physiologist seeks to trace the changes that occur in the germination of the seed, and during the subsequent life-history of the plant, to the production of seed again. The agricultural

[1] Opening Address in Section B (Chemical Science), at the Swansea meeting of the British Association, by J. H. Gilbert, Ph.D., F.R.S., V.P.C.S., F.L.S., President of the Section. Continued from p. 499.

[2] "On the Composition of Foods in relation to Respiration and the Feeding of Animals."

chemist takes the various vegetable products in the condition in which they are used on the farm, or sold from it. And as a very large proportion of what is grown, such as grass, hay, roots, tubers, and various green crops, are not matured productions, it comes to be a matter of great importance to consider whether or not any large proportion of the nitrogenous contents of such products is in such condition as not to be of avail to the animals which consume them in their food?

We cannot say that the whole of the nitrogen in the seeds with which we have to deal exists as albuminoids. But we may safely assume that the nearer they approach to perfect ripeness the less of non-albuminoid nitrogenous matters will they contain; and in the case of the cereal grains at any rate, it is probable that if really perfectly ripe they will contain very nearly the whole of their nitrogen as albuminoids. With regard to some leguminous and other seeds, which contain peculiar nitrogenous bodies, the range may however be wider.

But whatever the condition of the nitrogenous bodies in the seeds we grow or sow, with germination begins a material change. Albuminoids are transformed into peptones, or peptone-like bodies, or degraded into various amido- or other compounds. Such change into more soluble and more diffusible bodies is, it is to be supposed, essential to their free migration, and to their subserviency to the purposes of growth. In the case of the germination, especially of some leguminous seeds, asparagine has been found to be a very prominent product of such degradation of the albuminoids; but it would seem that this disappears as the green parts are developed. But now the plant begins to receive supplies of nitrogen from the soil, as nitrates or ammonia, and it would seem that amides constitute a considerable proportion of the produced nitrogenous bodies, apparently as an intermediate stage in the formation of albuminoids. At any rate, such bodies are found to exist largely in the immature plant; whilst the amount of them diminishes as the plant, or its various parts, approach to maturity.

But not only have we thus, in unripened vegetable productions, a greater or less, and sometimes a very large, proportion of the nitrogenous bodies formed within the plant, existing as amido-compounds, but we may have a large amount existing in the juices as nitric acid, and some as ammonia, &c. Thus, E. Schulze determined the nitric acid in various "roots;" and he found that, in some mangels, more than one-third of the total nitrogen existed in that form, and about one-tenth as much as ammonia. In a considerable series at Rothamsted, we have found an extremely variable proportion existing as nitric acid, according to the size, succulence, or degree of maturity, of the roots; the amount being, as a rule, the least with the ripest and less highly nitrogenous roots, and the most with the most succulent, unripe, and highly nitrogenous ones. In some cases it reached as much as from 20 to nearly 30 per cent. of the total nitrogen. In many other immature vegetable products nitric acid and ammonia have been found; but, so far as I remember, in none in anything like so large a proportion as in the so-called "root-crops," especially mangels. In many, however, the quantity appears to be immaterial; and it is remarkable that whilst there is so much in the "roots," little or none is found in potatoes.

No wonder that, in the experiments already referred to, we found the feeding result to be the worse the more succulent and immature the roots, and the higher their percentage of nitrogen, accordingly.

But it is to the difference in amount of the albuminoid bodies themselves, in different descriptions of vegetable produce, that I wish specially to direct attention, making, however, some reference to what is known of the proportion of the nitrogen existing as amido-compounds.

In some mangels E. Schulze found only from about 20 to 22 per cent. of their total nitrogen to exist as insoluble and soluble albumin. But he found in one case 32·5, and in the other 40·8 per cent. of the total nitrogen as amides. In a large series of determinations at Rothamsted, by Church's method, we found a variation of from under 20 to over 40 per cent. of the total nitrogen of mangels to exist as albuminoids; or, in other words, from nearly 60 to over 80 per cent. of it in the non-albuminoid condition.

In potatoes Schulze found from under 50 to 65 per cent. of the total nitrogen as soluble and insoluble albumin, and from 27·7 to 49·1 per cent. as neutral and acid amides. In a series of potatoes grown at Rothamsted, under very various conditions as to manuring, and in two different seasons, we found the nitrogen as albuminoids to range from little over 50 to more than 71 per cent. of the total nitrogen, leaving, of course, from less than 30 to nearly 50 per cent. to be accounted for in other ways.

Kellner determined the amount of nitrogen as albuminoids, and as amido-compounds, in a considerable series of green foods, both leguminous and gramineous, cut at different stages of their growth. The proportion of the total nitrogen not as albuminoids was, upon the whole, greater in the leguminosæ than in the gramineæ. In both, however, the proportion as albuminoids increased as the plants approached to maturity. The proportion as albuminoids was in all these products very much larger than in roots, and generally larger than in potatoes. In the case of first-crop meadow-hay we found in the separated gramineous herbage 76·4, in the leguminous herbage 82, and in the miscellaneous herbage 80·3 per cent. of the nitrogen as albuminoids; and in the second crop 86·2 per cent. in the gramineous, 88·3 per cent. in the leguminous, and 88·1 per cent. in the miscellaneous herbage. How far the higher proportion of the nitrogen as albuminoids in the second crops is to be taken as any indication of the characteristics of the autumn growth, or how far it is to be attributed to the accidental condition of the weather, may be a question.

These illustrations are sufficient to give some idea of the range and proportion of the nitrogen in different feeding crops which does not exist as albuminoids; and they are sufficient to show that a very large proportion of the non-albuminoid matter exists as various amido-compounds. The question arises, therefore, whether these bodies contribute in any way to the nutrition of the animals which feed upon them? We have but little experimental evidence on this point. As green herbage is the natural food of many descriptions of animal, we might suppose that characteristic constituents of it would not be without some value as food; but the cultivated root crops are much more artificial productions, and it is in them that we find such a very large proportion of non-albuminoid nitrogen. With respect to some of the amido compounds, at any rate, direct experiments seem to show that they are digested in the animal body, and increase the elimination of urea. Weiske and Schrodt found that rabbits receiving, as their only nitrogenous food, either asparagine or gelatin, wasted and died; but a rabbit receiving both asparagine and gelatin increased in weight and survived to the end of the experiment, which lasted seventy-two days. From the results of other experiments made with sheep, they concluded that both asparagine and gelatin protect the albuminoids of the body from oxidation.

These considerations lead me, in conclusion, to refer briefly, and I promise it shall be as briefly as is consistent with clearness, to the two very much disputed questions of *the origin of muscular power*, and *the sources of the fat of the animal body*. These subjects Mr. Lawes and myself have frequently discussed elsewhere; but as the controversy has assumed a new phase quite recently it seems desirable and appropriate that I should recur to it on the present occasion.

With regard to the question of the sources in the food of the fat of the animal body, Liebig originally maintained that although fat might be formed from the nitrogenous compounds within the body, the main source of it in the herbivora was the carbohydrates. In his later writings he sharply criticised the experiments and arguments of those who have maintained the formation of fat chiefly from the proteine compounds, but he at the same time seems to attach more importance to that source than he formerly did. He gives it as his opinion that the question cannot be settled by experiments with herbivora. He adds that what we know with certainty is that, with these animals, albuminates and carbohydrates work together to produce fat; but whether the non-nitrogenous product, fat, has its origin in the albumin or in the carbohydrate he considers it not easy to determine.

At the time when we commenced our experiments on the feeding of animals in 1847 the question whether the fat of the animals fed for human food was mainly derived from albuminoids or from carbohydrates had been scarcely raised, or at least it was not prominent. The question then was rather—whether the herbivora received their fat ready formed in their food, or whether it was produced within the body—the latter view being that which Liebig had so forcibly urged, at the same time maintaining that at any rate its chief source was the carbohydrates. Accordingly our experiments were not specially arranged to determine whether or not the whole of the fat produced could or could not be derived from the albuminoids.

For each description of animal, oxen, sheep, and pigs, such

foods as had been established by common experience to be appropriate were selected. The general plan of the experiments was to give to one set a fixed amount of a recognised good food, containing known quantities of nitrogen, fatty matter, &c., to another set the same amount of another food, of different characters in these respects; to other sets also fixed amounts of other foods in the same way; and then there was given to the whole series the same complementary food *ad libitum*. Or, to one set was supplied a uniform food rich in nitrogen, and to others uniform foods poorer in nitrogen, and so on, in each case *ad libitum*.

It will be seen that in this way a great variety of dietaries was arranged, and it will be observed that in each case the animals themselves fixed their consumption according to the requirements of the system.

As already indicated, the individual nitrogenous and non-nitrogenous compounds of the foods were not determined. As a rule, the constituents determined were—the total dry matter, the ash, the fatty matter, and the nitrogen; from which last the amount of nitrogenous compound it might represent was calculated by the usual factor. But, as already said, the results so obtained were only used with considerable reservation, especially in the case of all immature vegetable produce. Nor was the crude fibre determined; but, as in the case of the estimated nitrogenous substance, when interpreting the results, it was always considered whether or not the food contained much or little of probably indigestible woody matter.

The animals being periodically weighed, we were thus able to calculate the amounts of the so-estimated nitrogenous substance, and of the total non-nitrogenous substance, including and excluding fat, consumed—*for a given live-weight within a given time*, and *to produce a given amount of increase in live-weight*.

Experiments were made with a large number of sheep and a large number of pigs. And, even without making allowance for the different condition of the nitrogenous or of the non-nitrogenous constituents, in comparable foods, the results so uniformly indicated that, both the amount consumed by a given live-weight of animal within a given time, and that required to produce a given amount of increase, were determined much more by the amount of the non-nitrogenous than by that of the nitrogenous constituents which the food supplied. And when allowance was made for the different condition of the nitrogenous constituents, and for the greater or less amount of the non-nitrogenous ones which would probably be indigestible and effete, the indications were still more remarkable and conclusive.

In very many cases the animals were slaughtered, and carefully examined as to whether the tendency of development had been more that of growth in frame and flesh, or in fatness. Here, again, the evidence was clear, that the tendency to growth in frame and flesh was favoured by a high proportion of nitrogen in the food, and that to the production of fat by a high proportion of digestible non-nitrogenous constituents.

In a few cases the actual amount of fat in the animals in the lean, and in the fat condition, was determined; and the results admitted of no doubt whatever that a very large proportion of the stored-up fat could not have been derived from the fatty matter of the food, and must have been produced within the body.

So decisive and consistent were the very numerous and very varied results in regard to these points, that we had no hesitation in concluding—not only that much of the fat stored up was produced within the body, but that the source of much, at any rate, of the produced fat must have been the non-nitrogenous constituents of the food—in other words, the *carbohydrates*.

As already stated, however, as the question whether the source of the produced fat was the proteine compounds or the carbohydrates was not then prominent, we had not so arranged the experiments as to obtain the largest possible increase in fat with the smallest possible supply of nitrogenous compounds in the food, nor did we then even calculate whether or not there was sufficient nitrogenous matter consumed to be the source of the whole of the fat produced.

This question, indeed, excited very little interest, until, at a meeting of the Congress of Agricultural Chemists held at Munich in 1865 (at which I happened to be present), Prof. Voit, from the results of experiments made in Pettenkofer's respiration apparatus with dogs fed on flesh, announced his conclusion that fat must have been produced from the nitrogenous substance, and that this was probably the chief, if not the only, source of the fat, even of herbivora—an opinion which he subsequently urged much more positively.

In the discussion which followed the reading of Prof. Voit's paper, Baron Liebig forcibly called in question his conclusions; maintaining not only that it was inadmissible to form conclusions on such a point in regard to herbivora, from the results of experiments made with carnivora, but also that direct quantitative results obtained with herbivorous animals had afforded apparently conclusive evidence in favour of the opposite view.

Voit's paper excited considerable controversy, in which Mr. Lawes and myself joined. We maintained that experiments to determine such a question should be made not with carnivora or omnivora fed on flesh, but with herbivora fed on their appropriate fattening food, and on such herbivora as common experience showed to be pre-eminently fat-producers. We pointed out[1] that the pig comprised, for a given live-weight, a comparatively small proportion of alimentary organs and contents; that, compared with that of the ruminants, his food was of a high character, yielding, for a given weight of it, much more total increase, much more fat, and much less necessarily effete matter; that, in proportion to his weight, he consumes a larger amount of food, and yields a larger amount, both of total increase and of fat, within a given time; and, lastly, that he contains a larger proportion of fat, both in a given live-weight and in his increase whilst fattening.

It is obvious that with these characteristics there is much less probable range of error in calculating the amount and the composition of the increase in live-weight in relation to the amount and composition of the food consumed, than in the case of ruminants; and that therefore the pig is very much more appropriate for the purpose of experiments to determine the sources in its food of the fat it produces.

Accordingly we calculated a number of our early experiments made with pigs, to determine whether or not the nitrogenous substance they consumed was sufficient for the formation of the fat they produced. For simplicity of illustration, and to give every possible advantage to the view that nitrogenous substance might have been the source of the produced fat, we assumed the whole of the crude fat of the food to have been stored up in the animal—thus estimating a minimum amount to be produced. Then again we supposed the whole of the nitrogenous substance of the food to be perfectly digested, and to become available for the purposes of the system. Lastly, after deducting the amount of nitrogenous substance estimated to be stored up as such, the whole of the remainder was reckoned to be so broken up that no other carbon-compounds than fat and urea would be produced.

The result was that, even adopting these inadmissible assumptions in all the cases in which, according to common experience, the food was admittedly the most appropriate for the fattening of the animal, the calculation showed that a large amount of fat had been produced which could not have been derived from the nitrogenous substance of the food, and must therefore have had its source in the carbohydrates. Such a result is moreover entirely accordant with experience in practical feeding.

Reviewing the whole subject in great detail in 1869, Prof. Voit refers to these results and calculations. He confesses that he has not been able to get a general view of the experiments from the mass of figures recorded, and from his comments he shows that he has on some points misunderstood them. He admits, however, that as the figures stand, it would appear that fat had, in some instances, been derived from the carbohydrates. Still, he says, he cannot allow himself to consider that a transformation of carbohydrates into fat has thus been proved.

Prof. Emil von Wolff again in his "Landwirthschaftliche Fütterungslehre," referring to the same experiments, admits that they are almost incomprehensible unless we assume the direct concurrence of the carbohydrates in the formation of fat. He nevertheless seems to consider that evidence of the kind in question is inconclusive; and he suggests that experiments with pigs should be made in a respiration apparatus to determine the point.

Mr. Lawes and myself entertained, however, the utmost confidence that the question was of easy settlement without any such apparatus, provided only suitable animals and suitable foods were selected. I, accordingly, gave a paper on the subject in the *Section für Landwirthschaft- und Agricultur-Chemie*, at the Naturforscher Versammlung, held at Hamburg

[1] "On the Sources of the Fat of the Animal Body," *Phil. Mag.*, December, 1866.

in 1876.[1] The points which I particularly insisted upon were—that the pig should be the subject of experiment; that he should be allowed to take as much as he would eat of his most appropriate fattening food, so that his increase, and the fat he produced, should bear as large a proportion as possible to his weight, to the total food, and to the total nitrogenous substance consumed. Finally, it was maintained that, if these conditions were observed and the constituents of the food determined, and those of the increase of the animal estimated according to recognised methods, the results could not fail to be perfectly conclusive without the intervention either of a respiration apparatus or of the analysis of the solid and liquid matters voided.

Results so obtained were adduced in proof of the correctness of the conclusions arrived at. We at the same time admitted that although, for reasons indicated, we had always assumed that fat was formed from the carbohydrates in the case of ruminants as well as of pigs, yet, as in our experiments with those animals we had supplied too large amounts of ready-formed fat, or of nitrogenous matter, or of both, it could not be shown so conclusively, by the same mode of calculation in their case as in that of pigs.

In the discussion which followed, Prof. Henneberg agreed that it seemed probable that fat could be formed from the carbohydrates in the case of pigs. In the case of experiments with other animals, however, the amount of fat produced was too nearly balanced by the amount of fat and albuminous matters available, to afford conclusive evidence on the point.

Quite recently Prof. Emil von Wolff (*Landwirthschaftliche Jahrbücher*, Band viii. 1879, Supplement) has applied the same mode of calculation to results obtained by himself with pigs some years ago. He concluded that the whole of the body fat could not have been formed without the direct co-operation of the carbohydrates of the food. But what is of greater interest still is that he also calculated in the same way the results of some then quite recent experiments of Henneberg, Kern, and Wattenberg, with sheep. He thus found that, even including the whole of the estimated amides with the albumin, there must have been a considerable production of fat from the carbohydrates; and, excluding the amides, the amount reckoned to be derived from the carbohydrates was of course much greater.

I will only add, on this point, that on recalculating some of our early results with sheep, which did not afford sufficiently conclusive evidence when the whole of the nitrogen of the food was reckoned as albumin, show a very considerable formation of fat from the carbohydrates if deduction be made for the probable amount of non-albuminoid nitrogenous matter of the food.

We have now, then, the two agricultural chemists of perhaps the highest authority, both as experimenters and writers on this subject on the continent, giving in their adhesion to the view, that the fat of the herbivora, which we feed for human food, may be, and probably is, largely produced from the carbohydrates. I dare say, however, that some physiologists will not change their view until Voit gives them sanction by changing his, which, so far as I know, he has not yet done.

The question which has been currently entitled that of "The Origin of Muscular Power," or "The Sources of Muscular Power," has also been the subject of much investigation, and of much conflict of opinion, since the first publication of Liebig's views respecting it in 1842.

As I have already pointed out, he then maintained that the amount of muscular tissue transformed, the amount of nitrogenous substance oxidated, was the measure of the force generated in the body. He accordingly concluded that the requirement for the nitrogenous constituents of food would be increased in proportion to the increase of the force expended. In his more recent writings on the subject, he freely criticises those who take an opposite view. He nevertheless grants that the secretion of urea is not a measure of the force exerted; but, on the other hand, he does not commit himself to the admission that the oxidation of the carbohydrates is a source of muscular power.

The results of our own early and very numerous feeding experiments were, as has been said, extremely accordant in showing that, provided the nitrogenous constituents in the food were not below a certain rather limited amount, it was the quantity of the digestible and available non-nitrogenous constituents, and not that of the nitrogenous substance, that determined—both *the amount consumed by a given live-weight within a given time*, and *the amount of increase in live-weight produced*. They also showed that one animal, or one set of animals, might consume two or three times as much nitrogenous substance in proportion to a given live-weight within a given time as others in precisely comparable conditions as to rest or exercise. It was further proved that they did not store up nitrogenous substance at all in proportion to the greater or less amount of it supplied in the food, but that the excess reappeared in the liquid and solid matters voided.

So striking were these results, that we were led to turn our attention to human dietaries, and also to a consideration of the management of the animal body undergoing somewhat excessive labour, as, for instance, the hunter, the racer, the cab-horse, and the foxhound, and also pugilists and runners. Stated in a very few words, the conclusion at which we arrived from these inquiries (which were summarised in our paper given at Belfast in 1852) was, that unless the system were overtaxed, the demand induced by an increased exercise of force was more characterised by an increased requirement for the more specially respiratory, than for the nitrogenous, constituents of food.

Soon afterwards, in 1854, we found by direct experiments with two animals in exactly equal conditions as to exercise, both being in fact at rest, that the amount of urea passed by one feeding on highly nitrogenous food was more than twice as great as that fed on a food comparatively poor in nitrogen.

It was clear therefore that the rule which had been laid down by Liebig, and which has been assumed to be correct by so many writers, even up to the present time, did not hold good—namely, that "The sum of the mechanical effects produced in two individuals in the same temperature is proportional to the amount of nitrogen in their urine; whether the mechanical force has been employed in voluntary or involuntary motions, whether it has been consumed by the limbs or by the heart and other viscera"—unless, indeed, as has been assumed by some experimenters, there is, with increased nitrogen in the food, an increased amount of mechanical force employed in the "involuntary motions" sufficient to account for the increased amount of urea voided.

The question remained in this condition until 1860, when Bischoff and Voit published the results of a long series of experiments made with a dog. They found that, even when the animal was kept at rest, the amount of urea voided varied closely in proportion to the variation in the amount of nitrogenous substance given in the food—a fact which they explained on the assumption that there must have been a corresponding increase in the force exercised in the conduct of the actions proceeding within the body itself in connection with the disposal of the increased amount of nitrogenous substance consumed. Subsequently, however, they found that the amount of urea passed by the animal was, with equal conditions as to food, &c., no greater when he was subjected to labour than when at rest; whilst, on the other hand, the carbonic acid evolved was much increased by such exercise. They accordingly somewhat modified their views.

In 1866 appeared a paper by Professors Fick and Wislicenus, giving the results obtained in a mountain ascent. They found that practically the amount of urea voided was scarcely increased by the labour thus undertaken. Prof. Frankland gave an account of these experiments in a lecture at the Royal Institution in the same year; and he subsequently followed up the subject by an investigation of the heat developed in the combustion of various articles of food, applying the results in illustration of the phenomena of the exercise of force.

Lastly, Kellner has made some very interesting experiments with a horse at Hohenheim, the results of which were published last year. In one series the experiment was divided into five periods, the same food being given throughout; but the animal accomplished different distances, and drew different weights, the draught being measured by a horse-dynamometer. The changes in live-weight, the amount of water drunk, the temperature, the amount of matters voided, and their contents in nitrogen, were also determined.

The result was that with only moderate labour there was no marked increase in the nitrogen eliminated in the urine; but that with excessive labour the animal lost weight and eliminated more nitrogen. Kellner concluded, accordingly, that, under certain circumstances, muscular action can increase the transformation of albumin in the organism in a direct way; but that, nevertheless, in the first line is the oxidation of the non-nitrogenous matters—carbohydrates and fat, next comes in requisition the circulation-albumin, and finally the organ-albumin is attacked.

In reference to these conclusions from the most recent experi-

[1] The substance of that communication is given in the *Journal of Anatomy and Physiology*, vol. xi. part iv.

ments relating to the subject, we may wind up this brief historical sketch of the changes of view respecting it, with the following quotation from our own paper published in 1866:[1]—". . . all the evidence at command tended to show that by an increased exercise of muscular power there was, with increased requirement for respirable material, probably no increased production and voidance of urea, unless, owing to excess of nitrogenous matter in the food, or a deficiency of available non-nitrogenous substance, or diseased action, the nitrogenous constituents of the fluids or solids of the body were drawn upon in an abnormal degree for the supply of respirable material."

In conclusion, although I fully agree with Voit, Zuntz, Wolff, and others, that there still remains much for both Chemistry and Physiology to settle in connection with these two questions of "The Sources of the Fat of the Animal Body" and "The Origin of Muscular Power," yet I think we may congratulate ourselves on the re-establishment of the true faith in regard to them, so far at least as the most important practical points are concerned.

[1] Food in its relations to various exigencies of the animal body.—*Phil. Mag.*, July.

THE GERMAN ASSOCIATION

THE fifty-third congress of the Association of German Naturalists and Physicians has been held at Danzig during the past week. At the first general meeting on Saturday, September 18, Dr. H. Abegg, who filled the post of president, in a brief speech of welcome to his colleagues expressed his pleasure at finding that the congress was so numerously attended. There had been fears that Danzig, owing partly to its somewhat isolated position, would have kept many from visiting it who would otherwise have come, had the point of meeting been fixed in a more southerly part of Germany. But these fears were wholly groundless; from far and near he was rejoiced to see additions to their body; and to all and each of his esteemed colleagues he bade hearty welcome.

Herr von Ernsthausen, Prof. Bail, and the Chief Burgomaster of Danzig, also gave short addresses, in which they confirmed the sentiments of the President.

So far as the reports in the admirable *Tageblatt* go, the following are some of the principal papers and lectures:—

The first paper read was by Prof. Hermann Cohn of Breslau, "On Writing, Type, and the Increase of Shortsightedness." Myopia, *i.e.*, shortsightedness, or the inability to distinguish objects at a distance, was, as he said, rarely or never born with the subject; it is generally induced by an injurious method of study which strains the eye during childhood. In 1865 the Professor began to collect statistics such as the schools in his own native town offered to him, and from these he was able to establish the following facts:—

1. That cases of shortsightedness occur rarely in village schools; their frequency increases in proportion to the demand made upon the eye in higher schools and colleges; so that in gymnasia myopia is most prevalent.

2. That the number of shortsighted scholars in all schools and colleges increases in proportion as one examines the higher grades or classes.

3. That the average of myopia increases from class to class; *i.e.*, those who are shortsighted become more and more so.

These conclusions have since met with universal confirmation. Among the causes which tend to increase the malady, the Professor specified school-desks constructed regardless of hygienic principles, lesson-books of which the typography is cramped and indistinct, and badly and insufficiently lighted schoolrooms. All these as they now existed were more or less unsatisfactory, and could bear alteration with perceptible benefit to the scholar. Indeed to make reforms in this direction was, as he showed, the duty of the State; and he hoped that a Government commission might ere long be appointed to regulate the construction of school-desks, the typography of lesson-books, and the lighting of class-rooms. By this means the evil which was so rapidly increasing might be met, and the percentage of shortsightedness thereby reduced to a far lower minimum than was at present the case.

The next address was given by Prof. Eduard Strasburger of Jena, "On the History and the present State of the Cell Theory." Having sketched at some length the growth and the development of this theory, the learned professor remarked in conclusion:—

"The results of research into cell-structure are well adapted to teach us a great deal about the complicated nature of the fundamental substance of life; and complicated this must be, to produce such a series of phenomena in constant succession. We have merely to accustom ourselves to regard protoplasm, not as a simple substance, but, on the contrary, as a highly organised body, or we have otherwise no means of explaining the phenomena of life. It is at any rate a fact that a lump of protoplasm, the ovum, is capable, after union with another particle of protoplasm, of reproducing the entire parent organism in its complicated structure. That the properties of an egg are not essentially different from those of other protoplasm, but that rather only one part of the protoplasm in the egg is specially suited for reproduction is proved by the fact that other masses of protoplasm in the organism become often capable of reproducing it in a perfect form. The behaviour of *Begonia* leaves is specially striking; and I therefore submit a specimen of them to you. It is well known that new plants are engendered from such leaves. Microscopical investigation shows us that in these leaves there are separate epidermal cells which reproduce the whole plant; the protoplasm of a single such cell affords, therefore, the basis for an entirely new organism. Thus the process does not differ in principle from the formation of a germ from the egg.

"The attributing of all the functions of life to protoplasm is to be looked upon as a great advance in science; although it is impossible for us, so far, even to form hypotheses with regard to the forces which are at work in the protoplasm. It will be the task of the future to throw light upon this side of the question. Shall we ever be able to gain a deeper insight into the final, the invariable causes of life? At the present it were futile to attempt this. The progress which science has made in the last ten years, often yielding quite unexpected results, leads us to hope for yet further advance; and in the seeking for knowledge, rather than in its final acquisition, it is that our highest pleasure lies."

In the sectional sitting for Mathematics and Astronomy held on the following Monday, September 20, Director B. Ohlert read a paper "On the Rapid Motion of the inner Moon of Mars in the light of Laplace's Theory." He pointed out that the fact that the inner moon of Mars passes round the planet in a far shorter time than the latter needs for rotation on its own axis would seem to be in contradiction to the hypothesis of Laplace on the origin of our planetary system. The lecturer further showed that there was nothing very remarkable in the *rapidity of the motion of this moon*, which, owing to the slight distance from Mars, was wholly in agreement with the third law of Kepler; but rather that an explanation was needed of the *slow axial motion of the planet itself*, and similarly of the other planets. And hereupon Prof. Ohlert adduced proofs from which, according to his view, and in conformity with the assumption of Laplace, the rapidity of the axial motion of the planets in the final period of their formation would of necessity become diminished.

Dr. Franz then followed with a paper "On the Observation of Double-Stars made at the Königsberg Observatory, and on certain Peculiarities of the Königsberg heliometer."

The Section for Anthropology and Prehistoric Research held a sitting on the same day, with Dr. Stieda in the chair. Dr. Anger of Elbing exhibited a rich collection of anthropological specimens, chiefly illustrating the antiquity of the district.

In the Botanical Section Prof. Bail read a valuable paper "On Underground Fungi," in which he stated that the several species and varieties of these in Germany must certainly exceed the usually accepted number.

Prof. Moebius of Kiel, in the Section for Zoology and Comparative Anatomy, read (also on the same day) an interesting monograph "On the Importance of the Foraminifera for the Doctrine of Descent."

He began by quoting Dr. Carpenter's view that the genera and species of the Foraminifera cannot be determined after the usual method, but that the only natural classification of the great mass of different forms is to arrange them in accordance with their degree of relationship. Prof. Moebius himself had come to the conclusion from his researches among the Foraminifera which he had collected in Mauritius in 1874 that the repeatedly occurring peculiarities among the Foraminifera may serve and must serve us in forming an idea of their nature and zoological position.

The sarcode of the Foraminifera behaves with regard to the formation of the skeleton and shell just as does the protoplasm of the eggs of the Metazoa to the formation of the germs and of all organs proceeding from them. Like the protoplasm of the egg, it possesses a quite definite and hereditary capacity for self-development.

As confirmatory of Darwin's theory of descent, they possess a value neither greater nor less than that of all other animal classes. The lecturer's forthcoming work on the Foraminifera of Mauritius will contain much detailed evidence in support of his views.

In the discussion which followed, Herr Wacker suggested that the point of difference between Carpenter and Moebius lay in the fact that Carpenter had regard to the sarcode rather than to the skeleton, to which latter Moebius attached the greater importance.

The second paper was given by Dr. Gabriel, whose subject was "The Classification of the Gregarinæ." He objected to Stein's classification, hitherto the sole and undisputed one, on the grounds that it no longer fully represented the existing state of our knowledge. This view he was able to support, which he did at some length, and submitted to his hearers a new classification of his own.

In the Section for Anatomy and Physiology Prof. Tauber of Jena lectured upon "Two New Anæsthetics," with which he had experimented upon frogs, rabbits, and dogs. Both anæsthetics produced a scarcely appreciable change in the pulse and respiration, on which account they might be of great value for surgery. And in demonstration of their action Dr. Tauber proceeded to experiment upon a pigeon and a rabbit.

On Tuesday, September 21, at the second general sitting, Prof. Moebius of Kiel read a paper "On the Food of Marine Animals." In the sea therefore is generated by far the greater number of animal types, and these again in quantity and in bulk are throughout regulated by the existing supply of nourishment. This in its turn depends upon the organic matter of plants, which in the sea also supply nourishment to its inhabitants. In our own seas, the North Sea and the Baltic, marine grasses are discoverable near the coast, while twenty to fifty metres lower are other kinds of plants; deeper still, if we search, we shall find few or none. Loose strips of plants that have been torn away from their roots have been brought up from a depth of some hundred metres; in the Baltic and the North Sea these form a dark, soft, spongy mass. Nothing living is visible in this if placed in a tub; but if strained through a sieve, tiny mussels, snails, and crustacea become visible. In the depths of the sea-mud lining the bottom are countless worms, mussels, and little animals which feed upon the spongy mass. Flounders and other fish penetrate into these mud-depths and devour the animals that are there. Where the sea-bottom however is formed of soft clay, nothing beyond a few worms here and there will be found. Thus in the deeper portions of the Mediterranean, otherwise so rich in animal life, nothing at all is discoverable. The Professor in the course of his remarks went on to show that the supply of nourishment to the inhabitants of the sea was now and would be hereafter undiminished; and thus that the propagation of animal life in the sea would continue unchecked, so long as the mighty ocean itself should last.

SCIENTIFIC SERIALS

Bulletin de l'Academie Royale des Sciences (*de Belgique*), No. 7.—A Hyperoodon captured on the strand at Hillion (Côtes-du-Nord, France) in December, 1879, by M. van Beneden.—On Mysticetes with short fins, from the sands in the neighbourhood of Antwerp, by the same.—On determination of albuminoid substances of the blood serum by circumpolarisation (modified method of Hoppe Seyler), by M. Fredericq.—Contribution to a study of the *rôle* of insects in the pollinisation of heterostylous flowers (*Primula elatior*), by Mr. MacLeod.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, September 20.—M. Wurtz in the chair.—The following papers were read:—On the odours of Paris, by M. Sainte-Claire Deville. He analysed some of the moist black earth exposed in a trench in the Rue St. Jacques. The amount of salts in the impregnating liquid indicates considerable concentration (which can be easily explained). The dust from horses' shoes and from wheels of vehicles is thought to be the origin of sulphides and protoxide of iron, and of the dark coloration. The escape of gas, estimated at about a tenth of the gas circulating in the pipes, furnishes part of the sulphur, the carbonated hydrogen and the coal-tar which abounds. Through this escape the sub-soil is rendered wholesome (in the author's opinion), and cannot exhale any dangerous odour. There is a slight smell of sulphuretted hydrogen (not worse than that from sulphurous mineral waters), and a smell of healthy empyreumatic products.—M. de Tchihatchef presented a work of his on Spain, Algeria, and Tunis, but treating chiefly of Algeria. Such questions as the material and moral results of the annexation to France, the mode of action of the new administrative and social institutions, the assimilation of the Arab and the Christian elements, &c., are treated; the author has also studied the geology and botany of the country.—Observations of the new planet Coggia (287) at the Paris Observatory (equatorial of the western tower), by M. Bigourdan.—On a new experiment for showing the direction of the rotation communicated by bodies to polarised light, by M. Govi. A pure spectrum is produced with rectilinearly polarised light, and a plate of rock crystal is interposed, giving a dark band; also an analyser. The spectrum and analyser have a joint movement of rotation (one end of the spectrum being at the centre of the circle of which the spectrum represents the radius). The dark band moves along the spectrum (during rotation) one way or the other according to the nature of the quartz plate (dextrogyrous or lævogyrous). If the motion be sufficiently rapid for the impression on the eye to be continuous, one may trace out in space, or on a screen, opposite spirals. Curious variations are obtained by interposing plates of mica, gypsum, &c.—Study of telluric lines of the solar spectrum (Nice Observatory), by M. Thollon. With his powerful spectroscope, he has resolved the telluric groups B, D, and *a* of Ångström into their simple elements, separating these elements from each other, and from the other metallic lines.—On the liquefaction of ozone and on its colour in the gaseous state, by MM. Hautefeuille and Chappuis. They passed some highly ozonised oxygen (prepared by their new process) into a Cailletet apparatus. From the first strokes of the piston the capillary tube appeared azure blue. With several atmospheres' pressure the gas became of an indigo blue, the mercury meniscus looking steel blue through it. Sudden liberation from 75 atm. produced a mist, indicating liquefaction (300 atm. were necessary in the case of oxygen). Ozone is a little less easy to liquefy than carbonic acid. If the ozonised oxygen be not compressed slowly and in cold, the ozone is decomposed, giving a strong detonation and a yellowish flash. Thus the mixture contains an explosive gas.—On Brunton's tunnelling machine, by M. Biver. This gives an account of results with the machine as used in the lignite pits in the Fuveau Valley. It appears, *inter alia*, that of 51 horse-power of the motor only 12·4 was transmitted to the machine, 38·6 being lost.—Telescope with double action for pointing long-range guns, by M. de Broca.—On losses in manufacture of vinegar, by M. Garcin.

THE PLACE OF SCIENCE IN EDUCATION

THERE has been a great deal said and written on the subject of education during the past week. First of all we have the important address of Prof. Huxley at the opening of the Mason College, Birmingham, which we give in full on another page; then there is the brief but significant address of Sir Stafford Northcote at Tiverton; and lastly, the summary of Sir Charles Reed of the ten years' work of the London School Board. All this has furnished ample food for comment in the daily papers, and their misconceptions as to the real drift of Prof. Huxley's address must be amusing to those who know what science really means, and what are the opinions held by reputable men of science as to what constitutes sound and complete education. With regard to the institution which has been so generously founded and handsomely endowed by Sir Josiah Mason at Birmingham, it should be remembered that there was no intention to start it as a university. Its founder has had to push his way through life, and notwithstanding the unusual success of his career, he confesses that he has but little faith in the rule-of-thumb method, which was often his only guide. At every step, he admits, he was hampered and hindered by the want of scientific knowledge, by his ignorance of those exact methods, those laws and facts, which can only be satisfactorily acquired and utilised by a preliminary scientific training. Even at his advanced age the consciousness of this want is so strongly impressed upon him that, with true benevolence and rare generosity, he has founded the magnificent institution at Birmingham which was opened last Friday, in order that succeeding generations of boys may have a chance of equipping themselves at the outset with those weapons of precision, the want of which he who has fought successfully the battle of life had to deplore at every step. The Mason College at Birmingham is not a mere technical institute, as may be seen from our article in NATURE, vol. xxii. p. 514, in which the course of instruction provided is described. All departments of science are provided for, as well as certain special applications of some of them; the great principles and facts of these sciences first, and their special application afterwards. Wisely also the founder has provided for instruction in the English, French, and German languages; and even, as Prof. Max Müller stated in his brief but admirable address at the luncheon, for Greek and Latin. The deed of foundation makes ample provision for the widening of the programme, the extension of the subjects taught, and the adaptation of the institution to the times. Special reference is made to art, which will no doubt be added. At the same time the founder excludes from his programme "mere literary education." It is, we suppose, this exception—which looking at the programme of the College, seems to us somewhat vague—that has led the daily press to misconceive Prof. Huxley's address as a defence of science as a means of education, to the entire exclusion of literature. What Prof. Huxley maintains, as we read his address, and as we read his other utterances on the same point, is, that if a man is to have an education in only one aspect of things, then by all means let it be the scientific aspect; on the other side he can educate himself at his leisure, whereas, as Sir Josiah Mason forcibly testifies, when a man gets into the thick of the fight, it is all but impossible for him to make up for the want of scientific training in his youth. As a mental discipline and a means of culture science by itself is as good an implement as literature by itself, and probably a great deal better, as the former takes us into the very heart of nature in its widest sense, while the latter only deals with the outside of things. At the same time Prof. Huxley expressly states that exclusive training in either the one direction or the other is essentially lop-sided, and not to be encouraged; that it is essential to the completeness of a man's culture that it should have an æsthetic and literary, as well as a scientific side; and what other opinion could be held by one who himself seems familiar with "the best that has been said and thought" in all the languages of culture. We are much mistaken if Prof. Huxley would not endorse every word spoken by Prof. Max Müller, on the necessity for the study of the science of man, the science of thinking and of speaking, to a completely liberal education. The truth is that there is a widespread misconception as to what science really means; we have been so long accustomed to apply the term to certain groups of concrete facts, that we forget that it may be applied, and indeed is now frequently applied, to any branch of knowledge investigated on the method which has been so fruitful in the study of physical phenomena. Science indeed is merely the counterpart of sentiment; each of them has its proper place, and each of them is indispensable to the complete development of the human mind. To neglect training on either the one side or the other must produce an imperfect, a lop-sided result; but there is no reason why either should be neglected. Let the programme of elementary education only be developed in the direction so long advocated by Sir John Lubbock and those who think with him, and let the whole of the education of the country up to our colleges and universities be carried out on the same lines, and every side of the human constitution and every aspect of human learning will have fair play. Prof. Huxley did well to defend science as a method of mental discipline certainly equal to the old and merely literary methods which so long prevailed at our universities, and which have been so abused; but his address will be strangely misread if any idea of suppressing the old learning is attributed to him. It is interesting to notice that Sir Stafford Northcote, in his short address at Tiverton, followed the plan of that of Prof. Huxley, beginning by strenuously advocating the spread of scientific education in the country as the only means by which we can be able to cope with our neighbours, and concluding by maintaining that it would be a serious mistake to suppress literary training entirely. This is what we have all along maintained in these pages, and we are sure that Prof. Huxley is on our side. Science has had a hard fight to obtain a place in the education of the country, and she has not yet obtained the place she is entitled to; she will only have done so when in all our educational institutions she holds a position of perfect equality alongside of the subjects which until recently monopolised our

schools and colleges, and we trust that when another decade's work of the London or any other School Board has to be summarised, the so-called extra subjects will have become an integral part of the elementary education of the country. Such institutions as that opened at Birmingham will greatly help on the cause of scientific education. The standard of teaching we are glad to see is high, the best science schools of the Continent being taken as models; and we trust the Mason College will never degenerate into a mere technical training-school. Under the liberal principles for its conduct laid down by the founder, it is capable of the widest development in every direction; whether it may form the nucleus of a Birmingham University remains to be seen. Its working will be watched with the greatest interest by all who have at heart the raising of the standard of education in the country.

CHEMISTRY OF THE CARBON COMPOUNDS

Elements of Chemistry. By William Allen Miller, M.D., &c. Revised and in great part re-written by Henry E. Armstrong, Ph.D., F.R.S., and Charles E. Groves, F.C.S. Part III.—Chemistry of Carbon Compounds, or Organic Chemistry. Section I.—Hydrocarbons, Alcohols, Ethers, Aldehydes, and Paraffinoid Acids. Fifth edition. (London: Longmans, Green and Co., 1880.)

THE study of the laws governing the combinations of molecules containing carbon is of the very first importance to chemical science, inasmuch as this study so well illustrates and extends the general laws of molecular combinations, that is to say, the general laws of the science of chemistry.

An almost innumerable array of facts concerning carbon compounds is to be found in the ordinary text-books; papers in the chemical journals sometimes contain generalisations drawn from certain classes of those facts: the later supplements to Watts's "Dictionary" contain the more important of the comparatively recent generalisations; but there has undoubtedly existed for some time among students of chemistry a wish for a text-book in which the leading facts concerning the compounds of carbon should be clearly stated, the general properties of, and general relation between groups of these bodies should be indicated, and summaries of the evidence in favour of or against the generally adopted structural formulæ of the more important compounds should be presented to the student, in order that he might thus have in one text-book such a fair compendium of the present state of this branch of the science as should furnish him with suggestions for work, by showing him what is clearly known, where exact knowledge ceases, and where even analogy lends but little help.

The first part of such a text-book English chemistry now possesses; let us hope that the second part of this admirable book will soon follow, and be worthy of that now published.

In their preface the editors—had we not better say at once the authors?—write: "Notwithstanding the extraordinary increase in the number of the carbon compounds, their study is gradually becoming simplified as the possibility is extended of arranging them in series and of giving a general description of their chief properties applicable to all the members of the group."

There can be no hesitation in saying that the authors' work—more than any other text-book in the English language—will aid the advance of this, the only true method, of studying Organic Chemistry.

There are text-books of Organic Chemistry which tell the student that the structure of this or that compound "is represented by the following formula"; this book follows another and a better plan: the authors give a succinct and clear sketch of the evidence for and against all important structural formulæ, thus indicating the true value of these formulæ as condensed statements of chemical facts, and at the same time setting before the student examples of the application of the chemical method of inquiry.

The general principles underlying the formation of so-called structural formulæ are adverted to in more than one place by the authors.

These formulæ are based on the laws of "atom-linking," which again are deductions from the theory of quantivalence or valency, itself an outcome of the application of chemical methods of inquiry to the molecular theory of matter.

Although the volume before us is Part III. of a large work, the first part of which deals with chemical physics, it would nevertheless, we think, have been advisable to have given a brief sketch of the molecular theory of matter, and to have shortly stated—but more fully than is done on p. 42—the evidence on which is based the (chemically) all-essential difference between atom and molecule.

A little space might have been spared for an exposition of the laws of atom-linking, such as, but very much more condensed than, that in Lothar Meyer's "Modernen Theorieen."

In speaking of quantivalence, on p. 42, the authors do not explicitly state that it is the *atoms* of the elements which "are equivalent in combining or replacing power to one, two, three, four, five, or six monad atoms of hydrogen." Of course this is implied throughout the discussion which follows, but students sometimes fail clearly to grasp the difference between the old chemistry, which attempted, but failed, to determine equivalent weights of elements, and the new, which is so largely based on the equivalency of groups of atoms of the elements.

Frankland's "bond" explanation of valency is sketched, but so long as we have no definite physical conception of what a "bond" is, this explanation really explains nothing; such an expression as "two of the bonds neutralise each other" has no meaning, further than that the valency varies from a given number to two less than this number.

The authors give some examples of compounds, which seem to show that the valency of certain elementary atoms may vary from an odd to an even number; but they do not give examples which prove such a variation, *e.g.*, $MoCl_5$ and $MoCl_6$; WCl_5 and WCl_6; NO, NO_2, and NH_3.

The authors, probably wisely, do not very definitely express their opinion as to the exact meaning of a structural formula; they sometimes appear to regard these formulæ as real representations of the relative

mode of arrangement of atoms in a molecule, sometimes only as condensed statements of facts of formation and decomposition. If the former view be adopted it becomes a question whether the "structure" represented by the formula is that of the molecule when unacted upon by the molecules of foreign bodies, or only when a certain disposition of its parts has been induced by the action of the molecules of another substance.

Facts are certainly known which are best explained by supposing that a change of some kind precedes that process of complete molecular decomposition usually called a chemical reaction; indeed almost the only feasible hypothesis of chemical action supposes that chemical change—that is, change among the parts of the molecule—may be proceeding without a permanent molecular decomposition taking place. In the section on "Aldehydrols" the authors apparently admit some such hypothesis as this; they do not regard the non-isolation of a compound as proof of the non-existence of that compound; they explain processes of chemical change by supposing the existence of unstable molecular configurations intermediate between more stable and isolable configurations.

Recent work in chemical physics appears to lend some countenance to the idea that structural formulæ may roughly represent the configuration of molecules just previous to their passage into phases of "absolute instability" rather than their configuration when in phases which are themselves "absolutely stable."

Quite recently a distinct advance has been made in molecular theories by the recognition of what might be called *atomic induction*, that is, the influence exerted by one part of a molecule in modifying the chemical function of another part, or other parts, of the same molecule. Illustrations of this "orientation" are to be found in the production of the substituted derivatives of benzene and of the phenols; the generalisations made in these cases are clearly stated by the authors.

A very valuable section on the Van't Hof Le-Bel hypothesis of isomerism is to be found from pp. 983 to 993. (There is evidently an omission of part of a sentence at the top of p. 993.) The authors suggest a slightly modified form of this hypothesis. The fundamental assumption is made in these hypotheses that chemical energy is entirely potential, and that it is wholly due to the arrangement of the parts of the molecules. It seems possible however that chemical energy may be partly potential and partly kinetic, and that if any means could be found for measuring the change of entropy as well as the change of total intrinsic energy of chemical systems in their passage from one standard state to another, some light might be thrown on the question of isomerism.

In their general classification of carbon compounds the authors have adopted a scheme founded on the chemical function of these compounds; they group together hydrocarbons, alcohols, aldehydes, &c. They do not fail to indicate how function is associated with "structure." But in each of these great groups of compounds a classification founded more upon genetic relations is adopted; they consider a group of hydrocarbons, then the haloid derivatives of these hydrocarbons, and so on.

Most admirable tables are appended to all the more important groups; the usefulness of these tables may be illustrated by reference to that on pp. 458-459, wherein the ethylic alcohols are arranged in *really* homologous series.

The acids are classified into various sub-groups, and the dependence of the function of the "acid hydrogen" on the "structure" of the other part of the molecule is indicated.

In speaking of the higher aromatic or "benzenoid" hydrocarbons, the happy expression is used of a closed chain containing "*loops*," and it is pointed out that "the formation of each new loop in the chain of carbon atoms tends to reduce the combining power by two units."

The proof (p. 399) that the carbon atoms in the olefines are not arranged in a closed chain is noteworthy, and may be taken as typical of the authors' method of dealing with such questions; basing a generalisation on carefully collected facts, and then applying their generalisation boldly, but without dogmatism.

The nomenclature of the work before us is much more self-consistent than that adopted in any other treatise on organic chemistry. Certain new names are introduced: thus, the bodies supposed to exist in aqueous solutions of many aldehydes—substances characterised by the groups $CH(OH)_2$—are called *aldehydrols*. A systematic nomenclature for the carbohydrates is proposed: those of the composition $C_6H_{12}O_6$ have names ending in *ose*, glucose being the best known example of this class; those of the composition $C_{12}H_{22}O_{11}$, which like cane-sugar produce two molecules of glucose on inversion, have names ending in *on*, *e.g.*, saccharon; and those which on hydration give rise to the formation of a saccharon have names ending in *yn*, *e.g.*, amylin. As another instance of the authors' attempt to systematise nomenclature may be noted their rules for the use of the Greek letters α, β, &c., in distinguishing isomeric derivatives (pp. 861-2, *note*).

Finally, I would draw attention to the authors' manner of dealing with physical methods of solving chemical problems: the physical method is so described that one cannot forget that it is to be used by a chemist—there is not first a little physics, and then a little chemistry; the problem is clearly chemical, the method only is physical.

A suggestion made in the preface seems most admirable, it is that "Each chemical school" would do well to "make the preparation by its students of certain substances in a state of purity a part of the ordinary course of study, and to give notice that these particular compounds are at the disposal of experts for the determination of physical constants."

Is there any probability of a treatise being written on Inorganic Chemistry conceived in the same spirit and carried out, as far as possible, on general lines similar to those of this most excellent work by Armstrong and Groves?

M. M. PATTISON MUIR

OUR BOOK SHELF

An Elementary Treatise on Solid Geometry. By W. Steadman Aldis, M.A. (Cambridge: Deighton, Bell, and Co., 1880.)

THE term "elementary" diagnoses this handy book to solid geometry from the more thorough works on the same subject by Messrs. Salmon and Frost. It is, to our mind, exceedingly well adapted to the requirements of that large class of students who, whilst requiring an acquaintance with this branch of study, are unable, either

through want of time or the requisite ability, to extend their reading into the more recondite parts discussed by the above-named writers. As a proof that Mr. Aldis's labours have been appreciated, we need only say that this edition, improved by the addition of hints for the solution of some of the examples, is the third.

Familiar Wild Flowers: Figured and described by F. Edward Hulme. 2nd Series. With Coloured Plates. (London: Cassell, Petter, Galpin, and Co.)

WE have already called attention to the appearance of the first volume of this series, and of the second we can speak in equally favourable terms. In selecting for illustration a hundred of our familiar wild flowers, all chosen in some way for their beauty, a certain amount of arbitrariness must be allowed; but in the present instance very little complaint will be made on this head by the majority of readers. The coloured lithographs are somewhat unequal in excellence, but, as a rule, are extremely good. The book is one well adapted to awaken or to foster in young people a love of the floral beauties of our fields and hedges, woods and ditches.

A New and Easy Method of Studying British Wild Flowers by Natural Analysis. By Frederick A. Messer. (London: D. Bogue, 1880.)

THIS work indicates a very large amount of labour on the part of the author; whether the labour has been altogether well applied is another question. For the field botanist whose sole object is to determine the name of a wild flower it will no doubt be useful in assisting him to make out at least the order and genus, for beyond this it does not pretend to go. No botanist will be disposed to depreciate the value of field botany and of the study of critical species, which often leads to further study of some of the great questions connected with the life of plants. There is no doubt that species-botany had been exalted a quarter of a century ago to a far too prominent place by English workers, and had been much too exclusively followed, to the disregard of morphological and especially of physiological work. The inevitable reaction has set in, and is now perhaps at its height, when the number of botanists who have an accurate acquaintance with our British flora is extremely small. As an introductory work for those who are desirous of increasing this number, Mr. Messer's book may be recommended, always provided that the student does not imagine that it will materially help him in his study of the structural and genetic affinities of the different families of plants. The graphic illustrations are novel in design, and will no doubt help to impress the meaning of the technical terms on the beginner. Some few errors should not have been allowed to pass in a work bearing the date of the present year. Among these is the reference of *Selaginella selaginoides* to the genus *Lycopodium*, and the complete suppression of Selaginellaceæ as a British order of vascular cryptogams.

Manual of the Indigenous Grasses of New Zealand. By John Buchanan, F.L.S. (Wellington: James Hughes, 1880.)

THIS is one of those excellent manuals emanating from the Colonial Museum and Geological Survey Department of New Zealand under the admirable direction of Dr. Hector. The work is a reproduction in a handy form of the folio work ordered by the New Zealand Government in 1876, to be prepared "with nature-printed plates and descriptions of each species, and to be accompanied by an essay on the grasses and forage plants likely to prove useful in New Zealand." This explanation is extracted from the preface of the book before us, which preface has been written by Dr. Hector himself. We also learn from the same source that "the whole of the illustrations of the large edition were drawn from nature by Mr. John Buchanan. . . . The condition imposed—that the plates should be nature printed—rendered it necessary in the first instance to publish the work in folio, but, as this large size is both inconvenient and costly, only a small edition has been issued, and the present handy volume has been printed for more general distribution. The plates now given—sixty-four in number, and including eighty-seven different species and varieties of grasses—are reductions by the process of photo-lithography from the original folio plates, and depict the grasses as of one half the natural size of the original specimens."

There can be no doubt but that the book will be very valuable, not only to the botanist, but also to those who wish to know all about New Zealand grasses for their utility for fodder or for other purposes. The plan adopted in the book is to give under each genus a brief generic description and general distribution over the world, the names of the countries being given in capitals, so that they catch the eye at once; this is followed by the etymology of the generic name. The species are then separately enumerated, the generic and specific names standing first, followed by the common name, reference to the plate, synonyms, habit of the plant, time of flowering, specific description and distribution of the particular species, after which is a good account of the properties and uses of the grass, and a detailed reference to the figures. The book is extremely well printed, the plates are well done, and there are two capital indices, the first to genera and species, and the second to popular names. JOHN R. JACKSON

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.]

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Geological Climates

IN NATURE, vol. xxii. p. 200 *et seq.*, there occurs an important statement by Mr. J. Starkie Gardner, to the effect that fossil remains not distinguishable from *Araucaria Cunninghami* had been found among the Eocene plant beds of Bournemouth, in the south of England.

After reading Mr. Gardner's paper, I availed myself of an opportunity of studying the leaflets of the living and dead specimens of this species of *Araucaria* in the Kew Gardens, including the original specimens in the Herbarium named by Mr. Cunningham, and agree with Mr. Gardner as to the difficulty of separating the *A. Cunninghami* from the Sequoias by leaflets alone when in the fossil condition.

Assuming Mr. Gardner's conclusion to be true, viz., that the Eocene Bournemouth tree was identical, or nearly so, with the living *A. Cunninghami*, a question arises as to climate which will prove insoluble to geologists of the school of Lyell and his followers, who assume that all physical causes during geological time have been pretty much the same as at the present time and times immediately preceding the present.

The Moreton Bay Pine (*A. Cunninghami*) is found, as the name imports, on the shores of Moreton Bay, on the east coast of Australia, and has a range of 900 miles, from 14° S. lat. to 29° 30′ S. lat. along that coast. It does not extend more than eighty miles inland, where, instead of being 130 feet in height, which it is on the coast, it becomes a dwarf tree, and farther inland it entirely disappears.

This tree therefore becomes a most delicate self-registering thermometer, indicating to us precisely (after the well-known manner of plants) the exact conditions of the Eocene climate that existed in Bournemouth during the earlier Tertiary period. I propose to examine the evidence given by this thermometer, and to invite my *uniformitarian* friends to explain how this evidence can exist in conformity with their views.

The climate of the northern limit of the Moreton Bay Pine is as follows (as regards heat):—

Mean (January).	Mean (July).	Mean (Annual).
82°·0 F.	71°·0 F.	76°·5 F.

The climate of the southern limit is—

Mean (January).	Mean (July).	Mean (Annual).
72°·5 F.	57°·5 F.	65°·0 F.

The mean of both being—

Mean (January).	Mean (July).	Mean (Annual).
77°·25 F.	64°·25 F.	70°·75 F.

The present mean annual temperature of Bournemouth is only 50°·4 F., which is 20°·35 F. below its mean annual temperature in the Eocene period.

I want to know how Lyell and his followers propose to give to Bournemouth, from present existing forces and causes, this additional 20° F. of heat. If geologists really wish to earn the respect of their fellow-workers in more exact branches of knowledge, they must condescend to consider *quantitative* as well as *qualitative* questions, and enter into numerical details. To enable them to do so I lay down the two following statements:—

1. Of all places now existing on the same parallel of latitude as Bournemouth the highest mean temperature is in 20° W. long. (in the Atlantic), where the temperature is 53°·1 F., or only 2°·7 F. above that of Bournemouth.

Of all places on the same parallel the lowest mean temperature is found at 80° W. long. (on the borders of Labrador and Canada), where it is 29°·3 F., which is 21°·1 F. below that of Bournemouth, and 2°·7 F. below the freezing point of water.

Existing forces and circumstances might therefore benefit Bournemouth to the extent of 2°·7 F. degrees, or might injure it to the extent of 21°·1 F.; but how is Bournemouth to gain the 20° of heat necessary for the flourishing of the *Araucaria Cunninghami* on its Eocene sea-shore swamps, if existing causes only were at work?

2. The place in the northern hemisphere which is now most closely allied in climate to Moreton Bay, or to Bournemouth in Eocene times, is the central part of the Gulf of California, in Western Sub-tropical America.

Again, I ask geologists of the *uniformitarian* school to show me how they propose to convert the climate of Bournemouth into the present climate of the Gulf of California or that of Moreton Bay by mere transposition of land and water, without shifting the position of the earth's axis, which is an inadmissible hypothesis?

Trinity College, Dublin, September 25, 1880 — SAML. HAUGHTON

The Naini Tal Landslip

FOR the purpose of making a thorough inquiry into the details of the causes that led to the above lamentable disaster an able geologist would undoubtedly be required, as was suggested in your leader last week. I think, however, that to any one who, like myself, has resided even but temporarily at Naini Tal, the main cause of the recent slip must be sufficiently obvious without the aid of the geologist.

From the account of the particular buildings overwhelmed it is plain that the slip took place close to where an almost equally bad one occurred some years ago (in the winter of 1865, I believe), viz., just above the Victoria Hotel, on the shoulder uniting the two peaks of Cheena and Lyria Kanta.

The foot of this shoulder forms the northern border of the Tal, or lake, for which the station is justly famed; the strata composing it, as far as I can remember, dip *with* the slope of the hill southwards towards the lake. Moreover, it faces the direction from which the rain mostly comes. The conditions for the production of a landslip in the direction of the lake are thus amply fulfilled.

Though landslips are not at all infrequent from this hill (one occurred near Cheena when I was there, killing two natives), it is from its sunny aspect and *comparatively* gentle slope decidedly the favourite, the station being mainly built on its slopes or at its foot.

On the hill which forms the southern border of the lake the dip of the strata is in the opposite direction to the slope of the hill. It is consequently much freer from landslips, and much safer than the former, as only a few chips at most could be detached from it on the side facing the lake, by the action of rain. The nearly constant gloom however in which, from its northern aspect and its steepness combined, it is necessarily shrouded, as well as the lack of building area, naturally tends to limit its population. This hill again on its *southern* side, which faces the plains, repeats the same phenomena as the shoulder before mentioned; an enormous portion of it having become detached towards the plains, and called pre-eminently "*The* Landslip."

When staying in the Victoria Hotel in May and June, 1877, I always felt it would take very little to bring the whole hill, and especially Government House, which appeared almost vertically above us, down on top of us. The old landslip which I mentioned as being close to the present hotel buried its predecessor, and might be thought to have furnished ample warning against choosing such a dangerous spot upon which to rear a fresh one.

To guard against such disasters in future I would suggest that all houses in the hill-stations should, if possible, be built mainly where the strata dip in the opposite direction to the slope of the hill, and that where the strata dip in the same direction as the slope of the hill all proximity to steep slopes should be avoided, and only the gentler slopes utilised for building on.

I may add that the rainfall on the present occasion seems to have been phenomenal, if, as the *Times* says, it was thirty-three inches in seventy-two hours. Still, extraordinary and sudden downpours of this kind must be expected, where the summer rainfall has varied from forty inches in 1877 to 117 inches in 1862.

Tunbridge Wells, October 2

Branch-cutting Beetles

IT is rather curious that the story which Mr. Ober was told in the Carribbees (NATURE, vol. xxii. p. 216) should be generally believed in Southern Brazil also, viz., that a large beetle "seizes a small branch of a tree between its enormously long nippers, and buzzes round and round the branch till this is cut off." Only in the Antilles this cutting of branches is attributed to a huge Lamellicorn, the *Dynastes hercules*, and in Santa Catharina to a large Longicorn, the *Macrodontia cervicornis*.

Everybody here will tell you this story, but nobody, as far as I know, has ever seen the beetle at work. Branches *are* often cut off by some animal. On a camphor-tree in my garden six branches, from 9·5 to 13·5 centim. in circumference, have been cut off; and on a *Pithecolobium* for some time almost every morning a fresh branch had fallen down, some being even much thicker than those of the camphor-tree. The cutting is always in a plane perpendicular to the axis of the branch, as it would be were it made by a rotating beetle; but in this case an annular incision of equal depth all round the branch would be produced, and this I have never seen. On the contrary, the incision, which causes the branch to break off, consists of two parts, occupying the lower and the upper face of the branch, meeting on one or on either side of it, and being separated by a wedge-shaped interval, which is broken by the weight of the branch, and is narrower or broader according to its toughness.

Once—many years ago—I came to the *Pithecolobium* tree early in the morning, when a branch was just falling down, and with it came down the animal by which it had been amputated. It was a Longicorn beetle, the well-named *Oncideres amputator*, Fabr. I have since seen specimens of some other species of the same genus, which had been caught by others in the act of cutting branches. It is almost unnecessary to add that they do so by gnawing, and not by whirling round the branches.

Blumenau, Santa Catharina, Brazil, August 13 — FRITZ MÜLLER

The Tay Bridge Storm

IN NATURE, vol. xxi. p. 468, Mr. Ley asks, relative to my letter on the Tay Bridge storm, which appeared in NATURE, vol. xxi. p. 443, on what evidence I state "that when the velocity of the cyclone centre is very great, the strength of the wind for any gradients is increased, or at all events becomes more squally and gusty."

I much regret the circumstances which have prevented my replying to him sooner, but may now state shortly the three principal pieces of evidence which led me to that conclusion:—

1. My own observation in a large number of cyclones where the velocity of translation was very great, there has been a quality of gustiness or squalliness and intensity generally greater than is usual for the observed gradients.

2. Ever since the barometer was invented it has been known that a rapid fall of the mercury indicates worse weather than a slow one. Now we know that the rate at which this fall takes place at any station depends:—(1) On the steepness of the

gradients. (2) On the nearness of the observer to the path of the cyclone centre. (3) On the velocity of translation of that centre.

In a great many cases I have observed, especially in the west of Ireland, that when a rapid fall of the barometer is reported, the wind is much stronger than existing gradients would seem to justify.

From this it would seem than the rate at which the change of pressures is taking place has some influence on the strength of the wind.

3. Prof. Loomis has shown in his examination of the U.S. Weather Charts that in American cyclones the area of rain-cloud extends further in front when these storms are going fast than when they are going slow.

From this it would appear that another element of intensity besides wind, viz., precipitation, is increased when a cyclone centre moves with great rapidity.

It was mainly on these grounds that I based the statement in my former letter. RALPH ABERCROMBY

21, Chapel Street, Belgrave Square, October 5

Deltocyathus Italicus, Ed. and H.

I FIND that Prof. Ralph Tate, F.G.S., President of the Adelaide Philosophical Society, has lately written as follows in an anniversary address. "On the other hand the Geelong coral, *Deltocyathus italicus*, Ed. and H., better known from the Italian Miocenes, is considered by Count Pourtales and Sir Wyville Thomson to be specifically distinct from its living analogue inhabiting the deep waters of Florida—an opposite opinion to that held by Prof. Duncan." During the last conversation I had with the late M. de Pourtales he informed me that after having seen and studied the Italian types, he was satisfied that I was correct in the statement I had made regarding the specific identity of the Tertiary and recent forms.

P. MARTIN DUNCAN

Temperature of the Breath

MY attention has been directed to a communication under the above heading by R. E. Dudgeon, in NATURE, vol. xxii. p. 241. The speculations therein raised regarding the temperature of the breath are scarcely compatible with ascertained physiological truth. Mr. Dudgeon's friend's explanation, against which he argues, is undoubtedly correct. The great value of woollen clothing in preventing chill after exercise may be explained on the same principles. The hygroscopic state of the atmosphere (and material) is the condition which causes variation in different experiments. Different materials have effects corresponding to their hygroscopic properties. The following results of a few experiments which I recently made speak for themselves:—

No. 1.—Temp. of air, 87° F.—Air moderately dry (dew point not ascertained).
,, breath, 96° in mouth cavity.
,, ,, 102°·9.—Thermometer enveloped in four folds wool.
,, ,, 102°·2.—Thermometer enveloped in four folds silk.
,, ,, 100°·8.—Thermometer enveloped in four folds linen.

No. 2.—Temp. of air, 79° F.—Air very damp, raining heavily.
,, breath, 97° in mouth cavity.
,, ,, 99° ,, through four folds of silk.

Time occupied in each observation, three minutes.

Madras, September 9 C. J. MCNALLY

Swiss Châlets

I DO not know whether the idea has previously occurred to any one that the modern Swiss châlet is a descendant of the old lake dwelling, but I was strongly impressed with that conviction this autumn. Not only do they actually build the smaller châlets, used as storehouses, entirely on short piles, but very many of the dwelling-houses are still one half on piles, the steps leading up to the gallery passing through a hole in the middle, so that the modern exterior gallery would represent the original platform. In the lake dwelling the probability is (I would suggest) that there was a trap-door in the centre of the platform, inside the inhabited part, with a movable ladder, so that the latter could be drawn up and the trap-door closed if required. At the present day the ladder is represented by fixed wooden or stone steps leading up into the gallery. The house being now on land, the lower part is half or entirely closed in, and so forms an extra chamber, though the family still dwell above the platform (*i.e.* the gallery) as in days of yore. GEORGE HENSLOW

Fascination

FASCINATION originally meant a supposed power in man and snakes of controlling or arresting the movements of various animals by a glance. Your correspondent M. Chatel's personal anecdote, with his comment thereon, suggests that the snake in some way mesmerises his victim, not by its glance but by its movements. His supposition that "the rapid gyratory motion of a shining object" leads on to the debilitating nervous attack, is open to debate. In displays of fireworks such motion occurs before crowds without making any one sick or frightened or inclined to rush into the middle of a catharine-wheel. However then the motions of the snake, whether swift or slow, may avail in attracting and fixing attention, the final catastrophe is probably due to pure fright, according to the old saying, *Multis ipsum metuisse nocet*. We may safely infer that your correspondent himself would have felt no squeezing round his temples had he known at first that the snake was for him a harmless one, and not a viper nearly five feet long!

In the opening letter on this subject the basilisk and the bombshell seemed to be endowed alike with a semi-miraculous power of enchaining the victims that looked upon them. Now, that small birds should be paralysed with terror at the sight of a gesticulating snake is possible or probable enough; but that English officers should be rooted to the ground by mere alarm at the flight of shot or shell is an uncongenial explanation of facts which appear to me capable of interpretation on a different hypothesis.

In moral, as distinct from physical, perils, there is good reason to suppose that too close a concentration of thought upon a danger has a tendency to overpower the will and bend it to the commission of the very acts which the intellect has pronounced unchoiceworthy. But the acts so committed carry with them present gratification. To use the common simile, men fly to them as moths to a candle, not because they are panic-stricken, but because the sense of the danger is lost in the pleasure that attends it.

I am inclined, in the present state of the controversy, to group the effects of so-called fascination under three heads: (1) there is the effect of paralysing terror; (2) there is the effect of indecision; (3) there is the effect of qualities attractive and repulsive accidentally combined in the same object. The first and second effects are perhaps at times combined together in various degrees, and mixed with that absorbing curiosity of which Mr. Hodgson speaks (NATURE, vol. xxii. p. 383), but which by itself seems rather to deserve the name of abstraction than of fascination.

As to fascination in the original sense of the word, its nature may await discussion till observation proves that such a power in reality exists. THOMAS R. R. STEBBING

Tunbridge Wells, September 27

Air-Bladder of Herring

IN NATURE, vol. xxii. p. 520, there was an abstract of Mr. F. W. Bennett's paper on the "Visceral Anatomy of the Herring" (*Journ. Anat. and Phys.*, July 1880). It has escaped the notice of Mr. Bennett that Dr. E. H. Weber described and figured (Tab. vii. 63) the posterior opening of the air-bladder of *C. harengus* into the urogenital sinus in his "De Aure et Auditu Hominis et Animalium," pars i. 1820.

Zoological Museum, Cambridge ALFRED C. HADDON

The "Waiting Carriage"

M. HANREZ' proposed "waiting carriage" (NATURE, xxii. 519) has doubtless been schemed by many readers before now. A simpler form had long ago occurred to me, having the drum of cable in the *train* engine, the cable passing under the carriages and catching the waiting carriage at the tail. The running out of rope could be as well managed at one end of the train as at the other, and only an ordinary carriage without any special engine would be required, which would be dropped just before

picking up another at the next station, each carriage thus slowly shifting round the line.

But any such plan would entail a fresh build of carriages; and for discontinuous carriages a plan nearly as good would be to run a railway omnibus on the rails, with a small 6 or 8 h.p. engine all in one. This would be stopped anywhere between stations, at crossings, farmhouses, and hamlets along the line, and would serve the peasantry for going shopping, beside taking up baskets of garden produce. Passengers going a long journey would change at a main station and join the ordinary train, which would only stop about every hour at the ends of forty or fifty miles' stages. Country lines only running a train every two hours or so would be easily worked thus, the 'bus being shunted by telegraph if necessary, and the line signalled clear as usual. With double lines the 'bus would run on the goods line.

Bromley, Kent W. M. F. PETRIE

A NEW KIND OF ELECTRIC REPULSION[1]

DR. GOLDSTEIN has devoted a good part of the last ten years to an investigation of the discharge of electricity through gases, and amongst the many phenomena which he has brought to light, the one described in a memoir published in a separate form is not the least interesting and important. The facts may be stated in a few words: *A negative electrode exerts a strong repulsion on the rays of the glow proceeding from itself or from another negative electrode.* Before describing the experiments proving this statement, and the laws by which this phenomenon is regulated, we shall follow Dr. Goldstein in reminding the reader of a few facts connected with a discharge of electricity through gases which he will have to bear in mind.

It is well known that the negative electrode in a gas, for which Faraday's name of cathode may be conveniently used, is surrounded with a glow which expands as the pressure of the gas is reduced. We are able to distinguish four layers in this gas, though three of them only are easily recognised. As a first approximation we may assume the outline of these layers to be parallel to the outline of the electrode, though, as we shall have to mention, Dr. Goldstein has shown that this is not strictly correct.

The layer of the negative glow adjacent to the cathode is luminous, and shines in air with a yellowish-red tint. This first layer is surrounded by a second layer, which is very little luminous. This is the dark space mentioned by Mr. Crookes; but, as Dr. Goldstein shows, it is not entirely dark, but has in air a bluish tint. We next come to the third and fourth layers, which may very well be taken as one, and which are more generally designated by means of the term, negative glow. They form the outer boundary of the luminosity surrounding the cathode. If the pressure of the gas is sufficiently reduced to enable the glow to touch the glass, it becomes phosphorescent, and only the layer of the gas immediately touching the glass causes the phosphorescence. The phosphorescence gets stronger as exhaustion proceeds; at the same time the luminosity of the glow gets weaker. The appearance and extension of the glow does not depend on the position of the anode, while the luminous positive discharge varies very much with the relative position of the electrodes, and can be made to disappear altogether by bringing the electrodes sufficiently near.

Already Plücker, and especially Hittorf, have come to the conclusion that the negative glow is propagated in rectilinear rays from the cathode, and it can further be shown that the direction of propagation is generally in a direction nearly normal to the surface of the cathode. Dr. Goldstein draws a distinction between such elements of the cathode which lie near the edge, if the surface of the cathode has edges, and elements which are removed from the edge. While those elements not near an edge only send out rays within a cone of narrow aperture in a normal direction, the edges send out rays in all directions. This difference in the behaviour of different elements of the same surface is, it appears to us, well explained by Dr. Goldstein's discovery of a repulsion between the electrode and a ray proceeding from the cathode. A little consideration will show that this repulsion will, whenever cylindrical or plane electrodes are used, be in a nearly normal direction for any part of the surface which is sufficiently removed from the edge, while near the edge the resultant repulsion will be away from the surface and from the greater angle with the normal the nearer the ray is to the edge. This would prove of course that the repulsion is not an electrostatic one, for in that case it would always be at right angles to the surface. If the exhaustion is such that the glass becomes phosphorescent, the phosphorescence, being produced by the rays proceeding from the cathode, it is clear, will form a luminous ribbon surrounding the electrode, which is a little larger than the electrode.

If now a solid body is introduced between the cathode and the glass inclosure, a shadow of this body will appear in the phosphorescent light on the glass; the formation of the shadow is a direct consequence of the rectilinear propagation of the rays.

We now proceed to describe Dr. Goldstein's experiment in its simplest form.

In a cylindrical vessel two parallel electrodes of equal length are introduced at one end, while the other end contains a third electrode which shall always form the anode. Let the pressure be such that phosphorescence appears, and let only one of the two parallel electrodes be connected with the negative pole of the coil, while the other is insulated. A shadow of this insulated wire is seen in the phosphorescent light on the glass. Now let the insulated wire be brought into metallic contact with the other electrode, and the whole appearance will change. In the phosphorescent light of the glass we shall see two dark surfaces of equal size and shape, and with distinctly marked edges. The two dark surfaces are situated in such a way that a plane which passes through the electrodes cuts them into two equal halves. They are partly bounded by straight lines, partly by two semicircular arcs.

The parts formed by straight lines are parallel to the electrodes, and of equal length; these straight lines are joined at the lower end, that is, at the free end of the electrodes, by means of a half circle, which is partially repeated at the upper end; but where the electrodes are sealed into the glass the curve is interrupted. The dark surfaces are bordered by a bright line of light. It will facilitate the understanding of the position and shape of these dark surfaces if we mention already here that they are such as would be produced if the rays emanating from each electrode, and propagated in a normal direction from it, suffer a repulsion and consequent deflection in the neighbourhood of the other electrode, so that the dark space is formed by the absence of the phosphorescent light which would be produced by the rays coming from the farther cathode.

We cannot here give the further description of shape and the measurement of the size of these dark surfaces, but at once describe their properties. In the first place the size and shape are altogether independent of the position, form, and size of the positive electrode. The relative position of the two cathodes, on the other hand, materially affects their behaviour; and Dr. Goldstein gives their shape, for instance, if, instead of being parallel, they are at right angles to each other, either in the same plane or one in front of the other. We have already stated that in the case of parallel electrodes the parts of the outline forming straight lines are of equal length with the electrodes, and hence the length of these dark surfaces increases with the length of the electrodes, but the breadth and half-circle joining the straight lines

[1] "A New Kind of Electric Repulsion," by Dr. E. Goldstein. (Berlin: Julius Springer, 1880.)

does not vary with the length of the electrodes. The further removed the glass walls are from the two electrodes the greater is the width of the surfaces. All these and other properties follow at once if we consider that the luminosity is produced by the intersection of the rays proceeding from the cathodes with the glass walls. If we increase the thickness of one of the electrodes, the size of the dark surface nearest to it is increased. We now turn to the experiments which have been made in order to clear up the cause of the phenomena. By means of very ingenious experiments Dr. Goldstein proves that it is only light produced by the nearer electrode which is seen within the boundary of the dark surface, for although we have called them dark, they are only so by contrast, and they show a faint phosphorescence. Dr. Goldstein had, in a former paper, shown that when the cathode is perfectly smooth, the phosphorescent light produced by the glow shows inequalities. By twisting the aluminium electrodes he could obtain a series of spiral curves in the phosphorescent light more luminous than the rest. If one of the two cathodes is twisted in such a way and connected with the other, the spiral curves are interrupted in the dark space which is removed from the twisted electrode, but they are visible in the dark surface nearest to it.

The dark surface cannot be considered as enlarged shadows only of the electrodes, for their shape is different, but they might as regards shape be considered as shadows of the second and non-luminous layer of the negative glow. This remark we believe to be of importance, but Mr. Goldstein shows that they cannot really be such shadows, for they appear even when by an approach of the two electrodes the two non-luminous layers fuse into one and so lose their individuality.

The following experiment proves the repulsion. A metallic diaphragm is introduced between the two cathodes. A small hole is made in the diaphragm with its centre in a line joining the electrodes. Only some of the rays proceeding from each cathode can now reach the next, and consequently we observe only a small phosphorescent speck at the opposite side of the glass wall if one of the electrodes is insulated, but the dark shadow of the nearest electrode is visible in this phosphorescent speck. If now the two cathodes are joined the phosphorescent speck is seen to divide into two which separate and clearly show that the rays producing the phosphorescent light must have suffered a deflection as soon as the two cathodes were joined. Further experiments show that the deflection takes place at right angles to the surface of the electrode, and that it takes place at sensible distances from the repelling cathode, although it rapidly decreases in strength. Near the edge of a repelling cathode the repulsion does not take place in a normal direction, and Dr. Goldstein draws again a distinction between elements of a surface according as they are removed or near an edge. We believe this distinction to be unnecessary, and that all phenomena are explained by the fact that all parts of the electrode are repelling, and not only the elements nearest to the deflected ray.

Some remarkable secondary phenomena take place in a deflected system of rays. If, for instance, a system of rays forming a cone of narrow aperture passes near a second cathode, it is not only deflected but the aperture of the cone is increased. The phenomena are such as would be produced if a cathode not only repels the rays but also induces a state in the particles forming the ray such that they now repel each other. Also parts of the same cathode repel rays proceeding from other parts, and the repulsion increases the thicker the electrode. All these facts are illustrated and proved by a series of well-arranged experiments. Dr. Goldstein next examines the influence of an anode, but we shall not follow him, as it is found that the effect of an anode is exceedingly small, and most likely always produced by secondary causes.

The deflection is the same in all gases: air, hydrogen, carbonic oxide, and magnesium vapour having been tried.

The deflection is independent of the metal of which the cathode is formed; it is independent of the pressure. It is also independent of the intensity of discharge when the two electrodes are in metallic contact, so that the current is equally divided between the two cathodes. But remarkable changes take place if the current is not so equally divided. This can be done by joining the electrodes not metallically, but with a bad conductor, as for instance a moist thread. It is then found that the dark surface nearest the cathode through which the smaller discharge passes is much reduced in size, while the other dark surface is increased. It follows from experiments such as this that the repulsion does depend on the intensity of discharge, but that while a cathode through which more electricity passes more strongly repels, a ray which proceeds from such a cathode is less strongly deflected. If therefore we have seen that the dark surfaces do not vary in size, whatever the intensity of discharge, if the two poles are connected with a piece of metal; this is due to the fact that each cathode repels more strongly, but that the rays of the other electrode (owing perhaps to the greater velocity of the molecules proceeding from it) are less easily deflected, and that the two effects counterbalance each other. Dr. Goldstein considers, rightly no doubt, that the shadows seen when one apparently insulated metallic body is introduced between the cathode and the glass are due to a similar repulsion, because we may consider that a small part of the discharge always passes through such a body, the glass into which the body is necessarily sealed not being an absolute non-conductor. The shape of the shadow confirms this supposition.

Dr. Goldstein has also obtained the repulsion from electrodes consisting of glass and mica, so that the metallic or non-metallic nature of the electrode does not influence the phenomena. He has also proved that the source of electricity is immaterial, as might have been expected.

Dr. Goldstein has also endeavoured to prove that the deflecting power of a cathode does not act through a solid screen, but he has chosen metallic screens for his experiment.

If the repulsion is of the nature of electric repulsion a metallic body might act as a screen, while a non-metallic body would allow two bodies on opposite sides of it to repel each other. As it is impossible to form any idea on the cause of these phenomena unless we know whether the deflecting power is cut off by any solid body, it is much to be wished that Dr. Goldstein will repeat his experiments with non-metallic screens.

In the last part of his book Dr. Goldstein discusses various theories which might be proposed and have been proposed for the explanation of the phenomena taking place in the neighbourhood of the negative electrode. The result is that none of them are satisfactory. While this no doubt is true, Dr. Goldstein is too severe, we believe, in his criticisms of some of the suggestions which have been made, and which may, in our opinion, after all contain the germ of the true explanation, though in their present shape they may not be quite satisfactory. Some of the facts which to Dr. Goldstein are sufficient to reject a theory may, we believe, be explained without putting too great a strain on our present ideas, and sometimes we believe Dr. Goldstein to be in error, as when, for instance, he says that a body must necessarily move in a line of force. It would at least be a sad look-out for our earth if this was true, and Dr. Goldstein would in that case have occasion to study before long the electric phenomena on the surface of the sun. We will hope, for the sake of science, that both Dr. Goldstein and his molecules do not always move in lines of force, and that he will often favour us with such interesting and valuable contributions as the one before us.

ARTHUR SCHUSTER

PHYSICS WITHOUT APPARATUS[1]

VII.

IN the preceding articles on "Physics without Apparatus" it has been shown how a large proportion of the fundamental experiments in most branches of physics can be performed without employing expensive apparatus.

The next of these branches to claim consideration is the science of optics. Here again, as in electricity and in heat, we find that, while the higher quantitative laws of the science require for their experimental proof apparatus of the finest and most exact and therefore most expensive nature, the *elementary facts* of experiment are readily demonstrable with little or no apparatus of a formal kind.

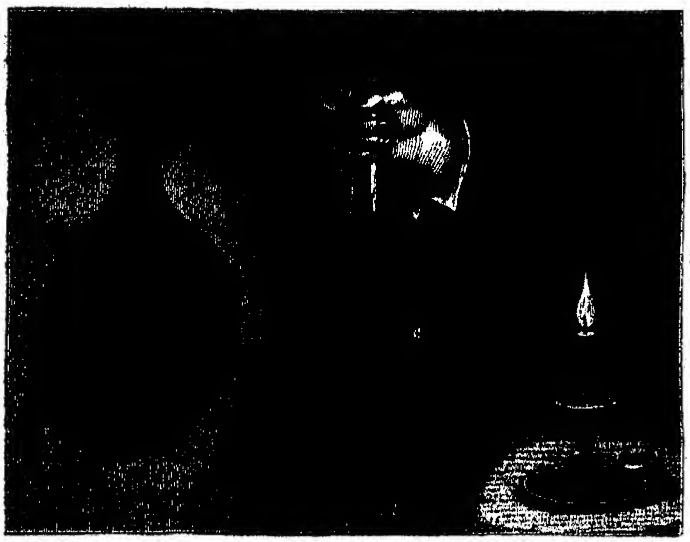

FIG. 22.

An ordinary looking-glass, a lighted taper, and a foot-rule or a measuring tape are quite sufficient to demonstrate the simple geometrical laws of reflection; for with their aid it is very easy to show that the image of the candle in the mirror is virtually situated at a distance behind the mirror equal to the actual distance of the candle in front, and that, when a ray falls obliquely on the mirror, the angle of incidence is equal to the angle of reflection. A teacher who wishes to go further into the matter, and to demonstrate the laws of reflection at curved surfaces, usually provides himself with the appropriate silvered mirrors of convex and concave form. Failing these, the exterior and interior surfaces of the bowl of a bright silver spoon will probably be as satisfactory a substitute as any. We have found even a saucer of common glazed earthenware to form a very fair concave mirror, giving upon a small tissue paper screen a beautiful little inverted image of a distant gas flame.

To illustrate the geometrical laws of refraction through lenses, a good reading-glass of large size is a desirable acquisition. Spectacle-lenses, though of smaller size, and therefore admitting less light, are also of service. In the absence of any of these articles, it is generally possible to fall back upon a water-decanter, provided one can be found of a good globular form, and not spoiled for optical purposes by having ornamental work cut upon the sides of the globe. Fig. 22 shows how this decanter, filled with water, is to be employed. It is held a few inches away from a white wall, and a candle is placed at the opposite side, so that its light falls through the decanter on to the wall. The candle is moved towards or away from the decanter until the position is found in which its rays focus themselves upon the wall giving a clear inverted image of the candle flame upon the wall. The experiment may be varied by setting down the candle on the table and then moving the decanter to and fro until a definite image is obtained. If a large hand reading-glass be available, the image will be much clearer than with the improvised water-lens; and a further improvement in the manner of experimenting may be made by using a screen of white paper or card instead of a whitened wall on which to receive the image. The sheet of paper should be set up in the simple fashion shown in Fig. 24, at one end of a table. The candle should be placed at the other end of the table, and the reading-lens moved about between them until a point is found at which it throws upon the screen a good clear image of the candle. It will be found that there are two such points, one near the candle, the other near the screen. In each case the image of the candle will be inverted, but in the first case it will be a magnified and in the second a diminished image, the size of the image, as compared with that of the real flame, being proportional to their respective distances from the lens. When the lens has been placed in a position of good focus, the candle may be removed and placed where the screen stood; if now the screen is placed where the candle was, it will be found that the image is again visible on the screen, still inverted, though altered in magnitude. This experiment, in fact, proves the law of conjugate foci.

The young beginner in science who repeats these experiments for himself will begin to understand how it is that in the photographer's camera the image in the instrument is inverted, and how it can also be true that the images cast on the sensitive retina of the eye are also inverted. The retina at the back of the eye-

FIG. 23.

ball answers to the white screen on to which the image is

[1] Continued from p. 489.

thrown by the lens in front of it. It is possible indeed to show in actual fact that the image in the eyeball is inverted; the experiment is very simple, but we believe that this is the first time that it has been described in print. Take a candle, and hold it in your right hand as you stand opposite a looking-glass. Turn your head slightly to the left while you look at the image of yourself in the glass. Open your eyes very wide and look carefully at the image of your left eye. Move the candle about gently, up, down, forward, &c., so that the light falls more or less obliquely on to the eyeball. You will presently notice a little patch of light in the extreme outer corner of the eye; it is the image of the candle on the inside of the eyeball, which you see through the semi-transparent horny substance of the eye. If you move the candle up, the little image moves down, and if you succeed well, you will discern that it is an inverted image, the tip of the flame being downwards. You thus prove to your own satisfaction that the image of the candle in your eyeball is really upside down.

Fig. 23 shows a magnifying-glass of very simple construction, which a few years ago found a great sale in the streets of London, at the price of one penny. A bulb blown at the end of a short glass tube is filled with water. When held in front of the eye, this form a capital lens for examining objects of microscopic dimensions, which may be secured in place by a bit of wire twisted round the stem.

The principle by which the intensity of two lights is compared in the photometer is very easily shown. The arrangement depicted in Fig. 24 shows how to measure the relative brightness of an Argand oil-lamp and of an ordinary candle. Both these lights are set upon the table, and are so arranged that each casts on to a screen of white paper a shadow of a tall narrow object. The most handy object for this purpose is another candle unlighted. The Argand lamp, being the brighter light, will cast the deeper shadow of the two, unless it is placed further away. The measure of the brightness is obtained by moving the brighter light just so far off that the intensity of the two shadows is equal, for then we know that the relative intensities of the

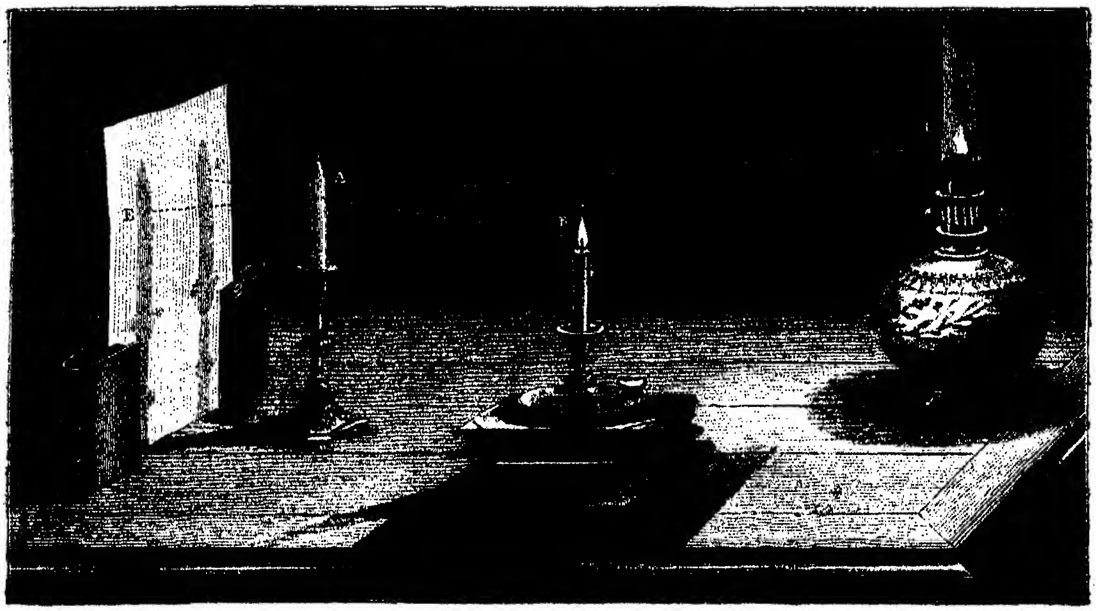

FIG. 24.

two lights are proportional to the squares of their distances from the photometer. All that remains, therefore, is to measure the distances and calculate out the intensities. If, for example, the distance of the lamp is double that of the candle when the two shadows are equally dark, we know that the brightness of the lamp is four times as great as that of the candle.

Many other facts in optics can be shown with no greater trouble than that entailed by such simple experiments as we have described. The pendant lustre of a chandelier will provide an excellent prism of glass for showing the dispersion of light into its component tints. A couple of spectacle glasses appropriately chosen will, when pressed together, afford capital "Newton's rings" at the point where they touch. Diffraction bands of gorgeous hue may be observed by looking at a distant gas-light, or at the point of light reflected by a silvered bead in sunshine, through a piece of fine gauze, or through a sparrow's feather held close in front of the eye. And yet more remarkable effects of diffraction are obtained if the point of light be looked at through substances of still finer structure, such as the preparations of woody structure, and of the eyes of insects which are sold as microscopic objects. But the explanation of these beautiful phenomena would lead us far beyond our subject.

(To be continued.)

THE JAMAICA HURRICANE AND THE BOTANICAL GARDENS

THE following letter from Mr. Morris has been forwarded to us from Kew for publication :—

Botanical Department, Gordon Town, Jamaica, September 7, 1880

At the Cinchona Plantation, besides damage to our buildings and sheds of about 650*l*., our nurseries and seed beds have suffered so much as to reduce our stock of available seedlings from something like 500,000 down to 80,000. These were intended for planting out in the latter part of this year and the beginning of the next year. We shall in consequence be unable to distribute seedlings as we intended, and so suffer considerably in expected

revenue. At the plantations vegetation is so literally swept away that only here and there can we see a standing tree. There is not a leaf left on either the indigenous or cinchona-trees. After a careful inspection we have estimated that 20,000 cinchona-trees of all ages have been uprooted or so severely damaged that they must be immediately barked. Though we had given up barking definitely till the return of dry weather next year, we are now obliged to take it up with great energy and send the bark down to be dried in the plains. We hope to get a return of about 1,500*l.* to 1,800*l.* for "broken and twiggy" bark, but this will be but a poor result considering the sacrifice made to secure the bark at all hazards before it has dried and hardened on the trees.

Out of the small garden at Castleton, covering only about five to six acres, I found fifty-five trees destroyed, and ninety-eight severely injured. Out of the trees severely injured, *i.e.* probably blown quite down and put up again with trimmed limbs and supports, I found the Para-rubber mangosteen, Tonquin-bean, cam-wood, olive, cinnamon, nutmeg, East Indian mango, chocolate, Liberian coffee, &c. Even if they live we shall get no fruit from them during the next season, and we shall be unable to supply plants in great demand for some time.

I am glad to say that the superintendent did not suffer personally, though the roof of the residence was partially blown away, and the office canted almost on its side.

The Parade Garden, Kingston, felt the hurricane greatly, but as we had nothing there except ornamental trees and shrubs we hope to recover our losses soon.

The cocoanut plantation at the Palisadoes had sixty-one bearing trees blown down, and forty-one rather young ones just coming into bearing. This plantation is on a narrow spit of sand running six miles out and inclosing Kingston Harbour. The force of the wind being from the south and against the plantation, the waves broke over it at several places, and the harbour being consequently filled, much damage was done to the wharves and shipping.

You will, I am sure, be sorry to hear that the Old Bath Garden has also shared in the general injury. The fine old cinnamon-tree, the camphor-tree, and the pinus are down. Till the place is cleared the keeper is unable to give me fuller particulars.

The King's House Gardens and grounds have fortunately escaped much injury. D. MORRIS

NOTES

MESSRS. CHARLES GRIFFIN AND CO. announce that they have at last in the press the memorial volume to the late Prof. Macquorn Rankine. It is entitled "A Selection from the Miscellaneous Scientific Papers of W. J. Macquorn Rankine, C.E., LL.D., F.R.S., late Regius Professor of Civil Engineering and Mechanics in the University of Glasgow, from the *Transactions* and *Proceedings* of the Royal and other Scientific and Philosophical Societies, and the Scientific and Engineering Journals, with an Introductory Memoir of the Author, by P. G. Tait, M.A., Professor of Natural Philosophy in the University of Edinburgh; edited by W. J. Millar, C.E., Secretary to the Institution of Engineers and Shipbuilders in Scotland." The volume will contain many papers of great weight and value, at present to be found only in the Records of the various scientific and philosophical societies, and in the scientific and engineering journals, to which they were originally contributed, and therefore inaccessible to the majority of scientific workers. No doubt the bringing-together in one volume of these successive important contributions to science will be acceptable to all who knew of Rankine's high position in science. A fine portrait on steel will be prefixed to the volume.

WE have a few further details on the meeting of the German Association at Danzig. Salzburg was unanimously chosen as the town in which the next year's congress of the Association should be held. Dr. Wernicke of Berlin gave an address "On the Scientific Standpoint in Psychiatry," and in the section for physics and meteorology Dr. L. Weber read a paper upon "Lightning Strokes in Schleswig-Holstein." In the section for the superintendence of instruction in mathematics and natural science Dr. Feyerabendt spoke with reference to mathematical school-books, which, as he showed, would bear much simplification and condensation. A point which he urged among others was that the matter taught should be divided, not upon scient fic principles, but with regard to its easy and ready comprehension by the scholar.

THE death is announced, on August 22, of the Hon. John Imray, M.D., of Dominica, West Indies. Dr. Imray had done much for the botany of his island, but is best known for his successful efforts to introduce Liberian coffee and the cultivation of limes into the West Indies. Another death is that of M. Edmond Barbier, the translator into French of some of the works of Mr. Herbert Spencer and Sir John Lubbock, at the age of forty-six years.

A LAUDABLE innovation has been made in the library of the French Academy, which is not open to the public. Any one wishing to consult any of the rare and precious books in the library has only to make an application to the librarian to receive the required authority.

DR. WATT, of the Bengal Educational Department, who is now engaged in the examination at Kew of his extensive collections of Indian plants, has been deputed by the Government of India to visit Manipur, on his return from furlough, for the purpose of reporting on the forest and vegetable resources of that territory.

Science, the new American record of scientific progress, states that the Rev. W. H. Dallinger has consented to become Governor and Professor of Natural Sciences of Wesley College, Sheffield, U.S.A.

MR. JAMES BLYTH of Edinburgh has been elected to succeed Prof. Forbes in the Chair of Natural Philosophy at Anderson's College, Glasgow.

DR. J. VOSMAER of the Hague intends publishing a detailed bibliography of the sponges, and it is to be hoped that all authors of works or papers on this interesting group will send copies of their writings to him at 73, de Ruyter Straat, Haag, Holland.

THE bureau of French meteorology has been revived for 1880-81, M. Hervé Mangon being continued president.

THE recent change of Ministry in France has brought forward for the second time since 1870 the Minister of Public Instruction to the direction of the Cabinet. M. Barthelemy St. Hilaire, the new head of the French Foreign Office, is not only a member of the French Senate, but also of the Academy of Moral and Political Sciences. He has published a large number of works on philosophy, among which the most considerable is a translation of the whole works of Aristotle, with a commentary. In order to be better able to understand physics and mechanics, he studied mathematics at the age of forty-five under the direction of his friend Corioles, then scientific director of the Polytechnic School. He was an intimate friend of Leverrier. He was born in Paris in 1809, and has just completed his seventy-first year.

THE Birmingham Natural History Society, which has hitherto met in the Midland Institute, has been provided with ample accommodation in the Mason Science College. The Society, which numbers 400 members, is making an effort to fit up the rooms in an appropriate and comfortable manner.

THE Epping Forest and County of Essex Naturalists' Field Club held the seventh, and probably the last, of the summer course of field meetings at High Beech and Monk's Woods on the 2nd inst., the purpose of the meeting being the observation of the *cryptogamic* flora of Epping Forest. The conductors were Dr. M. C. Cooke, Mr. Worthington Smith, F.L.S., Mr. James English, and Mr. E. M. Holmes, F.L.S.; and the party (upwards of fifty in number) included many well-known London naturalists. Several scarce *fungi* were noticed, although the weather proved very unfavourable for field-work. After tea, botanical demonstrations were given, one of the speakers being Prof. Max Cornu of Paris, who expressed the pleasure he had in being present, and said that he hoped to establish similar meetings in Paris. It is intended to make this "fungus meeting" an annual institution.

DR. ANDREW WILSON, F.R.S.E., has in the press a new work entitled "Chapters on Evolution," in which a popular *résumé* of the Darwinian and other theories of development is to be given. Messrs. Chatto and Windus are the publishers.

THE French Minister of War has authorised the erection of a meteorological observatory in the fort which has been recently constructed in the Ballon de Servance, in the Vosges.

THE Rev. A. E. Eaton states (*Entomologists' Monthly Mag.*) that "in Lisbon male field-crickets are sold in miniature cages by bird-fanciers at the rate of a penny a-piece. They are kept in stock by hundreds together in open tea-chests, lined for the first three or four inches from the top with slips of tin, and are fed upon lettuces. The natives like to have a 'grillo' chirping in the room, and make pets of them." Has this, or a similar custom, been observed by travellers in other parts of the South of Europe? No doubt there is a superstitious element in it, on the principle that sometimes induces our own people to send to the bakers for house-crickets "for luck." In China, and elsewhere, other Orthopterous insects are well known to be sold in little cages.

HITHERTO, we must confess, Trinity College, London, has been somewhat of a *nominis umbra* to us; but with its fat Calendar before us it can be so no longer. It was established in 1872 mainly for the promotion of musical education. The Council, we are glad to see, take a liberal view of what is necessary to constitute a well-educated musician, and provide the means of a really liberal education. There is a faculty of music in which, among other subjects, the physiology of the vocal organs and of the ear is taught. In the faculty of arts, besides ancient and modern languages, there are classes in mathematics, chemistry, zoology, botany, geology, and physiology. The College has not only its curriculum for students in London, but has centres for examination all over the three kingdoms, and judging from the lists of names of those who have passed, these examinations must be widely taken advantage of. The Calendar contains all necessary information as to the College and its work, with the examination papers for the past year and other matters. If it is able to carry out its programme, the institute ought to do much good.

AT the Exhibition in connection with the Sanitary Congress which has been held at Exeter, there are several things worthy of some notice. It may be mentioned that the marked features of the collection are the gas stoves, improved flushing apparatus, ranges for the saving of fuel, various appliances for house drainage, ventilation, and arrangements to prevent sewer gas from rising into houses through closets and sinks. The number of manufacturers who exhibit under these heads shows the principal directions in which practical sanitarians are working. First as to the gas-stoves. These are divided into heating-stoves and cooking-stoves. In the heating group the object is to attain as much radiation as possible; in the cooking group the object is to prevent loss of heat by radiation. The Exeter Gaslight and Coke Company, believing that gas will soon supersede coal for heating and cooking, whilst it will itself be superseded as a lighting agent, have offered four handsome silver medals for the best stoves. It is stated on the authority of a late cook of the Reform Club that the gas kitchener No. 99 in Class III. cooked 13 lbs. of meat in fifty-one minutes, at a cost of three farthings, the gas being at the rate of 3*s*. 6*d*. per thousand. The graduation of heat can be effectively regulated by the tap of the pipe which secures the gas burners. The gas water-heaters shown are of two kinds—those in which the gas jets are introduced under the bath, and those in which they are introduced into a separate boiler placed in the bath-room or outside it. No. 25, Class III., is an example of an upright cylindrical boiler with which water enough for a bath can in twenty minutes be obtained at 95°. It is impossible to draw attention to all the novelties, but there are some few deserving special attention. Class II., No. 3, is a "twin" door. Two doors a few inches apart are hinged so as to open together. There is an open space for ventilation between them. For housemaids' sinks on different landings, for closets, and for sculleries and kitchens, they are invaluable. In filters there is not much new. A French firm shows a modification of their well-known filters, it being an adaptation of their principle to table filters with the use of Carferal. The main point is that the Carferal can be so readily changed, and it is now well recognised that no filtering material is of any good after many days' use. The trouble involved is no more than that of making tea, and a lady can see to it herself without being at the mercy of careless servants.

THE *St. James's Magazine* for October contains the first instalment of an interesting series of articles on "Lightning Protection for Telegraphs."

THE remains of a lake village have been discovered in a marsh at Regnate, near Milan. They include, it is stated, shavings of flints apparently cut with bronze instruments.

THE *Daily News* Naples correspondent writes that in the excavations commenced a short time ago at Villagrande (Sardinia), there have come to light some instruments which are very remarkable if, as believed by competent persons, they belong to the bronze epoch, which, it is asserted, was exceptionally prolonged in this part of the island. The instruments in question are two bronze saws and a four-pronged fork, all is said to be found in the same repository. Near Taranto, in some new excavations opened in the vicinity of former ones, there have been found twenty-two skeletons, each in its respective tomb, not far below the surface of the ground. The tombs are all dug in the rock, disposed in various positions, and covered with square slabs of stone. Some of them were capable of holding two corpses.

MR. PFOUNDES will hold, on Saturday afternoon, at 1, Cleveland Row, St. James's, the first of a series of meetings at which Japanese art with native sketches, photographs, &c., will be exhibited, and some account given of the country and people.

THE Philadelphia Court has forfeited the charters of the Eclectic Medical College of Pennsylvania and the American University of Philadelphia for selling bogus diplomas. These were the medical colleges managed by Dr. Buchanan, who is now awaiting his trial here.

THE exhibition of the Photographic Society opened at the Galleries, 5A, Pall Mall East, on Monday, and is quite worth a visit. There are several productions of special interest: among these are some fine photographs from Novaya Zemlya taken during the second Dutch Arctic Expedition last year; several excellent views of the Tay Bridge disaster; Burnham Beeches, by Lieut. L. Darwin, R.E.; magnificent portraits of lions and

tigers taken, we presume, in the Zoological Gardens; several beautiful views taken of Siam, including a group of Laotian huts. There are also several specimens of new apparatus used in photography.

AN important innovation has been made in all the French colleges by M. Ferry. Any pupil wishing to be promoted to a superior class is obliged to pass an examination. The Government is asking important credits for the rebuilding of the principal colleges of Paris and the construction of new colleges outside of the fortifications.

Education is the title of a new international bi-monthly magazine, devoted to the science, the art, the philosophy, and the history of education. It is published at Boston, Mass., and by Trübner and Co., London.

A USEFUL exhibition is being held in Glasgow of apparatus for the utilisation of gas, electricity, oils, &c., and of hydraulic, architectural, mining, and sanitary appliances.

UNDER the name of Tong-pang-chong a Chinese remedy for skin diseases was brought to European notice some two years since. The material as brought to this country appeared like fragments of a woody root, and it was said to be produced by a plant growing in Siam, from whence it is sent to China, where its use had become quite general. From subsequent information received from China and from examination and comparison of specimens sent to this country with those already contained in the Kew Museum, there seemed but little doubt that the plant which produced the Tong-pang-chong of the Chinese was *Rhinacanthus communis*, an acanthaceous plant. A good deal of interest was attached to this remedy when it first came to notice, since which time nothing has been heard of it until within the last few weeks, when some of the material has been received in this country, and is now in the possession of Messrs. Christy and Co. of Fenchurch Street. Whether this consignment will prove to be identical with *Rhinacanthus communis*, and so prove the accuracy of the preliminary determination which was made from scant materials, or whether it will turn out to be produced by a distinct plant will no doubt, shortly be seen. The remedy is referred to in the *Kew Garden Report* for 1877, p. 41.

HERR TORNÖE has published in the *Sitzungsberichte der k. Akademie der Wissenschaft zu Wien* (81, 924) a detailed account of the estimations of salt in the Norwegian Sea, conducted by him during the late Norwegian North Sea Expedition. The paper is a valuable contribution to the physical history of the North Sea.

THE monster python which is kept alive in the Antwerp Museum having had inflammation of the jaw, a Belgian doctor volunteered to enter its cage in order to cure it; but the brute attempted to suffocate the poor doctor, who was glad to escape with his life.

THE Queenwood College Mutual Improvement Society seems to be doing much to encourage the study of natural science among its members. The Report of the Committee for the last summer term speaks highly of the various collections made for the exhibition; several useful papers were read and interesting excursions made.

IN the report of the awards made by the different juries of the Exhibition of Agriculture and Insectology at Paris it is stated that a public company has been formed in Spain for the rearing of the silkworm fed on the oak, and the number of cocoons to be collected this year will probably amount to no less than three millions. A special machine for weaving this new silk has worked during the whole time that the Exhibition has been open. A medal was awarded to an exhibitor for a lamp specially arranged to catch insects. It is suggested in the report that the same experiment should be tried by electric light, and a recent instance has been quoted to prove that it would be really successful. A certain number of electric lights, for ordinary illuminating purposes, were used this summer in the gardens of the Meaux Exhibition, in the vicinity of the Forest of Fontainebleau. No arrangements were made for catching the insects, and they fell round the lamps, except a few that got admittance through the holes of the regulator. The number of the latter was so large that two of these lamps placed at a coffee stall in the open air had to be removed, all the consumers being covered by moths of every description.

THE piscicultural experiments at Ercildoune, Victoria, Australia, have been unusually successful; 9,100 ova were collected, of which 2,000 were salmon trout.

THE additions to the Zoological Society's Gardens during the past week include a Purple-faced Monkey (*Semnopithecus leucoprymnus*) from Ceylon, presented by Mr. Wm. Collingwood; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. Henry Thimbleby; a White-cheeked Capuchin (*Cebus lunatus*) from Brazil, presented by Mr. Henry Ch. Marckman de Lichtabbell; two Common Cranes (*Grus cinerea*), European, presented by Mr. Norman W. Shairp; a Rose Hill Parrakeet (*Platycercus eximius*) from New South Wales, presented by Mr. Charles Porter; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Mr. Percy Day; a West African Python (*Python sebæ*) from West Africa, presented by Dr. F. Speer; a Bless-bok (*Alcelaphus albifrons*) from South Africa, a Prince Albert's Curassow (*Crax alberti*) from Columbia, deposited; a Sulphur-breasted Toucan (*Ramphastos carinatus*) from Mexico, purchased.

OUR ASTRONOMICAL COLUMN

THE BINARY STAR α CENTAURI.—Mr. W. L. Elkin, who has been recently a student at the University of Strassburg, has given, in a dissertation for the degree of Doctor, a new determination of the orbit of this remarkable star, in which he has had the advantage of a fine series of measures executed by Sir T. Maclear, Mr. W. Mann, and Mr. G. Maclear at the Royal Observatory, Cape of Good Hope, collected and forwarded to him by Mr. Gill. We subjoin his elements, which, though not considered definitive, yet appear to represent the whole course of micrometrical measures very satisfactorily. Mr. Gill's measures in 1877 seem to indicate well the position of the companion about its nearest approach to the principal star, which it was feared at one time there would be danger of losing at this passage of the periastre. For the sake of comparison the provisional orbit deduced in 1879 by Dr. Doberck is annexed; the most noticeable difference is in the period of revolution.

	Elkin.	Doberck.
Passage of periastre	1875·97	1875·12
Node	25° 47′	25° 32′
Node to periastre on orbit.	54° 47′	45° 58′
Inclination	79° 32′	79° 24
Excentricity	0·5260	0·5332
Semi-axis major	17″·50	18″·45
Revolution	77·42 years ...	88·536 years.

Mr. Elkin's orbit gives the following angles and distances:—

1880·0 ...	Position	185°·7 ...	Distance	4″·79
1881·0 ...	,,	192·4 ...	,,	6·81
1882·0 ...	,,	196·1 ...	,,	8·70
1883·0 ...	,,	198·5 ...	,,	10·42
1884·0 ...	,,	200·2 ...	,,	11·98

For the absolute parallax of α_2 Centauri, he states that the series of 156 altitudes observed on the same days, directly and by reflection with the Cape circle in the years 1856-60, assigns $+0''{\cdot}798 \pm 0''{\cdot}068$; Moesta from observations at Santiago had found $0''{\cdot}88$. Although a large parallax, the largest perhaps yet detected, may still be attributed to this star, it appears to be Mr. Elkin's conclusion that it yet remains to be determined within very narrow limits. Probably Mr. Gill, with the aid of the heliometer, may in due course give a good account of it.

THE VARIABLE R HYDRÆ.—Dr. Gould, at Cordoba, has given much attention to the changes in this variable star, respecting which Argelander remarked that so long as observations were confined to European latitudes little would probably be understood, and he has deduced a formula closely representing the observations, excepting one by Maraldi, about which there appears to be a large error. The earliest recorded observations of this celebrated variable Dr. Gould remarks were those of Hevelius in April, 1662, published in the scarce volume of the "Machina Cœlestis" in 1679. Montanari of Bologna comparing Bayer's Uranometry with the sky on April 15, 1670, remarked it as a star of the fourth magnitude, not entered upon the map, and notified it as a new object. Its variability was recognised by Maraldi at Paris in 1704, who watched it at intervals till 1712. There then appears to be a gap in the observations until we come to those of Pigott in 1784 and 1785. Argelander collected and discussed all the observations to the beginning of 1863, and deduced a formula which fairly represented the data since 1784. The length of the period is decreasing rapidly, amounting, as Dr. Gould says, to more than nine hours at each successive recurrence—a circumstance which impeded the determination of the number of periods elapsed between Montanari's observation in 1670 and the first maximum noted by Pigott. Twelve periods having elapsed since the latest maximum included in Argelander's investigation, present data allow of clearing up several doubtful points.

Dr. Gould finds that the number of periods between the maxima of 1670 and 1784 must have been eighty instead of eighty-four, as assumed by Argelander, and the number between the maxima of 1670 and 1704 must have been twenty-three instead of twenty-five. Assuming that Maraldi's second maximum is erroneously dated in 1708, instead of 1707, he finds that all existing observations except Maraldi's first, may be represented within quite tolerable limits, "by supposing a uniform diminution in the period, upon which are superposed variable terms, according to which a symmetric perturbation completes its cycle in seventy-two years," and the following formula is finally inferred. The days are counted from the beginning of the year 1875:—

$$T = 35{\cdot}6\text{d.} + 434{\cdot}445\text{d.}\, n - 0{\cdot}37974\text{d.}\, n^2 + 32{\cdot}0\text{d.} \sin(5^{\circ} n + 10^{\circ}) + 2{\cdot}6\text{d.} \sin(10^{\circ} n + 324^{\circ}) + 6{\cdot}8\text{d.} \sin(15'' n + 205^{\circ})$$

It will be found that the formula fixes the next maximum to January 18, 1881; Schmidt alone has observed the minima, which occur on the average at about 9-16ths of the interval between the maxima.

A NEW COMET.—On the evening of September 29 Dr. Ernst Hartwig of the Imperial Observatory, Strassburg, discovered a bright comet about 10° north of Arcturus, and having obtained observations on three consecutive nights, has calculated the following elements:—

Perihelion passage, September 6·9528 M.T. at Berlin.

	° ′
Longitude of perihelion	80 0·6
,, ascending node	43 32·3
Inclination of orbit	38 48·3
Logarithm of perihelion distance	9·56450

Motion—retrograde.

Hence he finds, for Berlin midnight:—

	R.A. h. m. s.	Decl. ° ′	Log. distance from Earth.	Log. distance from Sun.
Oct. 6	16 7 40	+24 35·5	9·8147	9·9231
8	16 29 22	22 46·2	9·8488	9·9432
10	16 47 18	21 3·5	9·8827	9·9623
12	17 2 15	19 29·6	9·9158	9·9805
14	17 14 51	+18 5·0	9·9476	9·9978

The intensity of light is rapidly diminishing, being on October 14 only one-sixth of that at the time of discovery.

The above orbit places the comet at 6 a.m. G.M.T. on September 12 near to Regulus, so that it is distinct from the object notified by Mr. Lewis Swift of Rochester, N.Y.

The comet was seen for a few seconds between clouds at the Royal Observatory, Greenwich, and at Mr. Barclay's observatory, Leyton, on the 5th, and is described by Mr. Talmage as "very bright," with a long tail."

CHEMICAL NOTES

IN connection with the subject of water of hydration the results of Van Bemmelen, described in the *Berliner Berichte*, are of interest. He has determined the quantities of water parted with, and also taken up by various hydrated oxides under different conditions of temperature and humidity of surrounding atmosphere. The results afford another instance of the graduation of chemical into physical actions. The amount of water taken up varies but little, but the strength of the combination varies much. The formation of hydrates appears to be a function of molecular weight of the oxide and of the temperature.

Two papers of great importance by Thomsen have just appeared in the *Berliner Berichte*. Thomsen attempts to base a general theory of the structure of carbon compounds on thermal determinations. He does this by measuring (indirectly, of course) the heat of dissociation of the carbon molecule, and from this and other data, finding a thermal value for the combination of two carbon atoms, to form a gaseous compound, by four, three, two, or one "link." Hence he deduces a thermal value for each "link." General equations are given for calculating the heats of formation of various isomers, assuming a certain "linking" of the atoms for each. In cases where various "linkings" may be assumed, a determination of the heat of formation may determine which "linking," and therefore which structural formula, is the more probable.

IN a paper read before the Owens College Chemical Society Messrs. Bevan and Cross detail experiments on jute fibre, which lead them to regard the intercellular portion of this fibre as probably consisting of an aromatic compound of the quinone class, together with a substance allied to the carbohydrates, and somewhat of the nature of cellulose. The presence of this intercellular substance confers on jute the power of retaining various dye-stuffs. The authors also describe a method of separating cellulose from jute fibre, based on the action of chlorine or bromine, subsequent boiling with dilute caustic lye, and washing in acid. Jute fibre which has been acted on by chlorine is coloured deep magenta by immersion in a solution of sodium sulphite. The work of Messrs Bevan and Cross promises results of considerable importance.

MR. O. HEHNER publishes in the *Analyst* the results of his determinations of phosphoric acid in potable waters. He concludes that the presence of more than 0·5 parts per million of P_2O_5 should be regarded with suspicion; also that absence of phosphates affords no positive proof of freedom from pollution.

IT is stated in the *Chemiker Zeitung* that if a solution of two parts of citric and one of molybdic acids be evaporated to dryness, heated to incipient fusion, and dissolved in 30 to 40 parts of water, a solution is obtained which imparts a blue colour to paper immersed in it, and dried at 100°. This paper is bleached by water, and may be used as a test for the presence of water in alcohol, ether, &c.

M. DE SCHULTER states in *Comptes rend.* that he has succeeded in preparing pellucid crystals of analcite by heating a solution of sodium silicate or caustic soda along with aluminous glass in sealed tubes to about 190°.

FROM analyses and determinations of specific heat of cerium tungstate, Cossa and Zecchini (*Gazetta chim. Italiana* for July) think that the atomic weight of cerium is better represented by 92, the number formerly adopted, than by 138, which—or more probably 141—is generally regarded as correct. The data of the Italian observers are as follows:—$Ce_2(WO_4)_3$ (Ce = 141) = 1026, × 0·0821 (sp. heat found) = 84·2, atomic heat of W = 6·4, of O = 4; hence molecular heat of $(WO_4)_3$ = 67·2, but 84·2 − 67·2 = 17, which ÷ 2 gives 8·5 as the atomic heat of cerium. $CeWO_4$(Ce = 92) = 340, × 0·0821 = 27·9; but 27·9 − 22·4 (that is, molecular heat of WO_4) gives 5·5 as the atomic heat of cerium. The careful determinations of the specific heat of metallic cerium made by Hillebrand, and the general analogies of the cerium salts, must however be regarded as of more value in determining the atomic weight of this metal than a series of estimations of the specific heat of a compound containing oxygen, concerning the influence of which element on the specific heat of compounds thereof we have so little exact knowledge.

THERE has of late been a considerable amount of discussion as to the existence of pentathionic acid, $H_2S_5O_6$. In a recent paper in the *Journal* of the Chemical Society, Messrs. Takamatsu and Smith bring forward evidence which appears conclusively to prove that this acid does exist.

HELL has studied the action of bromine on acids of the acetic series, and in a paper in the *Berichte* he shows that the substitution of bromine for hydrogen proceeds slowly, until from

10 to 20 per cent. of the change is completed, then more rapidly until about 60 per cent. is reached, and then again slowly. He also shows that the greater the molecular weight of the acid the more rapidly is the period of maximum action reached. In these phenomena we have fresh examples of the so-called "Chemical Induction" of Bunsen and Roscoe. This supposed special phase of chemical change would indeed appear to be of very frequent occurrence, being only absent in those changes—if such exist—which consist of a single part, the direct change only.

BERTHELOT, in the *Comptes rendus* of the Paris Academy, describes experiments which lead him to believe that by the electrolysis of dilute sulphuric acid a new oxide of sulphur—S_2O_7—is produced. This substance belongs to the class of peroxides, and is analogous with ozone and hydrogen peroxide; the formation of each of these substances is attended with absorption of heat. From the study of the thermal changes accompanying the solution of chlorine in aqueous hydrochloric acid and in water, the same author thinks that a trichloride of hydrogen, HCl_3, probably exists.

BOUSSINGAULT, in *Annales Chim. Phys.*, has examined the action of heat on barium dioxide under diminished pressure, and has shown that in a vacuum this substance parts with oxygen at a low red heat, and that oxygen is readily absorbed from the atmosphere by the baryta thus produced at about the same temperature, under ordinary pressures. It seems therefore that baryta may be employed as a carrier of oxygen from the atmosphere; hitherto the high temperature required for the decomposition of barium dioxide has brought about some molecular change in the baryta produced, which has rendered it incapable of absorbing more than very small quantities of oxygen from the atmosphere.

IN *Comptes rendus*, Hautefeuille states that he has obtained crystals of orthoclase and of quartz in the same tube by heating a mixture of acid potassium phosphate—previously fused with silica and alumina—with silica and a little potassium fluosilicate in a glass tube.

RADZISZEWSKI in Liebig's *Annalen* gives a careful study of the conditions under which various carbon compounds exhibit phosphorescence; he concludes that this phenomenon occurs with those compounds which combine, in presence of alkalis, with the active oxygen of ozone or other peroxide. Phosphorescence he regards as a special case of the phenomenon of combustion; during slow oxidation active oxygen is produced; hence it is in such processes of oxidation that phosphorescence is noticed. When oxidation is rapid much of the active modification of oxygen is produced, combination occurs rapidly between this and the oxidising substance, and we have the phenomenon of combustion. The phosphorescence of certain organised creatures is due, according to the author, to the slow oxidation, by the agency of active oxygen, of such compounds as lecithin, cholesterin, spermacetti, myricylic alcohol, sugar, fats, or ethereal oils. He shows that these substances are decomposed by cholin and neurin, and generally by bases of the formula $R_4 . N . OH$ (where R is a monovalent alcoholic radicle, *e.g.*, $CH_3 . C_2H_5$, &c.), and that this decomposition is attended with phosphorescence.

A SMALL pamphlet, "Report on Two Kinds of Coal submitted by the Chesapeake and Ohio Railroad Coal Agency," published by the Bureau of Steam-Engineering of the U.S. Navy Department, contains a detailed account of the methods of determining on the large scale the relative ratios of steam coals, which must be of very considerable service to any who require to perform such determinations.

IF aluminium hydrate, optained by precipitating a solution of alum by ammonia, be allowed to remain in contact with water for three or four months, it undergoes, according to M. Tommasi (*Comptes rendus*), a molecular change whereby it is rendered very much less soluble in acids, and is no longer capable of forming a compound with aluminium chloride.

PHYSICAL NOTES

THE conditions of geysers are investigated at length by Herr Otto Lang in a recent paper to the Göttingen Society of Sciences (*Nachr.*, No. 6). The theory of Bunsen he considers inadequate, and he proposes another, which has an interesting similarity to that of Mr. Mallet regarding the mechanism of the intermittent volcano at Stromboli.

OBSERVATIONS as to the changes of length of iron bars through magnetisation having been somewhat discordant, Prof. Righi has lately taken up the subject afresh (*Il Nuovo Cim.*, ser. 3, tom. vii.), and, to measure the displacements, he attached a fine steel spring, with mirror, to one end of the bar (which was magnetised by means of a spiral), the mirror being observed through a telescope. Changes in length were thus magnified 8,000 times. The results were as follows:—1. Magnetism produces in iron and steel an increase of dimension in direction of the magnetisation. 2. On cessation of the magnetising force a part of this increase remains, and more or less of it according to the coercive force. 3. The elongations are proportional to the square of the current's intensity when this is not very great. 4. When, after a strong current through the spiral, a weak current is sent in the opposite direction, it produces a shortening; but even when it is strong enough to demagnetise the bar, the latter retains a greater length than in the normal state. 5. During reversal of the polarity of a bar its length becomes momentarily less, and it oscillates in length. 6. A bar or wire of iron traversed by a current contracts at the moment of closing the circuit. 7. On opening the circuit it elongates, but this elongation is less than the initial contraction, indicating that transverse magnetism partly remains. 8. In reversal of the transverse polarity the bar elongates for a moment, and thus oscillates in length. 9. The contraction produced by the current is greater when the bar has before been longitudinally magnetised. 10. Some iron bars show a tendency to take spiral magnetisation, *i.e.* to rotate the magnetic axes of their molecules in the direction of the spiral. This is shown by the contractions caused by a current passing through the bars, which are different according to the direction of the current and that of the previous longitudinal magnetisation.

THE absorption of radiant heat in gases and vapours form th subject of a recent valuable paper to the Vienna Academy (July 1) by Messrs. Lecher and Pernter. They consider "vaporhesion" to have been an important source of error in Tyndall's experiments. In their own method the thermopile and the heat-source were brought into the same vessel. Air-currents were avoided by causing the surface of radiation to be heated in each case suddenly from without, by means of a steam jet, to 100° C. Among other results the absorption of water-vapour is found, in opposition to Tyndall, immeasurably small. Violle found, on Mont Blanc, that a metre of the air absorbed only 0·007 per cent. of the whole radiation; according to this, a layer of 300 m. length would be necessary to produce, with water-vapour saturated at 12°, that absorption which Tyndall obtains in 1·22 m. This and the authors' own experimental results are considered to prove beyond dispute the very small absorption of aqueous vapour. The authors' results for gases agree pretty well with Tyndall's. No simple connection between absorption and pressure of the substance was discoverable. The absorption, even for radiation of a heat-source of 100° C., is selective. The authors found the absorption of certain substances of the fat series examined to increase rapidly with increasing proportion of carbon. It seems to be otherwise, however, with bodies from other groups; thus, *e.g.* benzol, notwithstanding its six C-atoms, has a fairly small absorptive power.

MESSRS. A. P. LAURIE and C. I. Bruton of Edinburgh have devised a new electromotor engine, in which four electromagnets act successively upon an eccentric armature of soft iron rotating about a central shaft, thus avoiding the back pull of Froment's and other forms of electromotor. The gradual approach thereby secured between the armature and the active field-magnets is a feature common to this engine and to that of Mr. Wiesendanger. The principle has long been applied, though somewhat differently, in the little motors employed for whirling Geissler's tubes.

SIGNOR MACALUSO has recently described a new form of mercurial air-pump, on the Sprengel principle, sufficiently simple to be capable of construction from the materials at hand in any chemical laboratory, and requiring no india-rubber connections. An outline diagram of the pump is given in the August number of the *Beiblätter*.

HERR A. SCHERTEL has determined the fusing-points of a number of difficultly-fusible substances by comparing them with those alloys of gold and platinum in various proportions. He gives the fusion-point of basalt as 1,166° C.; that of adularia (from the St. Gotthardt) is stated as being between 1,400° and 1,420°; and nickel between 1,392° and 1,420°.

THE electric conductivity of gas-carbon and its variability under pressure has been re-examined by MM. Naccari and Pagliani. Carbon prisms were carefully covered at certain points of their surface with copper by electro-deposition to secure good contact with the wires by which they were inserted in a Wheatstone's bridge to determine their resistance. When subjected to great pressures the resistances of the rods of carbon showed scarcely any change. Hence it appears that the changes of conductivity which carbon exhibits in the microphone and in the carbon telephone under varying pressures are due not to any alteration of the contact between the particles in the intimate structure of the substance, but to mere changes in the external contact.

DR. WERNER SIEMENS has lately described to the Berlin Academy a new series of experiments on the electric conductivity of carbon, and the way it is affected by temperature. He finds that of gas retort carbon at 0° C. 0·0136 (mercury = 1), and the coefficient of increase of conductivity 0·000345 per degree Celsius. The artificial carbon rods produced by compression of carbon powder also show greater conducting power with increasing temperature, but the increase is not so great (as in retort carbon). Dr. Siemens thinks other experimenters may have been led to erroneous results by faulty connections. He effected the union of the carbon ends with the conducting wires by means of galvanic coppering. The property of conducting better at higher temperatures is regarded as a property of the carbon material itself, not as a consequence of its structure. It may be explained (Dr. Siemens says) as in the case of crystalline selenium, if we assume that the carbon is an allotropic modification (containing latent heat) of a hypothetical metallic carbon.

IN his theory of the bifilar magnetometer Gauss considered that the torsion of the suspending wires, and the induction of the earth's magnetism on that of the suspended magnet, might be neglected, as very small. In the course of several years' observations, Herr Wild having found this to cause serious discrepancy between theory and experience, has (at Pawlowski Observatory) developed the theory anew, taking account of those two factors. Substituting cocoon-threads for wires, he considers the moment of torsion can be reduced to considerably less than 0·3 per cent. of the moment of gravity (it was more than 5 per cent. with wires). The improved theory, while agreeing much better with experience, affords an excellent method of determining separately, from direct observation of the angle of torsion and the three durations of vibration of the magnet in the normal, reversed, and transverse position, its two kinds of induction-coefficients, viz., that in weakening, and that in increase of the magnetic moment by induction; also of determining the temperature-coefficient of magnets and of absolute measurement of the horizontal intensity (*Wied. Ann.*, No. 8).

IT appears from recent experiments by Herr Knoblauch (*Wied. Ann.*, No. 8) that in reflection of polarised heat-rays from metals, the rays of different heat-colours behave differently, in that they have in general different angles of polarisation, presenting, in the case of certain metals, as gold and silver, great differences, and in that of others, as copper and speculum metal, smaller. In the case of lead and arsenic these differences wholly disappear. With the former metals the transitions in reflection of different rays from linear to elliptic vibrations do not keep equal pace with each other; changing the angle of incidence from 0° to the angle of polarisation, the transformation of the vibration of one heat-tint is prominent, while in change of incidence from 90° to the angle of polarisation, it is that of another. With lead and arsenic, at all angles of incidence from 0° to 90°, the ellipses of certain constant heat-rays are always more extended than those of the other heat colours.

GEOGRAPHICAL NOTES

THE full details of the Franklin Search Expedition published in the *New York Herald* of September 23 and following numbers do not contain much of scientific interest in addition to what we gave last week. The narrative contains a graphic and interesting account of the sledge journeys of Lieut. Schwatka's party, of the various Eskimo tribes met with, of the country traversed, and the remains of the Franklin Expedition. Some precision is given to our knowledge of the country, and many valuable hints given as to how to brave an Arctic winter. Although the extreme cold endured, 103° F. below freezing, is not so great as has been experienced in one or two previous instances, we question whether an average temperature of 100° of frost for 16 days was ever before met with. A good many interesting relics of the Franklin party were collected, and there seems no doubt that the Eskimo did at one time have a number of books in a tin box belonging to the party who left the ships; but these, with gold watches and other mysteries, were given to the children for playthings, and have long ago disappeared. It is probable enough that among the books were some records of the progress of the expedition; but all hope of recovering them may now be abandoned. We trust that there will be no delay in the publication of the scientific observations which were doubtless made by Lieut. Schwatka's expedition.

THE new number of the Geographical Society's *Proceedings* provides us with an unusual supply of good readable papers of moderate length. Lieut. G. T. Temple furnishes "Notes on Russian Lapland," accompanied by a new map; the Rev. W. G. Lawes, the well-known missionary, "Notes on New Guinea and its Inhabitants"; the Rev. C. T. Wilson, lately of the Nyanza mission, a brief narrative of a journey over new ground in East Africa from Kagéi to Tabora; and lastly, Major W. M. Campbell, R.E., an account of his visit to the previously unknown (except from hearsay) Shorawak valley and the Toba plateau, Afghanistan. The Geographical Notes supply particulars regarding the murder of Messrs. Carter and Cadenhead in East Central Africa, and Capt. T. L. Phipson-Wybrants' expedition to Umzila's country, east of Matabele-land, as well as a French surveying expedition for West Africa. These are followed by a *résumé* of some of Père Duparquet's notes on Orampo-land, an Egyptian exploring expedition in Somali-land, M. Regel's journey in Eastern Turkestan, and a summary of the Indian Marine Survey Report for 1878–79. There are also some useful additions to our knowledge of Eastern Perak, and an abstract of a Consular report on the Chinese province of Shantung. We must not omit to mention that the present number contains the map (postponed from last month) of the country between Sind and Candahar, showing the course of the proposed railway, on which Sir Richard Temple recently lectured before the Society and at Swansea.

THE new expedition despatched by the London Missionary Society to Lake Tanganyika, and consisting of the Revs. A. J. Wookey and D. Williams, with Dr. Palmer, left Zanzibar on June 14, and crossing to the mainland at Saadani, marched thence to Ndumi. Here they remained for a few days, until they got their full complement of *pagazi*, and finally started for the interior on June 21. Accomplishing some twelve or fifteen miles a day, they reached Mpedapwa on July 14, and were most kindly received by the Church Missionary Society's agents. They were to recommence their journey to the lake on July 19. Their caravan consists of 309 men, the chief of whom is Ulia, who accompanied the Rev. Roger Price, when the bullock-waggon experiment was tried some four years ago.

FROM a letter in *L'Exploration* we learn that M. Wiener had in July reached Archedona, in his exploration of the Napo, one of the great tributaries of the Amazon; unless he meets with disaster, we may expect to hear of him by and by from Pará.

THE *Mittheilungen* of the German African Society, of which six parts are published, contains much very valuable information on recent exploration in Africa by German explorers. We have details of the progress of Herr Schütt's expedition in the Loanda region, of Rohlfs' attempt to push southwards from Tunis, of Dr. Büchner to Muata Janvo's kingdom, of Dr. O. Lenz's determined and so far successful attempt to push southwards through Morocco to Timbuctoo and beyond. We have, besides, records of the doings of the International African Association, and of the various other societies for the exploration of Africa throughout the world. In the double number, 4 and 5, Dr. Reichenau gives a detailed list of the collection of birds sent home from Malanga in Angola by Herr Schütt.

A TELEGRAM from New York, October 5, states that the commander of the United States steamer *Alert* reports the discovery of a submarine volcano near San Alessandro, an island in the Pacific.

THE eruption of the volcano Fuego in Guatemala, to which we referred some weeks ago, ceased almost suddenly in the second half of the month of July. M. de Thiersant, French representative in Guatemala, writes to *La Nature* that another volcano of the same country, Pacaya, seems inclined in its turn to resume activity. At Amatitlan, a small town on the slope of

the mountain, subterranean noises succeeded each other almost constantly on July 28.

INTELLIGENCE received at Lloyd's from Christiania, dated October 1, states that the *Neptune* steamer, Capt. Rasmussen, which arrived at Vardö, previous to September 25, from the Obi, reports that on September 19, in Jugor Straits, she fell in with the *Siberiakoff's* expedition proceeding eastward.

THERE is a useful article in the last number of *La Nature* on French Guiana and its forest produce, by Dr. J. Harmand.

SCIENCE AND CULTURE[1]

SIX years ago, as some of my present hearers may remember, I had the privilege of addressing a large assemblage of the inhabitants of this city, who had gathered together to do honour to the memory of their famous townsman, Joseph Priestley; and, if any satisfaction attaches to posthumous glory, we may hope that the manes of the burnt-out philosopher were then finally appeased.

No man, however, who is endowed with a fair share of common sense and not more than a fair share of vanity, will identify either contemporary or posthumous fame with the highest good; and Priestley's life leaves no doubt that he, at any rate, set a much higher value upon the advancement of knowledge and the promotion of that freedom of thought which is at once the cause and the consequence of intellectual progress.

Hence I am disposed to think that, if Priestley could be amongst us to-day, the occasion of our meeting would afford him even greater pleasure than the proceedings which celebrated the centenary of his chief discovery. The kindly heart would be moved, the high sense of social duty would be satisfied, by the spectacle of well-earned wealth, neither squandered in tawdry luxury and vain-glorious show; nor scattered with the careless charity which blesses neither him that gives nor him that takes; but expended in the execution of a well-considered plan for the aid of present and future generations of those who are willing to help themselves.

We shall all be of one mind thus far. But it is needful to share Priestley's keen interest in physical science; to have learned, as he had learned, the value of scientific training in fields of inquiry apparently far remote from physical science; to appreciate, as he would have appreciated, the value of the noble gift which Sir Josiah Mason has bestowed upon the inhabitants of the Midland district.

For us children of the nineteenth century, however, the establishment of a college under the conditions of Sir Josiah Mason's Trust, has a significance apart from any which it could have possessed a hundred years ago. It appears to be an indication that we are reaching the crisis of the battle, or rather of the long series of battles, which have been fought over education in a campaign which began long before Priestley's time, and will probably not be finished just yet.

In the last century, the combatants were the champions of ancient literature, on the one side, and those of modern literature on the other; but, some thirty years ago, the contest became complicated by the appearance of a third army, ranged round the banner of Physical Science.

I am not aware that any one has authority to speak in the name of this new host. For it must be admitted to be somewhat of a guerilla force, composed largely of irregulars, each of whom fights pretty much for his own hand. But the impressions of a full private, who has seen a good deal of service in the ranks, respecting the present position of affairs and the conditions of a permanent peace, may not be devoid of interest; and I do not know that I could make a better use of the present opportunity than by laying them before you.

From the time that the first suggestion to introduce physical science into ordinary education was timidly whispered, until now, the advocates of scientific education have met with opposition of two kinds. On the one hand they have been pooh-poohed by the men of business who pride themselves on being the representatives of practicality; while on the other hand they have been excommunicated by the classical scholars, in their capacity of Levites in charge of the ark of culture and monopolists of liberal education.

[1] An Address delivered on the occasion of the opening of Sir Josiah Mason's Science College, at Birmingham, on October 1, by Thomas H. Huxley, F.R.S.

The practical men believed that the idol whom they worship—rule of thumb—has been the source of the past prosperity, and will suffice for the future welfare of the arts and manufactures. They were of opinion that science is speculative rubbish; that theory and practice have nothing to do with one another; and that the scientific habit of mind is an impediment rather than an aid in the conduct of ordinary affairs.

I have used the past tense in speaking of the practical men—for although they were very formidable thirty years ago, I am not sure that the pure species has not been extirpated. In fact, so far as mere argument goes, they have been subjected to such a *feu d'enfer* that it is a miracle if any have escaped. But I have remarked that your typical practical man has an unexpected resemblance to one of Milton's angels. His spiritual wounds, such as are inflicted by logical weapons, may be as deep as a well and as wide as a church door, but beyond shedding a few drops of ichor, celestial or otherwise, he is no whit the worse. So if any of these opponents be left I will not waste time in vain repetition of the demonstrative evidence of the practical value of science; but, knowing that a parable will sometimes penetrate where syllogisms fail to effect an entrance, I will offer a story for their consideration.

Once upon a time, a boy, with nothing to depend upon but his own vigorous nature, was thrown into the thick of the struggle for existence in the midst of a great manufacturing population. He seems to have had a hard fight, inasmuch as, by the time he was thirty years of age, his total disposable funds amounted to twenty pounds. Nevertheless middle life found him giving proof of his comprehension of the practical problems he had been roughly called upon to solve, by a career of remarkable prosperity.

Finally, having reached old age with its well-earned surroundings of "honour, troops of friends," the hero of my story bethought himself of those who were making a like start in life, and how he could stretch out a helping hand to them.

After long and anxious reflection this successful practical man of business could devise nothing better than to provide them with the means of obtaining "sound, extensive, and practical scientific knowledge." And he devoted a large part of his wealth and five years of incessant work to this end.

I need not point the moral of a tale which, as the solid and spacious fabric of the Scientific College assures us, is no fable, nor can anything which I could say intensify the force of this practical answer to practical objections.

We may take it for granted then, that, in the opinion of those best qualified to judge, the diffusion of thorough scientific education is an absolutely essential condition of industrial progress, and that the College opened to-day will confer an inestimable boon upon those whose livelihood is to be gained by the practice of the arts and manufactures of the district.

The only question worth discussion is, whether the conditions, under which the work of the College is to be carried out, are such as to give it the best possible chance of achieving permanent success.

Sir Josiah Mason, without doubt most wisely, has left very large freedom of action to the trustees, to whom he proposes ultimately to commit the administration of the College, so that they may be able to adjust its arrangements in accordance with the changing conditions of the future. But, with respect to three points, he has laid most explicit injunctions upon both administrators and teachers.

Party politics are forbidden to enter into the minds of either, so far as the work of the College is concerned; theology is as sternly banished from its precincts; and finally, it is especially declared that the College shall make no provision for "mere literary instruction and education."

It does not concern me at present to dwell upon the first two injunctions any longer than may be needful to express my full conviction of their wisdom. But the third prohibition brings us face to face with those other opponents of scientific education, who are by no means in the moribund condition of the practical man, but alive, alert, and formidable.

It is not impossible that we shall hear this express exclusion of "literary instruction and education" from a College which, nevertheless, professes to give a high and efficient education, sharply criticised. Certainly the time was that the Levites of culture would have sounded their trumpets against its walls as against an educational Jericho.

How often have we not been told that the study of physical

science is incompetent to confer culture; that it touches none of the higher problems of life; and, what is worse, that the continual devotion to scientific studies tends to generate a narrow and bigoted belief in the applicability of scientific methods to the search after truth of all kinds. How frequently one has reason to observe that no reply to a troublesome argument tells so well as calling its author a "mere scientific specialist." And, as I am afraid it is not permissible to speak of this form of opposition to scientific education in the past tense; may we not expect to be told that this, not only omission, but prohibition of "mere literary instruction and education" is a patent example of scientific narrow-mindedness?

I am not acquainted with Sir Josiah Mason's reasons for the action which he has taken; but if, as I apprehend is the case, he refers to the ordinary classical course of our schools and universities, by the name of "mere literary instruction and education," I venture to offer sundry reasons of my own in support of that action.

For I hold very strongly by two convictions—The first is, that neither the discipline nor the subject-matter of classical education is of such direct value to the student of physical science as to justify the expenditure of valuable time upon either; and the second is, that for the purpose of attaining real culture, an exclusively scientific education is at least as effectual as an exclusively literary education.

I need hardly point out to you that these opinions, especially the latter, are diametrically opposed to those of the great majority of educated Englishmen, influenced as they are by school and university traditions. In their belief culture is obtainable only by a liberal education, and a liberal education is synonymous not merely with education and instruction in literature, but in one particular form of literature, namely, that of Greek and Roman antiquity. They hold that the man who has learned Latin and Greek, however little, is educated; while he who is versed in other branches of knowledge, however deeply, is a more or less respectable specialist, not admissible into the cultured caste. The stamp of the educated man, the University degree, is not for him.

I am too well acquainted with the generous catholicity of spirit, the true sympathy with scientific thought, which pervades the writings of our chief apostle of culture to identify him with these opinions; and yet one may cull from one and another of those epistles to the Philistines, which so much delight all who do not answer to that name, sentences which lend them some support.

Mr. Arnold tells us that the meaning of culture is "to know the best that has been thought and said in the world." It is the criticism of life contained in literature. That criticism regards "Europe as being for intellectual and spiritual purposes one great confederation, bound to a joint action and working to a common result; and whose members have for their common outfit a knowledge of Greek, Roman, and Eastern antiquity, and of one another. Special local and temporary advantages being put out of account, that modern nation will in the intellectual and spiritual sphere make most progress which most thoroughly carries out this programme. And what is that but saying that we too, all of us as individuals, the more thoroughly we carry it out shall make the more progress!"

We have here to deal with two distinct propositions. The first, that a criticism of life is the essence of culture; the second, that literature contains the materials which suffice for the construction of such a criticism.

I think that we must all assent to the first proposition. For culture certainly means something quite different from learning or technical skill. It implies the possession of an ideal, and the habit of critically estimating the value of things by comparison with a theoretic standard. Perfect culture should supply a complete theory of life, based upon a clear knowledge alike of its possibilities and of its limitations.

But we may agree to all this, and yet strongly dissent from the assumption that literature alone is competent to supply this knowledge. After having learnt all that Greek, Roman, and Eastern antiquity have thought and said, and all that modern literatures have to tell us, it is not self-evident that we have laid a sufficiently broad and deep foundation for that criticism of life which constitutes culture.

Indeed, to any one acquainted with the scope of physical science, it is not at all evident. Considering progress only in the "intellectual and spiritual sphere," I find myself wholly unable to admit that either nations or individuals will really advance if their common outfit draws nothing from the stores of physical science. I should say that an army without weapons of precision and with no particular base of operations might more hopefully enter upon a campaign on the Rhine than a man, devoid of a knowledge of what physical science has done in the last century, upon a criticism of life.

When a biologist meets with an anomaly, he instinctively turns to the study of development to clear it up. The rationale of contradictory opinions may with equal confidence be sought in history.

It is, happily, no new thing that Englishmen should employ their wealth in building and endowing institutions for educational purposes. But, five or six hundred years ago, deeds of foundation expressed or implied conditions as nearly as possible contrary to those which have been thought expedient by Sir Josiah Mason. That is to say, physical science was practically ignored, while a certain literary training was enjoined as a means to the acquirement of knowledge which was essentially theological.

The reason of this singular contradiction between the actions of men alike animated by a strong and disinterested desire to promote the welfare of their fellows, is easily discovered.

At that time, in fact, if any one desired knowledge beyond such as could be obtained by his own observation, or by common conversation, his first necessity was to learn the Latin language, inasmuch as all the higher knowledge of the western world was contained in works written in that language. Hence Latin grammar, with logic and rhetoric, studied through Latin, were the fundamentals of education. With respect to the substance of the knowledge imparted through this channel, the Jewish and Christian Scriptures, as interpreted and supplemented by the Romish church, were held to contain a complete and infallibly true body of information.

Theological dicta were, to the thinkers of those days, that which the axioms and definitions of Euclid are to the geometers of these. The business of the philosophers of the middle ages was to deduce from the data furnished by the theologians, conclusions in accordance with ecclesiastical decrees. They were allowed the high privilege of showing, by logical process, how and why that which the Church said was true, must be true. And if their demonstrations fell short of or exceeded this limit, the Church was maternally ready to check their aberrations, if need be, by the help of the secular arm.

Between the two, our ancestors were furnished with a compact and complete criticism of life.

They were told how the world began and how it would end; they learned that all material existence was but a base and insignificant blot upon the fair face of the spiritual world, and that nature was, to all intents and purposes, the playground of the devil; they learned that the earth is the centre of the visible universe, and that man is the cynosure of things terrestrial; and more especially was it inculcated that the course of nature had no fixed order, but that it could be, and constantly was, altered by the agency of innumerable spiritual beings, good and bad, according as they were moved by the deeds and prayers of men. The sum and substance of the whole doctrine was to produce the conviction that the only thing really worth knowing in this world was how to secure that place in a better which, under certain conditions, the Church promised.

Our ancestors had a living belief in this theory of life, and acted upon it in their dealings with education, as in all other matters. Culture meant saintliness—after the fashion of the saints of those days; the education that led to it was, of necessity, theological; and the way to theology lay through Latin.

That the study of nature—further than was requisite for the satisfaction of every-day wants—should have any bearing on human life was far from the thoughts of men thus trained. Indeed, as nature had been cursed for man's sake, it was an obvious conclusion that those who meddled with nature were likely to come into pretty close contact with Satan. And if any born scientific investigator followed his instincts he might safely reckon upon earning the reputation, and probably upon suffering the fate, of a sorcerer.

Had the western world been left to itself in Chinese isolation, there is no saying how long this state of things might have endured. But, happily, it was not left to itself. Even earlier than the thirteenth century, the development of Moorish civilisation in Spain and the great movement of the Crusades had introduced the leaven which, from that day to this, has never ceased

to work. At first, through the intermediation of Arabic translations, afterwards, by the study of the originals, the western nations of Europe became acquainted with the writings of the ancient philosophers and poets, and, in time, with the whole of the vast literature of antiquity.

Whatever there was of high intellectual aspiration or dominant capacity in Italy, France, Germany, and England, spent itself for centuries in taking possession of the rich inheritance left by the dead civilisations of Greece and Rome. Marvellously aided by the invention of printing, classical learning spread and flourished. Those who possessed it prided themselves on having attained the highest culture then within the reach of mankind.

And justly. For, saving Dante on his solitary pinnacle, there was no figure in modern literature at the time of the Renascence to compare with the men of antiquity; there was no art to compete with their sculpture; there was no physical science but that which Greece had created. Above all, there was no other example of perfect intellectual freedom—of the unhesitating acceptance of reason as the sole guide to truth and arbiter of conduct.

The new learning necessarily soon exerted a profound influence upon education. The language of the monks and schoolmen seemed little better than gibberish to scholars fresh from Virgil and Cicero, and the study of Latin was placed upon a new foundation. Moreover, Latin itself ceased to afford the sole key to knowledge. The student who sought the highest thought of antiquity, found only a second-hand reflection of it in Roman literature, and turned his face to the full light of the Greeks. And after a battle, not altogether dissimilar to that which is at present being fought over the teaching of physical science, the study of Greek was recognised as an essential element of all higher education.

Thus the Humanists, as they were called, won the day; and the great reform which they effected was of incalculable service to mankind. But the Nemesis of all reformers is finality; and the reformers of education, like those of religion, fell into the profound but common error of mistaking the beginning for the end of the work of reformation.

The representatives of the Humanists, in the nineteenth century, take their stand upon classical education as the sole avenue to culture, as firmly as if we were still in the age of Renascence. Yet surely the present intellectual relations of the modern and the ancient worlds are profoundly different from those which obtained three centuries ago. Leaving aside the existence of a great and characteristically modern literature, of modern painting, and, especially, of modern music, there is one feature of the present state of the civilised world which separates it more widely from the Renascence, than the Renascence was separated from the middle ages.

This distinctive character of our own times lies in the vast and constantly increasing part which is played by Natural Knowledge. Not only is our daily life shaped by it, not only does the prosperity of millions of men depend upon it, but our whole theory of life has long been influenced, consciously or unconsciously, by the general conceptions of the universe, which have been forced upon us by physical science.

In fact, the most elementary acquaintance with the results of scientific investigation shows us that they offer a broad and striking contradiction to the opinions so implicitly credited and taught in the middle ages.

The notions of the beginning and the end of the world entertained by our forefathers are no longer credible. It is very certain that the earth is not the chief body in the material universe, and that the world is not subordinated to man's use. It is even more certain that nature is the expression of a definite order with which nothing interferes, and that the chief business of mankind is to learn that order and govern themselves accordingly. Moreover this scientific "criticism of life" presents itself to us with different credentials from any other. It appeals not to authority, nor to what anybody may have thought or said, but to nature. It admits that all our interpretations of natural fact are more or less imperfect and symbolic, and bids the learner seek for truth not among words but among things. It warns us that the assertion which outstrips evidence is not only a blunder but a crime.

The purely classical education advocated by the representatives of the Humanists in our day, gives no inkling of all this. A man may be a better scholar than Erasmus, and know no more of the chief causes of the present intellectual fermentation than Erasmus did. Scholarly and pious persons, worthy of all respect, favour us with allocutions upon the sadness of the antagonism of Science to their mediæval way of thinking, which betray an ignorance of the first principles of scientific investigation, an incapacity for understanding what a man of science means by veracity, and an unconsciousness of the weight of established scientific truths, which is almost comical.

There is no great force in the *tu quoque* argument, or else the advocates of scientific education might fairly enough retort upon the modern Humanists that they may be learned specialists, but that they possess no such sound foundation for a criticism of life as deserves the name of culture. And, indeed, if we were disposed to be cruel we might urge that the Humanists have brought this reproach upon themselves, not because they are too full of the spirit of the ancient Greek, but because they lack it.

The period of the Renascence is commonly called that of the "Revival of Letters," as if the influences then brought to bear upon the mind of western Europe had been wholly exhausted in the field of literature. I think it is very commonly forgotten that the revival of science, effected by the same agency, although less conspicuous, was not less momentous.

In fact, the few and scattered students of nature of that day picked up the clue to her secrets exactly as it fell from the hands of the Greeks a thousand years before. The foundations of mathematics were so well laid by them that our children learn their geometry from a book written for the schools of Alexandria two thousand years ago. Modern astronomy is the natural continuation and development of the work of Hipparchus and of Ptolemy; modern physics of that of Democritus and Archimedes; it was long before modern biological science outgrew the knowledge bequeathed to us by Aristotle, Theophrastus, and Galen.

We cannot know all the best thoughts and sayings of the Greeks unless we know what they thought about natural phenomena. We cannot fully apprehend their criticism of life unless we understand the extent to which that criticism was affected by scientific conceptions. We falsely pretend to be the inheritors of their culture, unless we are penetrated, as the best minds among them were, with an unhesitating faith that the free employment of reason, in accordance with scientific method, is the sole guide to truth.

Thus I venture to think that the pretensions of our modern Humanists to the possession of the monopoly of culture and to the exclusive inheritance of the spirit of antiquity must be abated, if not abandoned. But I should be very sorry that anything I have said should be taken to imply a desire on my part to depreciate the value of classical education, as it might be and as it sometimes is. The native capacities of mankind vary no less than their opportunities; and while culture is one, the road by which one man may best reach it is widely different from that which is most advantageous to another. Again, while scientific education is yet inchoate and tentative, classical education is thoroughly well organised upon the practical experience of generations of teachers. So that, given ample time for learning and destination for ordinary life, or for a literary career, I do not think that a young Englishman in search of culture can do better than follow the course usually marked out for him, supplementing its deficiencies by his own efforts.

But for those who mean to make science their serious occupation; or who intend to follow the profession of medicine; or who have to enter early upon the business of life; for all these, in my opinion, classical education is a mistake; and it is for that reason that I am glad to see "mere literary education and instruction" shut out from the curriculum of Sir Josiah Mason's College, seeing that its inclusion would probably lead to the introduction of the ordinary smattering of Latin and Greek.

Nevertheless, I am the last person to question the importance of genuine literary education, or to suppose that intellectual culture can be complete without it. An exclusively scientific training will bring about a mental twist as surely as an exclusively literary training. The value of the cargo does not compensate for a ship's being out of trim; and I should be very sorry to think that the Scientific College would turn out none but lop-sided men.

There is no need however that such a catastrophe should happen. Instruction in English, French, and German is provided, and thus the three greatest literatures of the modern world are made accessible to the student.

French and German, and especially the latter language, are absolutely indispensable to those who desire full knowledge in any department of science. But even supposing that the know-

ledge of these languages acquired is not more than sufficient for purely scientific purposes, every Englishman has, in his native tongue, an almost perfect instrument of literary expression; and, in his own literature, models of every kind of literary excellence. If an Englishman cannot get literary culture out of his Bible, his Shakspere, his Milton, neither, in my belief, will the profoundest study of Homer and Sophocles, Virgil and Horace, give it to him.

Thus, since the constitution of the College makes sufficient provision for literary as well as for scientific education, and since artistic instruction is also contemplated, it seems to me that a fairly complete culture is offered to all who are willing to take advantage of it.

But I am not sure that at this point the "practical" man, scotched but not slain, may ask what all this talk about culture has to do with an Institution, the object of which is defined to be "to promote the prosperity of the manufactures and the industry of the country." He may suggest that what is wanted for this end is not culture, nor even a purely scientific discipline, but simply a knowledge of applied science.

I often wish that this phrase, "applied science," had never been invented. For it suggests that there is a sort of scientific knowledge of direct practical use, which can be studied apart from another sort of scientific knowledge, which is of no practical utility, and which is termed "pure science." But there is no more complete fallacy than this. What people call applied science is nothing but the application of pure science to particular classes of problems. It consists of deductions from those general principles, established by reasoning and observation, which constitute pure science. No one can safely make these deductions until he has a firm grasp of the principles; and he can obtain that grasp only by personal experience of the processes of observation and of reasoning on which they are founded.

Almost all the processes employed in the arts and manufactures fall within the range either of physics or of chemistry. In order to improve them, one must thoroughly understand them; and no one has a chance of really understanding them who has not obtained that mastery of principles and that habit of dealing with facts which is given by long-continued and well-directed purely scientific training in the physical and the chemical laboratory. So that there really is no question as to the necessity of purely scientific discipline, even if the work of the College were limited by the narrowest interpretation of its stated aims.

And, as to the desirableness of a wider culture than that yielded by science alone, it is to be recollected that the improvement of manufacturing processes is only one of the conditions which contribute to the prosperity of industry. Industry is a means and not an end; and mankind work only to get something which they want. What that something is depends partly on their innate, and partly on their acquired, desires.

If the wealth resulting from prosperous industry is to be spent upon the gratification of unworthy desires; if the increasing perfection of manufacturing processes is to be accompanied by an increasing debasement of those who carry them on, I do not see the good of industry and prosperity.

Now it is perfectly true that men's views of what is desirable depend upon their characters; and that the innate proclivities to which we give that name are not touched by any amount of instruction. But it does not follow that even mere intellectual education may not, to an indefinite extent, modify the practical manifestation of the characters of men in their actions, by supplying them with motives unknown to the ignorant. A pleasure-loving character will have pleasure of some sort; but, if you give him the choice, he may prefer pleasures which do not degrade him to those which do. And this choice is offered to every man, who possesses in literary or artistic culture a never-failing source of pleasures, which are neither withered by age, nor staled by custom, nor embittered in the recollection by the pangs of self-reproach.

If the Institution opened to-day fulfils the intention of its founder, the picked intelligences among all classes of the population of this district will pass through it. No child born in Birmingham, henceforward, if he have the capacity to profit by the opportunities offered to him first in the primary and other schools, and afterwards in the Scientific College, need fail to obtain, not merely the instruction, but the culture most appropriate to the conditions of his life.

Within these walls, the future employer and the future artisan may sojourn together for a while, and carry through all their lives the stamp of the influences then brought to bear upon them. Hence, it is not beside the mark to remind you that the prosperity of industry depends not merely upon the improvement of manufacturing processes, not merely upon the ennobling of the individual character, but upon a third condition, namely, a clear understanding of the conditions of social life on the part of both the capitalist and the operative, and their agreement upon common principles of social action. They must learn that social phenomena are as much the expression of natural laws as any others; that no social arrangements can be permanent unless they harmonise with the requirements of social statics and dynamics; and that, in the nature of things, there is an arbiter whose decisions execute themselves.

But this knowledge is only to be obtained by the application of the methods of investigation adopted in physical researches to the investigation of the phenomena of society. Hence, I confess, I should like to see one addition made to the excellent scheme of education propounded for the College, in the shape of provision for the teaching of Sociology. For though we are all agreed that party politics are to have no place in the instruction of the College; yet in this country, practically governed as it is now by universal suffrage, every man who does his duty must exercise political functions. And if the evils which are inseparable from the good of political liberty are to be checked, if the perpetual oscillation of nations between anarchy and despotism is to be replaced by the steady march of self-restraining freedom; it will be because men will gradually bring themselves to deal with political, as they now deal with scientific questions; to be as ashamed of undue haste and partisan prejudice in the one case as in the other; and to believe that the machinery of society is at least as delicate as that of a spinning-jenny, and not more likely to be improved by the meddling of those who have not taken the trouble to master the principles of its action.

In conclusion, I am sure that I make myself the mouthpiece of all present in offering to the venerable Founder of the Institution, which now commences its beneficent career, our congratulations on the completion of his work; and in expressing the conviction, that the remotest posterity will point to it as a crucial instance of the wisdom which natural piety leads all men to ascribe to their ancestors.

ON A SEPTUM PERMEABLE TO WATER, AND IMPERMEABLE TO AIR, WITH APPLICATION TO A NAVIGATIONAL DEPTH GAUGE[1]

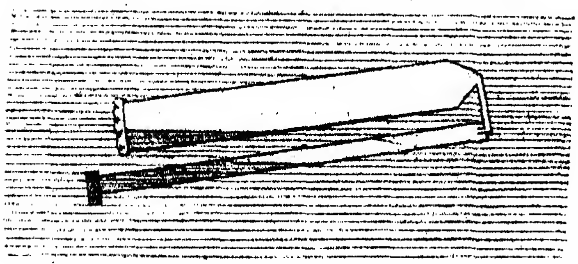
A SMALL quantity of water in a capillary tube, with both ends in air, acts as a perfectly air-tight plug against difference of pressure of air at its two ends, equal to the hydrostatic pressure corresponding to the height at which water stands in the same capillary tube when it is held upright, with one end under water and the other in air. And if the same capillary tube be held completely under water, it is perfectly permeable to the water, opposing no resistance except that due to viscidity, and permitting a current of water to flow through it with any difference of pressure at its two ends, however small. In passing it may be remarked that the same capillary tube is, when not plugged by liquid, perfectly permeable to air.

A plate of glass, or other solid, capable of being perfectly wet by water, with a hole bored through it, acts similarly in letting air pass freely through it when there is no water in the hole; and letting water pass freely through it when it is held under water; and resisting a difference of air-pressures at the two sides of it when the hole is plugged by water. The difference of air-pressures on the two sides which it resists is equal to the hydrostatic pressure corresponding to the rise of water in a capillary tube of the same diameter as the narrowest part of the hole. Thus a metal plate with a great many fine perforations, like a very fine rose for a watering-can for flowers, fulfils the conditions stated in the title to this communication. So does very fine wire cloth. The finer the holes, the greater is the difference of air-pressures balanced, when they are plugged with water. The shorter the length of each hole the less it resists the passage of water when completely submerged; and the greater the number of holes, the less is the whole resistance to the permeation of water through the membrane.

[1] Paper read at the British Association by Sir William Thomson.

Hence, clearly, the object indicated in the title is more perfectly attained, the thinner the plate and the smaller and more numerous the holes. Very fine wire cloth would answer the purpose better than any metal plate with holes drilled through it; and very fine closely-woven cotton cloth, or cambric, answers better than the finest wire cloth. The impenetrability of wet cloth to air is well known to laundresses, and to every naturalist who has ever chanced to watch their operations. The quality of dry cloth to let air through with considerable freedom, and wet cloth to resist it, is well known to sailors, wet sails being sensibly more effective than dry sails (and particularly so in the case of old sails, and of sails of thin and light material).

An illustration was shown to the meeting by taking an Argand lamp-funnel, with a piece of very fine closely-woven cotton cloth tied over one end of it. When the cloth was dry, and the other end dipped under water, the water rose with perfect freedom inside, showing exceedingly little resistance to the passage of air through the dry cloth. When it was inverted, and the end guarded by the cloth was held under water, the water rose with very great freedom, showing exceedingly little resistance to the permeation of water through the cloth. The cloth being now wet, and the glass once more held with its other end under water, the cloth now seemed perfectly air-tight, even when pressed with air-pressure corresponding to nine inches of water, by forcing down the funnel, which was about nine inches long, till the upper end was nearly submerged. When it was wholly submerged, so that there was air on one side and water on the other, the resistance to permeation of air was as decided as it was when the cloth, very perfectly wet, had air on each side of it.



Water indicated by horizontal shading; Air by white paper.

Once more, putting the cloth end under water; holding the tube nearly horizontal, and blowing by the mouth applied to the other end:—the water which had risen into the funnel before the mouth was applied, was expelled. After that no air escaped until the air-pressure within exceeded the water pressure on the outside of the cloth by the equivalent of a little more than nine inches of water; and when blown with a pressure just a very little more than that which sufficed to produce a bubble from any part of the cloth, bubbles escaped in a copious torrent from the whole area of the cloth.

The accompanying sketch represents the application to the Navigational Depth Gauge. The wider of the two communicating tubes, shown uppermost in the sketch, has its open mouth guarded by very fine cotton cloth tied across it. The tube shown lower in the diagram is closed for the time of use by a stopper at its lower end. A certain quantity of water (which had been forced into it during the descent of the gauge to the bottom of the sea) is retained in it while the gauge is being towed up to the surface in some such oblique position as that shown in the sketch. While this is being done the water in the wide tube is expelled by the expanding air. The object of the cloth guard is to secure that this water is expelled to the last drop before any air escapes; and that afterwards, while the gauge is being towed wildly along the surface from wave to wave by a steamer running at fourteen or sixteen knots, not a drop of water shall re-enter the instrument.

ON THE CLASSIFICATION OF BIRDS[1]

ABOUT twelve years ago Prof. Huxley had taken up the subject of the classification of birds in his usual zealous and original way, and from quite a new point of view. Prof. Huxley, treating birds mainly from their bones and as if they were extinct animals of which these parts of their structure only were known, had proposed an entirely new plan of arrangement, based mainly upon the characteristic variations of the palatal bones, which had passed almost unnoticed by previous writers. The author, who had long been dissatisfied with the Cuvierian system, which with certain modifications he had employed up to 1872, had in that year been constrained to consider the whole subject in order to decide what arrangements should be adopted in the "Nomenclator Avium Americanarum" (a joint work by Mr. O. Salon and himself), then ready for publication. Prof. Huxley had commenced his system with the lowest and most reptilian birds, and had ended it with the highest and most specialised. But it seemed to the author that by exactly reversing this arrangement he would obtain a scheme which would not very far deviate from that which he had previously employed for the first three orders, and would offer many improvements on the Cuvierian system in the remaining ones. Such a scheme had accordingly been promulgated in the Introduction to the "Nomenclator" and followed in that work. In the various subsequently issued editions of the "List of Vertebrated Animals in the Zoological Society's Gardens" a nearly similar arrangement had been followed. A certain amount of adhesion having been secured to this system, the author had been recently induced to devote some labour to its improvement and development. As now elaborated it did not profess to be in any respects original, except as regarded certain small details on points to which he had devoted special attention. The arrangement was in fact simply that of Huxley reversed, with slight modifications consequent upon the recent researches of Parker and Garrod on the anatomy and osteology of little known forms.

The author then proceeded to explain further the "Systema Avium" thus advocated, as shown in the subjoined table, in which the approximate number of known species was added after each Order.

ORDERS OF EXISTING BIRDS

SUBCLASS CARINATÆ (10,121 SPECIES)

		Species.			Species.
I.	Passeres	5,700	XIII.	Gallinæ	320
II.	Picariæ	1,600	XIV.	Opisthocomi ...	1
III.	Psittaci	400	XV.	Hemipodii ...	24
IV.	Striges	180	XVI.	Fulicariæ ...	150
V.	Accipitres... ...	330	XVII.	Alectorides ...	60
VI.	Steganopodes ...	60	XVIII.	Limicolæ ...	250
VII.	Herodiones ...	130	XIX.	Gaviæ	130
VIII.	Odontoglossæ ...	8	XX.	Tubinares ...	100
IX.	Palamedeæ ...	3	XXI.	Pygopodes ...	65
X.	Anseres	180	XXII.	Impennes ...	20
XI.	Columbæ	355	XXIII.	Crypturi	40
XII.	Pterocletes ...	15			

SUBCLASS RATITÆ (18 SPECIES)

XXIV.	Apteryges	4	XXVI.	Struthiones ...	4
XXV.	Casuarii	10			

In submitting this arrangement, as one which on the whole he was disposed to regard as the best to be adopted after many years' study of the Class of Birds, the author observed that it should be recollected that, although a linear system is an absolute necessity for practical use, it could never be a perfectly natural one. It would always be found that certain groups were nearly equally related to others in different places in the linear series, and that it was a matter of difficulty to decide with which of the allied forms they were best located. But, a linear arrangement being an absolute necessity, it became our duty to make it as natural as possible.

[1] Abstract of a paper read at the British Association by P. L. Sclater, M.A., Ph.D., F.R.S.

THE GREEN COLOUR OF OYSTERS

IN NATURE, vol. xvi. p. 397, mention was made of the fact that the green colour observed in oysters in certain localities is caused by a variety of navicula, to which the name *Navicula ostrearia* has been given. Further particulars of experiments made by M. Puységur, at Sissable, are not without interest.[1]

"The green slime was collected by lightly scraping the margin of one of the 'clears' with a spoon, and was put in flasks, shaken for a moment and then allowed to settle, so as to get rid of the mud, some admixture of which is inevitable. The coloured fluid, containing little or nothing besides diatoms, was then poured off into other flasks. Care and some little dexterity are requisite, as if there is too much silt or too large a quantity

[1] *Revue maritime et coloniale*, February, 1880.

of water, which is generally the case when the task is intrusted to a subordinate, it is sometimes next to impossible to concentrate the fluid enough to show the results with the desired plainness.

"Returning home, we poured the fluid into soup-plates set on a table before a window. The diatoms speedily settled on the sides and bottoms of the plates, coating them with a green slime, the thickness and tint of which varied with the proportion of diatoms present. In each plate, according to its size, we put three to six perfectly white oysters which had never been in the 'clears,' and the shells of which had previously been washed and brushed clean. In similar plates like numbers of the same oysters were laid in ordinary sea-water. Twenty-six hours after the commencement of the experiment the oysters in the water charged with diatoms had all acquired a marked greenish hue; the other oysters remained unaltered. The experiment was repeated many times with identically the same results. The green colour in the oysters was found to be more decided in proportion as the water was more highly charged with diatoms. In the course of the experiments the shell of one of the oysters was perforated, so as to lay bare the mantle. After the oyster had turned green, it was laid in ordinary sea-water for a few days, when the greenness disappeared altogether. It reappeared when the oyster was replaced in fresh water containing *Navicula ostrearia*. The experiment was repeated, with like results, in the laboratory of M. Decaisne, Jardin des Plantes, Paris, to which a supply of white oysters and sealed flasks of the water containing the diatoms was forwarded.

"In the course of the experiments it was observed that by the opening and closing of their valves the oysters induced currents in the water, by means of which they drew towards them and surrounded themselves with the particles of matter suspended therein. The existence and direction of these currents were shown by the disappearance of the slime and the consequent laying bare of the sides and bottoms of the plates, the diatoms remaining only at points out of reach of the currents.

"Directed towards the buccal aperture by the ciliæ with which the branchiæ are provided, the naviculæ enter the stomach of the mollusc, and there part with their nutritive constituents. The yellow chlorophyll is digested and decomposed; the soluble colouring matter passes direct into the blood, to which it imparts its colour. Thus it happens that the most vesicular portions of the structure, as the branchiæ, are the most highly coloured.

"Examination of the digestive tubes of the oysters experimented upon proved the fact of the absorption of the diatoms. The stomachs, intestines, and exuviæ were strewed with carapaces of naviculæ. The carapaces, being siliceous, are not affected by the digestive juices, and it would seem extraordinary that with so tenacious a covering their contents should be evolved, were it not for the knowledge of the fact that the covering is not continuous, the line of suture separating the valves composing the frustule being scarcely silicified at all."

It would therefore appear to be established beyond dispute that the green hue in oysters is due exclusively to their absorption of certain naviculæ contained in the circumambient water. The facts are in perfect keeping with the observations of growers that heavy rains (which increase the supply of fresh water) cause the disappearance of the green from the "clears," while, on the other hand, dry north-east gales, which greatly increase the saturation of the water, bring it, as it is called, "into condition."

Two points of special interest in connection with the subject remain for future investigation. These are:—

1. Does the navicula in question remain all the year in the waters where it is found in winter?

2. Is the coloration of the beds accidental or temporary?—in other words, does this alga disappear from the reservoirs when the water changes its colour, or does it become itself discoloured for a time?

H. M. C.

MODERN ENTOMOLOGY[1]

IT is the good fortune of your president on this occasion to welcome you to his native heath, where our favourite science has been longer, more uninterruptedly, and perhaps more zealously cultivated than anywhere else in the New World. Here, in the last century, Peck studied the Canker-worm and the Slug-worm of the Cherry, and in late years *Rhynchænus*, *Stenocorus*, and *Cossus*—all highly destructive insects. Here lived Harris, who cultivated entomology in its broadest sense, and whose classic treatise was the first important Government publication on injurious insects. Here to-day we have two associations for our work, consisting, it will be confessed, of nearly the same individuals, and not many of them, but meeting frequently —one in Boston, the other in Cambridge. Harvard acknowledges the claims of our study in supporting not only an instructor in entomology at its Agricultural School, but a full Professor of the same in the University at large.

In our own day the spreading territory of the United States, the penetration of its wilds, and the inersection of its whole area by routes of travel, the wider distribution and greatly-increased numbers of local entomologists, as well as the demand for our natural products abroad, have set before *us* temptation to study only new forms and to cultivate descriptive work, to the neglect of the choicer, broader fields of our ever-opening science. It is this danger to which I venture briefly to call your attention to-day, not by way of disparaging the former, but rather in the hope that some of our younger members, who have not yet fallen into the ruts of work, may be induced to turn their attention to some of the more fruitful fields of diligent research.

We should not apply the term descriptive work merely to the study of the external features of insects. The great bulk of what passes for comparative anatomy, physiology, and embryology is purely descriptive, and is only to be awarded a higher grade in a scale of studies than that which deals with the external properties when it requires a better training of the hand and eye to carry it out, and greater patience of investigation. We pass at once to a higher grade of research when we deal with comparisons or processes (which of course involve comparisons). All good descriptive work indeed is also comparative; but at the best it is so only in the narrowest sense, for only intimately allied forms are compared. In descriptive work we deal with simple facts; in comparative work we deal with their collocation. "Facts," said Agassiz one day, "facts ar stupid things, until brought in connection with some general law."

It is to this higher plane that concerns itself with general laws that I would urge the young student to bend his steps. The way is hard; but in this lies one of its charms, for labour is its own reward. It is by patient plodding that the goal is reached; every step costs and counts; the ever-broadening field of knowledge exhilarates the spirit and intensifies the ambition; there is no such thing as satiety—study of this sort never palls.

It is hardly necessary to point out that so-called systematic work never reaches this higher grade unless it is monographic; unless it deals in a broad way with the relationship and general affinities of insects. It is not my purpose to call attention here to the needs of science in this department, as they are too patent to escape observation; but if one desires a model upon which to construct such work, one need not look further than the "Revision of the Rhynchophora," by Drs. LeConte and Horn. Rather than linger here we prefer to pass directly to some of the obscurer fields of study.

When we compare the number of insect embryologists in America with that of their European colleagues, the result is somewhat disheartening and discreditable; although perhaps the comparison would be not quite so disproportionate were some of our students to publish their notes. But take all that has been done upon both sides of the water, and what a meagre showing it makes! Of how many families of Coleoptera alone have we the embryonic history of a single species?

In following the post-embryonal history of insects there is work for all. While allied forms have in general a very similar development, there are so many which are unexpectedly found to differ from one another, that every addition to our knowledge of the life histories of insects is a gain, and they are to be praised who give their close attention to this matter. Here is a field any entomologist, even the most unskilled, may cultivate to his own advantage and with the assurance that every new history he works out is a distinct addition to the science. The importance of an accumulation of facts in this field can hardly be over-estimated, and those whose opportunities for field-work are good should especially take this suggestion to heart. Nor, by any means, is the work confined to the mere collection of facts. How to account for this extraordinary diversity of life and habits among insects, and what its meaning may be, is one of the problems of the evolutionist. There are also here some specially curious inquiries, to which Sir John Lubbock and

[1] Annual Address before the Entomological Club of the American Association for the Advancement of Science, by the President, Mr. S. H. Scudder, of Cambridge.

others have recently called attention, and to which Mr. Riley has contributed by his history of *Epicauta* and other *Meloidæ*. I refer to the questions connected with so-called hypermetamorphosis in insects. In these cases there are changes of form during the larval period greater than exist between larva and pupa, or even between larva and imago, in some insects. There are also slighter changes than these which very many larvæ undergo; indeed it may safely be asserted that the newly-hatched and the mature larvæ of all external feeders differ from each other in some important features. The differences are really great (when compared to the differences between genera of the same family at a similar time of life) in all lepidopterous larvæ, as well as in all Orthoptera which have come under my notice. No attempt to co-ordinate these differences, or to study their meanings, or to show the nature of their evident relationship to hypermetamorphosis has ever been attempted.

Not less inviting is the boundless region of investigation into the habits of insects and their relation to their environment. The impulse given to these studies by the rise of Darwinism, and the sudden and curious importance they have assumed in later investigations into the origin and kinship of insects, need only to be mentioned to be acknowledged at once by all of you. The variation in coloration and form exhibited by the same insect at different seasons or in different stations, "sports," the phenomena of dimorphism, and that world of differences between the sexes, bearing no direct relation to sexuality; mimicry also, phosphorescence and its relations to life, the odours of insects, the relation of anthophilous insects to the colours and fructification of flowers, the modes of communication between members of communities, the range and action of the senses,[1] language, commensalism—these are simply a few topics selected quite at random from hundreds which might be suggested, in each of which new observations and comparative studies are urgently demanded.

The fundamental principles of the morphology of insects were laid down by Savigny in some memorable memoirs more than sixty years ago; the contributions of no single author since that time have added so much to our knowledge, notwithstanding the aid that embryology has been able to bring. Nevertheless there remain many unsolved problems in insect morphology which by their nature are little likely to receive help from this source. Let me mention three:—

The first concerns the structure of the organs of flight. The very nomenclature of the veins shows the disgraceful condition of our philosophy of these parts; the same terminology is not employed in any two of the larger sub-orders of insects; names without number have been proposed, rarely however by any author with a view to their applicability to any group outside that which formed his special study; and a tabular view which should illustrate them all would be a curious sight. A careful study of the main and subordinate veins, their relations to each other, to the different regions of the wing, to the supporting parts of the thorax and to the alar muscles, should be carried through the entire order of insects; by no means, either, neglecting their development in time, and possibly deriving some assistance in working out homologies by the study of their hypodermic development.

The second concerns the mouth parts. The general homologies of these organs were clearly and accurately enough stated by Savigny, though one may perhaps have a right to consider the last word not yet said when one recalls Saussure's recent claim to have found in *Hemimerus* a second labium. What I refer to, however, is another point: it relates to the appendages of the maxillæ and the labium. Considering the labium as a soldered pair of secondary maxillæ, we have at the most, on either pair of maxillæ, three appendages upon either side. These appendages, as you know, are very variously developed in different sub-orders of insects, or even in the same sub-order; and it has at least not been shown, and I question if it can be done, that the parts bearing similar names in different sub-orders are always homologous organs. Here is a study as broad and perhaps as difficult as the last.

The third is the morphological significance of monstrosities, especially of such as are termed monstrosities by excess. The literature of the subject is very scattered, and the material much more extensive than many of you may think. At present this subject is, so to speak, only one of the curiosities of entomology, but we may be confident that it will one day show important relations to the story of life.

[1] Notice Meyer's beautiful studies on the perception of sound by the mosquito.

After all the labours of Herold, Treviranus, Lyonet, Dufour, and dozens of other such industrious and illustrious workers, is there anything important remaining to be done in the gross anatomy of insects? some of you would perhaps ask. Let the recent work of some of our own number answer, which has shown in the Hemiptera and Lepidoptera the existence of a curious pumping arrangement by which nutritious fluids are forced into the stomach. It is certainly strange that after all that has been said as to the mode in which a butterfly feeds, no one should have dissected a specimen with sufficient care to have seen the pharyngeal sac which Mr. Burgess will soon show us. No! the field is still an open one, as the annual reviews clearly show. The curious results of Flögel's studies of the brain, the oddly-constructed sense-organs found by Graber and Meyer (earlier noticed briefly by Leydig) in the antennæ of Diptera, the important anatomical distinctions discovered by Forel in different groups of ants, the strange modification of the tip of the spiral tongue in *Ophideres*, which Darwin, Brietenbach, and Künckel have discussed, and, above all, the extensive investigations of the nervous system in insects generally which Brandt has recently undertaken, the exquisite memoir of Grenacher on the structure of the compound eye, and the keen researches of Graber in various departments of insect anatomy, show by what has been accomplished how many harvests are still unreaped. The microtome, too, has put a new instrument of precision into the hands of the investigator in the field.

If these few words shall arouse in any one a higher ambition, leading to better work, their aim will have been accomplished.

SCIENTIFIC SERIALS

American Naturalist, August 1880.—D. P. Penhallow, the fabrication of Aino cloth.—H. D. Minot, English birds compared with American.—J. S. Gardner, on the age of the Laramie formation as indicated by its vegetable remains.—J. E. Todd, on the flowering of *Saxifraga sarmentosa*.—Prof. A. N. Prentiss, distribution of obnoxious insects by means of fungoid growths.—Recent literature.—General notes.—Scientific news.

September.—J. Walter Fewkes, the Siphonophores:—No. 1, the anatomy and development of Agalma.—Prof. A. N. Prentiss, destruction of obnoxious insects by means of fungoid growths (concluded); the result of these experiments would seem to indicate plainly that yeast cannot be regarded as a reliable remedy against such insects as commonly affect plants cultivated in greenhouses or in windows, but the general question is by no means as yet decided.—O. B. Johnson, birds of the Willamette Valley, Oregon (concluded).—C. O. Whitman, Do flying-fish fly?

Annalen der Physik und Chemie, No. 8.—On electric expansion (continued), by G. Quincke.—Clausius' law and the motion of the earth in space, by E. Budde.—On the dependence of the electric conductivity of carbon on the temperature, by W. Siemens.—On the phenomena in Geissler tubes under external action, by E. Reitlinger and A. v. Urbanitzky.—Complete theory of the bifilar-magnetometer and new methods of determining the absolute horizontal intensity of the earth's magnetism, as also the temperature and induction coefficients of magnets, by H. Wild.—On the comparison of the electrodynamic fundamental law with experience, by R. Clausius.—On a direct transformation of the vibrations of radiant heat into electricity, by W. Hankel.—On fluorescence, by E. Lommel.—On the behaviour of different heat rays in the reflection of polarised rays from metals, by H. Knoblauch.—Remark on the heat conductivity of mercury, by H. Herwig.—Remarks on H. Weber's memoir on heat-conduction in liquids, by A. Winkelmann.—On air-resistance, by G. Recknagel.—On the action of hollow, in comparison with that of solid, steel magnets, by W. Holtz.

No. 9.—On the compressibility of gases, by F. Roth.—On the electric conductivity of some salt solutions, by J. H. Long.—New experimental researches on fluorescence, by O. Lubarsch.—On constants of refraction, by L. Lorenz.—Experimental researches on refraction constants, by K. Prytz.—Theory of reflection and refraction at the limit of homogeneous, isotropic, transparent bodies, with generalisation and extension of the foundations of Neumann's method, by M. Réthy.—Thermal theory of development of electricity, by J. L. Hoorweg.—On the behaviour of electricity in gases, and especially in vacuum, by F. Narr.—Defence of the law of corresponding boiling temperatures, by U. Dühring.—Equation of the state of atmospheric

air, by G. Schmidt.—Time of discharge of the Ley den battery, by P. Riess.

Journal of the Royal Microscopical Society, vol. iii. No. 4 (August, 1880), contains: John Badcock, notes on Acinetina (*Trichophrya epistylidis* and *Podophrya quadripartita*) with a plate.—J. W. Stephenson, on the visibility of minute objects mounted in phosphorus, solutions of sulphur, bisulphide of carbon, and other media.—Dr. George Hoggan and Dr. F. Elizabeth Hoggan, on the development and retrogression of blood vessels, with a plate.—Dr. Jas. Edmunds, on a parabolised gas slide.—The record of current researches relating to invertebrata, cryptogamia, microscopy; bibliography, and proceedings of the society.

Journal de Physique, September.—On the alternating currents and the electromotive force of the electric arc, by M. Joubert.—On the formula of interpolation of M. Pictet, by M. Szily.—Absolute measurement of Peltier's phenomenon in contact of a metal, and its solution, by M. Bouty.

Bulletin de l'Académie Royale des Sciences (*de Belgique*), No. 8.—On the embryonal leaves and the notochord in Urodela, by M. van Bambeke.—Researches on the spectrum of magnesium in relation to the constitution of the sun, by M. Fiévez.—On the presence of phosphoric acid in the urine of cows, by M. Chevron.—Excretory apparatus of Trematodes and Cestoides (2nd paper), by M. Fairfont.—Researches on fusel oil (amylic alcohol, &c.) in commercial alcohol, brandies, &c., by M. Jorissen.—On the structure of the venomous apparatus of Araneides, by Mr. MacLeod.—On the gastric gland of the American ostrich, by M. Remouchamps.—On the geometric representation of co-variants of a biquadratic form, by M. Le Paige.

Morphologisches Jahrbuch (*Gegenbaur's*), Bd. vi., Heft 3.—J. E. V. Boas, on the heart and arch of the aorta in Ceratodus and Protopterus, with three plates and woodcuts (a memoir both descriptive and critical of the various researches on this subject by Hyrtl, Owen, Peters, Lankester, and Günther).—G. v. Koch, notes on corals, with a plate.—George Ruge, researches on the process of development of the sternum, and on the sterno-clavicular attachments in man, with three plates.—W. Salensky, contribution to the developmental history of the ear cartilages in mammals, with a plate.

Zeitschrift für wissenschaftliche Zoologie, Bd. xxxiv., Heft. 3, July.—Gustav Häuser, physiological and histological investigations on the organ of smell in insects, three plates (finds in most insects well-marked nerves springing from the cephalic ganglia distributed to the antennæ, where special hypodermic cells receive them; the development and structure of these are beautifully illustrated).—O. Zimmermann, on a peculiar formation in the abdominal vessels in an Ephemeris larva.—Prof. F. E. Schulze, researches on the structure and development of the sponges: No. 9, the Plakinidæ, three plates (three new genera and five new species described).—John Hönigschmied, brief notices concerning the distribution of the gustatory papillæ in mammals.—Dr. J. W. Spengel, contribution to a knowledge of the Gephyrea, four plates (*Echiurus Pallasii*).

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, September 27.—M. Wurtz in the chair.—The following papers were read:—On the non-recurrence of the anthracoid affection, by MM. Pasteur and Chamberland. Their experiments prove that in the case of *charbon*, as in that of chicken cholera, inoculations that do not prove fatal are preventive of a recurrence of the disease. M. Pasteur argues against M. Chauveau's theory that such non-recurrence is due to production of matters adverse to the proliferation of the bacterium. Experiments had been made with a view to testing a remedy for charbon devised by M. Louvrier, but were indecisive.—On the results obtained by M. Rondaire in his exploration of the Tunisian and Algerian chotts, by M. de Lesseps. M. Rondaire's conclusions are entirely favourable to filling the basin situated between the Gulf of Gabes and the projected line of railway from Biskra to Tuggurt. This would make an interior sea about 400 km. in length and 1,600 km. in circumference.—A vapour-tension manometer for analysing liquids and measuring pressures, by M. Perrier. A glass tube, tapering at the lower end, stands with this (open) end in mercury, contained in, but not filling, an oblong closed bulb, a few drops of a volatile liquid being imprisoned above the mercury. The liquid to be determined is heated in a small boiler and the bulb referred to is placed in the vapour. The liquid of the manometer (which should emit vapour of greater tension than the liquids examined) acts by its vapour on the mercury, forcing it up the tube to various heights.—On a property of Poisson's function, and on the integration of equations with partial derivatives of the first order, by M. Gilbert.—On the theory of sines of superior orders, by M. Farkas.—On the invention of binocular telescopes, by M. Govi. The invention is commonly attributed to the Capuchin monk Schyrleus de Rheita, who published an account of it in 1645. M. Govi finds, from the papers of Peirescq in the Bibliothèque Nationale, that a spectacle maker in Paris, D. Chorez, made and presented binocular glasses to the king in 1625, *i.e.* twenty years earlier.—On the difficulty of absorption and the local effects of the poison of *Bothrops jararaca*, by MM. Couty and Lacerda. Whichever the mode of introduction, cellular, muscular, or serous tissue, brain, heart, or lung, and whatever the quantity of poison injected (vascular ruptures and antecedent wounds apart), there is no distinct sign of penetration of the poison into the blood. There is always local inflammation, which for some organs may prove rapidly fatal. The lung is most sensitive in this respect, the stomach and intestine least.—Study of the vertebræ in the order of Ophidians, by M. Rochebrune.—On the ciliated embryo of the *Bilharzia*, by M. Chatin. The signification assigned by helminthologists to this embryo in the cycle of development of the species requires (in the author's opinion) to be profoundly modified (a superiority of constitution being observed).—Researches on the presence of micrococcus in the diseased ear; considerations on the *rôle* of microbes in auricular furuncle (boil) and general furunculosis; therapeutic applications, by M. Loewenberg. He has observed a microbe in furuncle of the ear. These small abscesses spread in the ear by what he calls *autocontagion*, and from individual to individual contagiously. In treatment he employs thymic or boric acid. In cases of neglected otorrhea or wetness of the ear, especially with fetidity, he has always found micrococcus in large quantity.

THE INDIAN FAMINE COMMISSION

THE recently issued Report of the Government Commission appointed some time ago to inquire into Indian Famines is of great practical value and full of suggestiveness as to the lines which further inquiry should pursue. This first part of the Report relates to Famine Relief, and bears evidence that the Commission have done their work with great thoroughness and breadth of view, and the results are recorded with clearness and method. On the question as to what measures of relief would be the most effectual to adopt, we need not touch here; no doubt they will receive attention in the proper quarter. The discussion of the various questions involved is prefaced by an excellent concise sketch of the geography, population, and climate of British India. Here also some important information is given as to the degree in which each part of the country is exposed to famine. This is followed by a statement of the measures which, in the opinion of the Commission, it would be advisable to adopt for famine relief, and a very complete and instructive review of past famines and the measures adopted to meet them. The immensity of the problem with which the Commission had to deal may be learned from the fact that the total area of British India is about one and a half million square miles with a population of 240 millions. Of this, 900,000 square miles, with a population of 190 millions, is under direct British rule, the remainder belonging to the native States. The great bulk of this population belongs to the classes on whom the dire effects of famine are sure to fall, so that the responsibility of our government in the matter cannot be magnified; they are bound to leave no means untried either to prevent the recurrence of famines or to meet them effectually if they do occur. The Commission, of course, could not but come to the conclusion that the devastating famines to which the provinces of India have from time to time been liable are in all cases to be traced to the occurrence of seasons of unusual drought, the failure of the customary rainfall leading to the failure of the food crops on which the subsistence of the population depends. The Commission have therefore justly conceived it to be an important part of their inquiry to ascertain what can be known as to the periodicity of rainfall throughout the year, and over periods of greater extent if possible. The yearly periodicity of rainfall in India and other tropical countries is well known. In India a strongly marked yearly periodicity is everywhere observed, the chief fall occurring, with few exceptions, in the summer months, between May and October, in the season commonly known as the south-west monsoon. On a part of the Madras coast, on the east of the peninsula, heavy rain falls after the cessation of these summer rains, in the months of November and December, at the beginning of what is termed the season of the north-east monsoon. In the more northern provinces, again, a well-marked season of winter rain occurs, commencing about Christmas and extending to February, but its effects hardly reach south of the tropic, and it has no sensible influence on the agriculture of Southern India. The main agricultural operations of the country correspond with these principal seasons of rain, and their relative importance is in a great degree dependent on the local distribution of the rainfall at the various seasons of the year, as the period and amount of rain differ much in the several provinces of India.

A most valuable feature of the Report is the numerous excellent maps which accompany it, and which are a great assistance to understanding the results of the inquiry. One map, for instance, shows the general features of the distribution of annual rainfall. The fall on the Western Ghats and on the tract between them and the sea is very heavy, being from 70 to 100 inches at the sea level, and as much as 250 inches on the mountain face exposed to the south-west rain-bearing winds. Along the east coast of the Bay of Bengal, and in the eastern districts of the Bengal Province, as also along the foot and outer slopes of the Himalaya throughout its whole extent, the rainfall is also extremely heavy, reaching 100 inches or more. Subject to these exceptions, it may be said generally that the portion of India east of the 80th meridian has a rainfall of more than 40 inches, while the portion west of the same meridian has less than 40 inches. The region in which the fall is less than 30 inches includes almost the whole of the Punjab, a considerable part of the North-West Provinces, a large part of Rajputana and Kathiawar, as well as almost the whole of the Deccan and Mysore. In Sindh and in the southern portion of the Punjab and most western part of Rajputana the rainfall is extremely small and irregular, being less than 15 inches. Of the area in which the rainfall is below 15 inches, it may be said that it is either actual desert or that agriculture is impossible without artificial irrigation; and hence it has followed that where the rain is least copious the population has made itself in a great degree independent of the local rainfall. In the opposite direction it is also generally true that where the rain is most abundant, exceeding 40 or 50 inches, the occurrence of such drought as will cause serious scarcity is rare. The region in which the average rainfall is between 20 and 35 inches is that which suffers most from droughts. Here, though on the average of years the rain is sufficient to support an agricultural population, the greater deficiencies which reduce the quantity below what is essential, as well as the smaller which seriously damage the crops, are so frequent as to lead to repeated seasons of scarcity of greater or less severity. From this it can easily be ascertained what are the parts of the country most subject to drought. These are (1) the western and southern parts of the North-Western Provinces and that portion of the Punjab territory which lies east of the Satlej; (2) the western and northern States of Rajputana and of the central plateau which border on the North-Western Provinces; (3) the districts of Bombay above the Western Ghats, and the districts of Madras above the Eastern Ghats, together with the southern and western region of Hyderabad and all Mysore, except the strip lying close along the Western Ghats; (4) the districts of Madras along the east coast and at the extremity of the peninsula. The more detailed account of the known droughts of the past hundred years, which are given, show how frequently the region whose total rainfall is from 20 to 35 inches has been subject to severe scarcity, and that within it have

occurred the great famines of 1837-38 in the North-West Provinces, of 1868-69 in Rajputana, and of 1876-77 over nearly the whole of the peninsula of Southern India. These droughts were mainly due to the failure of the south-west monsoon. The drought of 1865-66, and some of the earlier scarcities in Madras, arose from failures of the rain of the north-east monsoon on the east coast, a failure which in 1865-66 extended into Western Bengal. The famine of 1873-74 in Northern Bengal was exceptional, and is an instance of a great scarcity suddenly arising in a region of abundant average rainfall. This drought arose from a premature cessation of the rain, apparently due to an abnormal extension to the eastward of the margin of the comparatively dry area of North-Western India.

The Report touches briefly on a part of the subject which we deem of the greatest importance, namely, the supposed periodicity of fluctuations in the rainfall from year to year. These, the Report states, are in all parts of the country very considerable, variations of as much as 50 per cent. on either side of the average being often registered. The Commission refer to the opinion of those "qualified by their scientific knowledge to judge of such matters that there is evidence of these fluctuations being in some measure synchronous with those periodical variations in the condition of the sun which are indicated by the varying extent or number of sun-spots; and the recurring cycle of about eleven years, with which prolonged observation has shown that the period of sun-spot variation on the average accords, has been thus considered to correspond to the annual variations of the rainfall, the maximum and minimum of the one approximating in period to those of the other."

Of course the Commission, in the present unsettled state of this all-important question do not feel themselves justified in recommending any anticipatory measures to be taken in view of the probable recurrence of famine, on the basis of this theory. The subject, it is admitted, is scarcely advanced enough to warrant such recommendations. What they do recommend, however, demands the serious attention of the Indian Government. They state that the subject "is one deserving of careful investigation, and that it does not seem contrary to reasonable expectation that some relation should be established between the variations of the rainfall from year to year and those of the conditions of the sun's surface, on the heat derived from which, unquestionably, all terrestrial meteorological phenomena closely depend. For various reasons India is a country in which the investigation of this matter may be carried out with especial facilities, and for this reason (though other grounds are not wanting) we would urge that, as the expense of such researches would be small, the measures which have recently been taken by the Government of India to carry them out should be continued, and even extended in the future."

"As at present no power exists of foreseeing the atmospheric changes effective in producing the rainfall, or of determining beforehand its probable amount in any season, such as would admit of timely precautions being taken against impending drought, the necessity becomes the greater for watching with close attention the daily progress of each season as it passes, for ascertaining with accuracy and promptitude the actual quantity of rain in all parts of the country, and for forming the best and earliest judgment possible from the facts as they occur, whether the supply will be sufficient or otherwise. For the present at least, so far as the rainfall directly affects the subject under consideration, these are the only precautions that appear possible. Within the last few years a very satisfactory system of meteorological observations has been established all over British India, and in our opinion it is of primary importance that it shall be maintained in complete efficiency, and shall so far be strengthened and improved as to insure the early and punctual supply of information to the executive governments, and to the officials in all departments concerned with the agriculture of the country or the preparations required to meet famines, as to the actual progress of the periodical seasons of rain in all parts of the provinces for which those governments or officers are respectively responsible. So far as it may become possible, with the advance of knowledge, to form a forecast of the future, such aids should be made use of, though with due caution.

"We are also satisfied of the importance of the diffusion of more sound and accurate knowledge of the causes and mode of occurrence of the periodical rains, on which the well-being of India is so largely dependent, not only among the officers of the Government, but also among all classes of the community. Any measures which the Government may find possible with a view to the publication and diffusion of such knowledge cannot fail to be highly beneficial."

We shall look with interest for the further information on this subject, which is promised in the appendix to the Report. We need not add anything in support of the strong recommendation of the Commission. The Government would certainly not have appointed them at all unless it meant to take action upon their recommendations, and surely no line of inquiry is more promising, or could be fraught with more useful results. If the laws (for there can be no doubt that such exist) which regulate the periodicity of droughts can be clearly ascertained, it would reduce to the limit of simplicity the measure to be adopted either to prevent the occurrence of famines or to be prepared long beforehand to prevent their natural consequences.

Other recommendations of the Commission are quite in keeping with that to which we have just referred. They advocate the introduction of a more scientific method into administration and statistics, the institution of a separate agricultural department, and the need of improved agricultural, vital, and economical statistics.

Besides the map already mentioned, there are others showing the extent and comparative severity of the famines in various districts of India, from the beginning of the century downwards. Altogether the Commission have faced their task in a thoroughly business-like and scientific method; while they have sought information from every quarter likely to yield useful results, they have never lost sight of the object they had in view, and their Report is likely to be of permanent value. We shall look for the further record of their proceedings with the greatest interest.

GAMGEE'S "PHYSIOLOGICAL CHEMISTRY"

Physiological Chemistry of the Animal Body. By Arthur Gamgee, M.D., F.R.S., Brackenbury Professor of Physiology in the Owens College, Manchester. Vol. i. (London: Macmillan and Co., 1880.)

THE title of this book, since it seems to indicate that the work treats of a division or kind of chemistry, suggests the question whether it ought not to have been written (and reviewed) by a chemist rather than by a physiologist. And indeed there was a time when the view that the chemistry of living beings was a kind of chemistry distinct from the ordinary chemistry had some measure of support, and when consequently the phrase physiological chemistry had a very definite meaning. At the present time however all or nearly all are ready to admit that the chemical events which take place in living bodies are in reality of the same kind as and subject to the same chemical laws as those which take place in lifeless things; and hence physiological chemistry has come to mean the same thing as chemical physiology. The study of the chemical phenomena of animals and plants may be undertaken either by the chemist who understands physiology or by the physiologist who knows chemistry. The day must sooner or later come,—may its advent be more speedy than the present outlook promises!—when the chemist will be able, on the strength of his general knowledge, to foretell with sureness and precision the varied chemical events of the animal body; but hitherto and as yet, each chemical twist and turn of the vital machine has to be worried out by direct observation and experiment, so that physiological chemistry really means at present the physiological investigation of the chemical phenomena of living beings, and thus naturally falls into the hands of the physiologist.

For some years past there has been a great want of an adequate English treatise on the subject, a treatise which should deal with the matter much more fully and completely than could possibly be done in the text-books of physiology or chemistry. The preparation of such a treatise, however, is a task of great labour, and Prof. Gamgee assumed a heavy responsibility when he undertook to bring out the work, the first volume of which is now before us. But we believe that we may congratulate him and his readers on the accomplishment, so far, of his task.

The first instalment comprises, besides a preliminary chapter on proteids, an account of the chemistry of blood, pus, lymph, and of the elementary tissues, contractile, nervous, connective, and epithelial. About 200 pages are devoted to blood alone, and these not only contain a full description and discussion of the phenomena of coagulation, of the chemistry of the serum, and of the red corpuscles, both of their stroma and their hæmoglobin, but include a special chapter "on the changes which the blood undergoes in disease," and a section on the "characters presented by the blood of invertebrate animals." Prof. Gamgee's object has been apparently threefold, viz., (1) to give the chemical data as fully and as exactly as possible, with abundant references to original memoirs and other authorities; (2) to explain even in detail the methods by which the data are determined, and in this the reader will have at once his attention arrested and his progress assisted by the illustrations of apparatus, spectra, &c., the number and excellence of which form a very striking feature of the work, distinguishing it in a most marked manner from its predecessors; and (3) to point out and discuss the physiological bearings of the data expounded. Thus under the heading of "Oxy-hæmoglobin" will be found a description of the various methods of preparation of this substance (some eight special methods being given in detail in small print), followed by an account of its elementary composition, crystalline form, general reactions, and absorption-spectra. The physiological properties of hæmoglobin are in large measure postponed to the chapter on respiration; but the *technique* of spectroscopic examination is fully described, including the method of recording absorption-bands in wave-lengths; and hæmatin, with other derivatives and allies of hæmoglobin, as well as the action of carbonic oxide and other gases, are treated at length. The account of blood ends with a "description of certain methods of research not described in preceding sections," such, for instance, as the determination of the specific gravity of blood, the quantitative estimation of its various constituents, normal and abnormal, the extraction and measurement of the gases of blood, the measurement of the total quantity of blood in the body, &c., &c.

The other parts of the book are written in a similar fashion, and as far as we have at present, from the sections which we have subjected to a more detailed examination, been able to judge, the author has spared no pains to insure accuracy in his facts and statements, as he has certainly shown judgment in his selections, while his descriptions are remarkably clear and easy to understand.

The prominence given to methods, and the richness in illustrations, make the book one of great value to the student. There are books, some of them professedly written for students, which, though of much worth in other respects, are from the student's point of view practically useless: books of which the student's own judgment is that "he cannot find what he wants" in them. We venture to think that it will be the student's own fault if he cannot find what he wants in Prof. Gamgee's work; that is to say, if he wants what he ought to want. If he seeks in it a compendium which will give him just that amount of knowledge which may be required for an examination, so prepared as to be most easily absorbed and retained for the few weeks which precede his ordeal, he will very probably be disappointed. But if he desires to understand the chemistry of the animal body he will find it an admirable guide, and especially a most valuable book of reference. Throughout the whole of physiology, and at least no less in the chemical than in other parts, the value of the data and the trustworthiness of the conclusions founded on them depend very largely on the methods employed; and no student can form an intelligent judgment on the chemical phenomena of the body who has not understood and appreciated the methods by which the various investigations have been carried out. Hence we lay especial stress on this feature of the book before us as most important for the student.

Prof. Gamgee has gone largely into detail and even into controversy; and in this point too we think he is right. The outlines of physiological chemistry are already present in the various text-books of physiology; what

was emphatically wanted was a history and discussion of details to give shape and fulness to the more meagre accounts found elsewhere. Doubtless many will say that the work contains a great deal more than can possibly be wanted by the student of medicine or even of physiology. We will not presume to answer the difficult question, How little physiology a medical student may know without his educational status being considered "mean"; but this we may say, that there is not a page in this work, the study of which will not prove profitable not only to the medical student, but even to the medical practitioner.

We trust that the author will as soon as possible be able to complete a work of which the first part will increase his already high reputation, and certainly must be regarded as a most noteworthy addition to English physiological literature.

M. FOSTER

PEAT-MOSSES

The Sphagnaceæ or Peat-Mosses of Europe and North America. By R. Braithwaite, M.D., F.L.S. (London: David Bogue, 1880.)

THE peat-mosses are a peculiarly interesting group of cryptogamic plants, which has attracted the attention of even ordinary observers from a very early period. No group of plants is more clearly defined in structure, in family likeness, and by the localities in which they are found. The wanderer over our moorlands, the sportsman in pursuit of game, are as familiar as is the botanist with their dense green or ruddy-coloured tufts, now covering over some damp spot or filling up some bog hole with a vast mass of vigorous vegetation. Nor is there wanting to them an economic value, and that of too great an importance to be overlooked by even the most careless, for it is past generations of these bog-mosses which form the vast deposits of peat, for which as an article of fuel no substitute is in many parts of Europe attainable. The name sphagnus was first used, by writers like Theophrastus and Pliny, to indicate some of the spongy lichens, but was restricted to a genus of mosses by Dillenius more than a century and a half ago, "which were like none of the terrestrial mosses, but were produced always in bogs and marshes."

Dr. Braithwaite, in the volume before us, gives a most excellent sketch of the literature of the genus, tracing it from Dillenius, Linneus, Hedwig, to Müller, Wilson, Sullivant, Schimper, Lindberg, and others. For a long time Prof. Schimper's work was the best on the subject, and Dr. Braithwaite mentions it as very complete in its details of structure, both descriptive and pictorial, and as leaving hardly anything to be desired. Of works more especially relating to the development and minute anatomy of the group, allusion is made to the important memoirs of von Mohl, Carl Nägeli, Dozy, Hofmeister, Russow, Piré, and Rozé. He then proceeds in a second chapter to some general observations on collecting, preparing, and on the points to be observed in the determination of a species.

In a third chapter the vegetative system of the group is discussed. To our mind this chapter might well have been extended. The details given of the germination of the spores are too few, nor is the following chapter on the reproductive system free from the same defect; and as to the illustration of these two chapters, it will suffice to mention that it is confined to a single plate. As the charming plates illustrating the descriptive portion of the work are, we trust, likely to serve for more than one edition of it, we would suggest that, in the event of a second edition, some half-dozen supplementary plates might be given, on which would be represented the embryology of the group.

Between fifty and sixty species of Sphagnum are known, of which about one-third are tropical. They are most abundant in the north and south temperate zones, in the higher latitudes of which they often cover over a large expanse of surface. Dr. Braithwaite describes twenty species as found in Europe and North America, that is about one-third of all the known species. Of the others, seven species are described as from Brazil, seven from Central America, four from Guadaloupe, seven from Australia and New Zealand, four from the Eastern Archipelago, two of these, *S. sericeum*, C. Müll., and *S. Holleanum*, Dozy and Molk, known only in a barren state, but remarkable for having the stem leaves precisely like the branch leaves in form and structure, their hyaline cells being without fibres, but with a single apical pore. The only species from tropical Africa is *S. Africanum*, Duby.

Dr. Braithwaite points out that the range of variability in the species is in this group most extensive, so that in their determination one must rely on minute anatomical distinction for their essential characters, as in many cases size, colour, direction of leaves, habit, presence or absence of fibres in the hyaline cells of the stem leaves, will all alike fail. In the separation of the Sphagninæ as a subclass from the Bryinæ or frondose mosses, Dr. Braithwaite follows the earlier views of the illustrious Schimper. He groups the species described in nearly the same manner as Lindberg, adopting his three sections—Eusphagnum, Hemitheca, and Isocladus. The European species are all located in the first section. The descriptive details are very clearly given. The synonymic lists are evidently made out with great care, and the varieties which in many of the species are, as is well known, very marked, are not only described, but in several cases figured. The twenty-eight beautiful coloured plates illustrating the species and varieties are all from drawings by the author, and they contain complete anatomical details of the stem and leaf structures. The work is brought out in a style worthy of the subject, and we trust will find its way not only into the hands of the botanist, but, as it well deserves to do, into the possession of all who take an intelligent pleasure in studying our native mosses.

OUR BOOK SHELF

Vox Populi: a Sequel to the "Philosophy of Voice." By Charles Lunn. (London: W. Reeves, 1880.)

WE are told in the preface that "the present work is a reprint of articles that appeared in the *Orchestra*," and that "now it has been discovered Galen (A.D. 180), 'the father of physicians,' as he is called, advanced the same physical views as those for which I (Mr. Lunn) have contended, my controversial work is ended:—it is scarce worth while to re-write." Was it then worth while to re-print? In the introduction the author tells us that his articles were written "to clear up some ambiguous points in my (Mr. Lunn's) 'Philosophy of Voice,'" and that "this without the former work is incomplete, as that

without this." Some time ago the present writer honestly endeavoured to understand Mr. Lunn's "Philosophy of Voice," and utterly failed in his attempts. He cannot find any assistance towards understanding it in the present little tract (pp. 88) of loose writing, wonderful reasoning, and jumping exposition. Let us hope that Mr. Lunn's teaching is better than his preaching. His axioms are however rather startling, especially the second (p. 7), "All voices are naturally beautiful. All ugliness in vocal tone is the result of transferred habits acquired by the artificial use of voice in speech." If this use is "artificial," what use is "natural"? But attempts to understand and criticism are all thrown away. Notwithstanding Mr. Lunn's initial confession that he is a mere follower of Galen, he declares in his introduction (p. 1): "It is a *fait accompli*. *I* have founded a New Profession standing midway between the Musical and the Medical worlds, with Art on its one side, Science on the other; firm and irrefutable." In this state of suspension, like Mahomet's coffin, "midway between" two "worlds," and belonging to neither Science nor Art, which seems fitly to describe the nature of the book, we are content to leave it to the happy conviction of the author that what he says (of course when others can find out what it is) is "firm and irrefutable."

Practical Plane Geometry and Projection for Science Classes, Schools, and Colleges. By Henry Angel. Vol. I., Text; Vol. II., Plates. Collins's Advanced Science Series. (London and Glasgow, 1880.)

A VERY practical and useful book by an experienced teacher: it is designed to meet the requirements of students at the Royal School of Mines, at the Royal Military Academy, at Cooper's Hill, and elsewhere, and embraces great part of the two higher stages of the Science and Art Department syllabus. There is no great scope for absolute novelty in such a work, and our author acknowledges his indebtedness to the works of many, if not most, of his well-known predecessors, but the arrangement appears to be judicious, and the constructions good and clearly enunciated. In the Practical Geometry (six chapters) the student is taught the use and construction of scales, of triangles and polygons, and there are numerous problems on areas, on circles in contact, and on other plane curves with their tangents and normals. The orthographical portion treats of the projection of the five regular solids, of other simple solids, of flat and curved surfaces, intersected by cutting planes, and of solids inscribed in, or circumscribed to, the surfaces of other solids; of the interpenetration of solids, of the projection of shadows, on isometric projection, on the solution of the spherical triangle, and on horizontal projection—a very extensive and varied bill of fare. In addition there are numerous questions for practice, many of which are taken from examination papers, and the text is illustrated by several clearly-drawn figures. Part ii. contains eighty-one large-page plates to further illustrate the constructions. The two parts together ought to enable any painstaking student to take a creditable place in his examination and to acquire a solid acquaintance with the subject.

Teorica delle Forze Newtoniane e sui applicazioni all' Elettrostattica e al Magnetismo del Prof. Enrico Betti. 365 pp. (Pisa, 1879.)

IN the session 1863-64 Prof. Betti delivered at Pisa a course of lectures, subsequently (1865) printed in the *Nuovo Cimento* under the title "La Teorica delle Forze che agiscono secondo la legge di Newton e sua applicazione alla elettricità statica"; the volume before us is what may be looked upon as its greatly enlarged second edition. It consists of an introduction and three chapters. The first chapter, in twenty-three sections, treats of Potential Functions and of Potentials (§ 11 gives Green's theorem and some others due to Gauss; § 12 Stokes's theorem for transforming a double integral into a simple integral, and the properties of a surface which has on one face a stratum of attracting, and on the opposite face an equal stratum of repulsive, matter; the other sections appear to contain nearly all the known properties of these functions). Chapter II., on Electrostatics, in sixteen sections, discusses several cases of electrostatical distribution, the method of images (Sir W. Thomson's theory) and condensers; Chapter III., on Magnetism, is divided into ten sections (on p. 304 Prof. Betti announces the theorem, "Se la superficie di un corpo è semplicemente connessa ed ha un numero finito di poli, questo numero sarà sempre pari," an advance upon Gauss, who has shown that if there be three poles there must also be a fourth).

Kalkül der Abzählenden Geometrie. Von Dr. Hermann Schubert. (Leipzig: Teubner, 1879.)

DR. SCHUBERT in this work gives us, in the form of a treatise of 359 pages, the principal results as yet arrived at in the "Numerical Geometry," a branch of mathematics originated by M. Chasles and subsequently studied by Zeuthen, Sturm, Halphen, Klein, and in this country by Dr. Hirst ("On the Correlation of Two Planes," vol. v.; "Correlation in Space," vol. vi.; "Note on the Correlation of Two Planes," vol. viii.; London Math. Soc. *Proceedings*). The book closes with a full historical and bibliographical list in the form of notes to the several chapters.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Spectrum of Hartwig's Comet

THE spectrum of this comet was examined here on the evening of October 7 with a spectroscope having a single prism of 45°, and was found to consist of three bright bands and a continuous spectrum corresponding to the nucleus. The middle and brightest band was compared with the band at W.L. 5198 in the spectrum of a vacuum tube containing alcohol vapour, and three micrometer measures gave the position of the less refrangible edge of the comet band at W.L. 5184, 5215, and 5204 tenth metres respectively. The breadth of the band was about 40 tenth metres. These measures would indicate that the principal comet-band is coincident with the band at W.L. 5198 of the vacuum-tube spectrum of carbon-compounds, and not with that of the Bunsen flame at W.L. 5165. The observations however were made under unfavourable circumstances, the comet being low, and involved in haze and cloud. The positions of the other two bands were not determined. W. H. M. CHRISTIE

Royal Observatory, Greenwich, October 11

Wire Torsion

I HOPE you will allow me to seek information, through your aid, on a subject which is perplexing me a good deal at present. I am engaged in studying a gravimeter designed by the late J. Allan Broun, in which gravity is balanced by the torsion of a single wire; or is intended to be so. As the function of the instrument depends largely on the law of torsion in wires, I have been making experiments to satisfy myself on some points. It is in the results of one of these that I have met with my difficulty. I was using thin brass wire (diam ·02), and after stretching it till it broke, twice, I supposed it to be at or near its maximum elasticity, and proceeded to use it in the intended way. At each end of a 6-foot plank I inserted into the edge a 2-inch screw. The wire was fastened upon these so as to get a strain by turning them. The wire was in two pieces, attached to opposite sides of a ring in the middle. By turning this ring the two wires were

severally twisted in opposite directions. A straight thick wire passed through the ring, the weight of which afforded a ready means of varying the force necessary to balance the torsion of the wire. My first object was to prove that the force of the latter was, at any rate to some considerable extent, independent of the tension. Suppose that with this arrangement, the wire being horizontal, a balance has been effected when the ring has been turned about the wire as an axis three or four times. What will happen when the wire is further strained? I think it would be a natural expectation (apart from special knowledge) that the weight will rise; on the other hand, a knowledge of the law of torsion teaches (?) that there is no increase of the force sustaining the weight, which therefore will *not* rise. But who would suppose that, on the contrary, it would sink? Such, nevertheless, is what takes place. I continued increasing the strain, and the weight continued to sink. I had to go on lessening the weight again and again (by shifting the balancing cross-rod), in order to restore the horizontality of the ring; until at last there was scarcely any force of torsion left! To repeat the experiment of course the ring had to receive three or four fresh turns. I did so several times, always continuing, as I thought, to increase the strain. All the time the wire was absorbing the torsion, and did not break. I then thought to try the effect of a high initial torsion. But I did not seem to get any such by turning the ring more than five or six times. I then thought to see how much twisting the wire would bear. Expecting it every instant to break, I counted up to 100 half turns. *By this time the wire was quite slack!* I added *another hundred* half turns. The wire was now half an inch longer, without any strain having been kept on it except just enough to keep it straight. I went on twisting. At 218 one wire broke. The other then had only sixteen half-turns of twist in it, out of the 230 or more received. I afterwards went on twisting, mending each time that the wire broke, till the twist (quite visible under the microscope) amounted to sixteen turns per inch. The length kept on increasing. After breaking, the wire always untwisted one turn in four inches.

I feel myself here in presence of laws of which I know *nothing;* and my object in writing this short experience is to ascertain whether it is sufficiently in accord with what *is* known to cause no surprise to any one but myself. In that case I shall be greatly obliged to any one who will tell me where I can learn all about it. J. HERSCHEL

Collingwood, October 4

I forgot to say that in no case did slackening of the strain reverse the sinking of the weight due to increase of strain.

The Magnetic Storm

BY the mail just arrived from Australia I have received copies of the photographic traces produced by the declination magnetograph at the Melbourne Observatory during the magnetic storm of August 12 to 14, kindly forwarded by Mr. Ellery, the Government astronomer there.

A comparison of these curves with those from the Kew instrument for the same period shows that the disturbance commenced and ended at both places at the same time.

It is not easy however to trace much similarity in the two sets of curves, as the individual excursions of the magnet east and west of the normal position which form the record of the magnetic storm, cannot be at all times followed in both curves, but the periods of greater disturbance seem to have been simultaneous. For example, the commencement of the disturbance was well marked at August 11d. 8h. 10m. p.m. at Melbourne, which corresponds to 11d. 10h. 33m. a.m. G.M.T., whilst here (*vide* Mr. Ellis's letter in NATURE, vol. xxii. p. 361) it commenced at 10h. 30m. a.m.; then again the large deviation to the eastward noted in the Rev. S. J. Perry's letter in NATURE, which occurred here between 12d. 11h. 30m. a.m. and 12h. 30m. p.m., seems to have had its effect, as a movement of the needle at Melbourne to the westward between 12d. 9h. 15m. p.m. and 10h. 30m. p.m. The maximum deflection which exceeded the limits of registration of the instrument, I estimate to have taken place at 10 p.m. The corresponding G.M. times for the above are 12d. 11h. 38m. a.m., 12h. 53m. p.m., and 12h. 23m. p.m.; the maximum deflection recorded here seems to have been at 12h. 25m. p.m.

The disturbed period may be considered to have died out at Kew at 14d. 8h. a.m. G.M.T., and at Melbourne at about 14d. 7h. a.m., but there is no very distinctive movement which would enable us to fix this limit with accuracy.

These interesting comparisons are extremely satisfactory, for it is but recently that the Government of Victoria was considering the advisability of discontinuing the system of photographic registration of the magnetometers at Melbourne, and consulted the Kew Committee upon the subject.

A circular was accordingly issued to the leading physicists of Europe, and their replies being almost unanimously in favour of the continuance of the recording system, the Government erected a new magnetic observatory, and decided upon carrying on the work.

Mr. Ellery has also forwarded a month's curves for the purpose of assisting in the international comparison of magnetograms now being prosecuted by the Kew Committee.

The preliminary results of their investigations have been already indicated by Prof. Adams in his recent speech at Swansea (NATURE, vol. xxii. p. 416). G. M. WHIPPLE

Coral Reefs and Islands

I HAVE been greatly interested in Mr. John Murray's paper on coral reefs and islands published in NATURE, vol. xxii. p. 351. I hope you will allow me space to draw scientific attention to the fact that as early as 1857 I published a paper on the Formation of the Peninsula and Keys of Florida (*Am. Jour.* vol. xxiii. p. 46), in which I maintain that the theory of Darwin, although so beautifully (as I thought) explaining the phenomena of the Pacific reefs, *wholly fails to explain those of the Florida coast.*

In 1851 I spent the months of January and February on the Keys of Florida, assisting Prof. Louis Agassiz in his investigations on the growth of reefs and formation of keys in this region. An abstract of these investigations and their results was published in the Report of the United States Coast Survey for 1851, p. 145 *et seq.*[1]

In this report Agassiz shows that the Keys and nearly the whole Peninsula of Florida have been formed by the growth of successive reefs, one beyond the other from north toward the south. In my paper above alluded to, and also in my "Elements of Geology," p. 152, I state further, that the reefs of Florida, if we accept Darwin's theory, are entirely peculiar. For according to Darwin barrier-reefs are formed *only by subsidence*, while on the Florida coast we have well-marked barriers with channels 10-40 metres wide where there cannot be any subsidence, for continuous increase of land is inconsistent with subsidence. Again, according to Darwin barriers and atolls always show a *loss of land*, only a small portion of which is recovered by coral and wave agency; while on the Florida coast, on the contrary, there has been a continuous growth of the Peninsula by coral accretion, until a very large area, viz., about 20,000 square miles, has been added.

I have attributed the formation of *successive* reefs from north toward the south to the successive formation of the depth-condition necessary for coral growth; and this latter, in the absence of any evidence of elevation, to the steady building up by sedimentary deposit, and extension southward, of a submarine bank within the deep curve of the Gulf Stream. The formation of barriers instead of fringes on a coast which has certainly not subsided—for continuous land-growth negatives the idea of subsidence—I attribute to the shallowness and muddiness of the bottom along this coast. Only at a distance of twenty to forty miles, where the depth of twenty fathoms is reached, and where, therefore, the bottom is no longer chafed by the waves, the conditions necessary for coral growth would be found, and here a line of reefs would be formed, limited on one side by the depth and on the other by the muddiness of the water.

In brief then, according to my view, the Peninsula and Keys of Florida were formed by the co-operation of several agents:—1. The Gulf Stream building up and extending a submarine bank within its loop. 2. Corals building successive barriers on the bank as the latter was pushed farther and farther southward. 3. Waves beating the reefs into lines of islands. 4. *Débris* from the reefs and keys on the one side and the already formed mainland on the other filling up the successive channels and converting them first into swamps and finally into dry land.

Whether this view is true in all its parts or not, there can be

[1] This report has been recently published in full as one of the memoirs of the Harvard Museum of Comparative Anatomy, but I have not yet seen it.

no doubt that the southern coast of Florida affords exceptional advantages for the successful study of the formation of coral reefs.

Geological Climates

THE dilemma into which Dr. Houghton thrusts the rigid uniformitarian school is one which was enlarged upon some years since, when reef-building corals were asserted, upon the evidence afforded by fossils, to have existed during the Miocene and Oligocene ages in seas where Tasmania now exists in the south and Hampshire in the north. There are no instances of large masses of reef-building corals in corresponding latitudes at the present day, and the range of these surface-living, high-temperature-requiring zoophytes is well known.

Uniformitarians may take comfort, however, and slip under the horns which Dr. Houghton so ably presents for their transfixment. Where I now write, on the Bagshot sands and gravels of Cooper's Hill, facing the cold north with a touch of the east, there is a patch of bamboo canes in full leaf. They were in full leaf at this time last year. The plant survived out of doors the extreme frost and fogs of last winter and other evidences of a temperate climate, and it has been in beautiful leaf all this summer.

Now everybody knows that in torrid India the bamboo grows. Therefore if the palæontologist of the year A.D. 18800 should dig up the Cooper's Hill stalks and leaves, and should have the opportunity of examining in some future Kew the bamboos of the hot parts of the earth, he would logically, geologically, palæontologically, but somehow unreasonably, come to the conclusion that Cooper's Hill and India enjoyed corresponding and intensely tropical climates in 1880, during the geological age when the earth's polar axis was certainly inclined nearly 23½° to the plane of the ecliptic.

The Yang-tse, the Yellow River, and the Pei-ho

I HAVE been much interested in the paper on the above rivers, published in NATURE, vol. xxii. p. 486. To the extent of the writer's personal observations the calculations appear to have been careful and accurate, and as near the truth as the observations of a single year are likely to be. A reference to Sir Charles Hartley's observations of the Danube, extending over *ten* years, shows that the mean maximum discharge of that river for one year exceeded the minimum by 3 to 1.

It is however to the use of *one* observation of the Yellow River made in 1792 by Sir Geo. Staunton that I feel compelled to enter a protest, firstly, because *one* observation is misleading in drawing general inferences, and, secondly, is especially to be suspected when it is at variance with other well-authenticated examples.

According to the writer of the paper, the mean discharge of the Yang-tse is 770,397 cubic feet per second, carrying to the sea 6,428,800,000 cubic feet of sediment per year, but the Yellow River having only a mean discharge of 116,000 cubic feet per second delivers, according to Sir George Staunton, 17,520,000,000 cubic feet of sediment per year into the Gulf of Pe-Chili. With Dominie Sampson we may well exclaim "prodigious!" It has struck me as an explanation of this anomaly that Sir George Staunton probably measured the deposit from "the gallon and three-quarters" of the Yellow River water as *wet mud*.

If so this will at once account for the excessive amount of it. The deposit of Nile mud in the reservoirs of the Cairo water-works often amounts to 1 inch in 10 feet of water,[1] or $\frac{1}{120}$ part of the bulk. Dr. Letheby's analyses show that in August the proportion by weight of sediment (dried) being the maximum of the year, in Nile water is $\frac{1}{670}$[2]: thus taking the specific gravity of the dry mud at 1·9, the measurement of the wet deposit by bulk exceeds the dry about 10½ times.

If the 80 grains to the pint of the Yellow River water be divided by 10½, we arrive at between 7 and 8 grains per pint of dry sediment, corresponding closely with the proportion given by the writer for the Pei-ho and Yang-tse.

I would also point out that the discharge of the River Plate as given in the table is not the *mean*, which has not yet been ascertained, but the *dry weather flow*.[1] Still another little error, for which the writer is in no way responsible, being a quotation from Huxley's "Physiography." The discharge of sediment by the Thames is a calculation by Prof. Geikie on an *hypothesis*, not on observation; and instead of 1,865,000 should be 18,650,000—this printer's error has been copied from Geikie's original paper by writer after writer without discovery.

I should feel obliged if the writer would explain why the surface-current of the Yang-tse and Pei-ho should vary so in velocity with the same average depth of water. It seems anomalous.

Miller's Elements of Chemistry—Part III. Organic Chemistry

IN his notice of the new edition of this work, by Mr. Groves and myself, which appears in NATURE, vol. xxii. p. 530, Mr. Muir refers to an obvious omission at p. 933. May I request those who possess the book to insert at the top of the page the words "Probably, however, the most weighty objection that can be raised to the" . . . Although in the revise, by some strange mischance this line has been dropped in printing off.
HENRY E. ARMSTRONG

Swiss Châlets

IDENTICAL suggestions to those of Mr. George Henslow with regard to the connection in descent of modern Swiss châlets with ancient pile lake-dwellings will be found expressed in Dr. J. J. Wild's "At Anchor" (Marcus Ward and Co.), p. 106, and with some detail in my "Notes by a Naturalist on the *Challenger*" (Macmillan and Co.), p. 399. Dr. Wild, who is a native of Switzerland, and I arrived at the same conclusions independently, as we only found out on reading one another's books, from the study of the modern pile dwellings of the Malay Archipelago during the voyage of the *Challenger*, and we both amongst other conclusions identified the balcony of the châlet with the ancient platform, as does Mr. Henslow.

Spectre of the Brocken at Home

HAVING occasion ten days ago to go into my garden about half past ten o'clock at night I found there was a thick white fog, through which, however, a star could be seen here and there. I had an ordinary bedroom candlestick in my hand with the candle lighted, in order to find the object I wanted. To my great surprise I found that the lighted candle projected a fantastic image of myself on the fog, the shadow being about twelve feet high, and of an oddly distorted character, just as the spectre of the Brocken is said to be. It is of course usual on going into the open air to use a lantern with a solid back for any light that may be wanted, and with this, of course, such a shadow would not be seen; but in this charmingly foggy valley of the Thames, and in these days of "Physics without Apparatus," the effect I saw can probably be seen only too often. May not the gigantic spirits of the Ossianic heroes, whose form is composed of mist, through which the stars can be seen, be derived from the fantastic images thrown upon the mountain fogs from the camp fires of the ancient Gaels? In a land where mists abound a superstitious people might very readily come to consider a mocking cloud-spectre to be supernatural, though it was really their own image magnified. If it be true that in our earlier stages of development we resemble more nearly the past forms of life and thought, I may mention in this connection that, thinking to amuse a little child of three, I threw a magnified shadow of her on the wall with a candle, and then, by moving it in the usual way, made the figure suddenly small. Instead of the changing shadow giving the pleasure intended, the child was terrified, as the warriors of Morven may have been when they saw their shadows on the clouds.

Putney, October 8

Ice under Pressure

THERE is a point in Dr. Carnelley's letter (NATURE, vol. xxii. p. 435) which I have been hoping to see cleared up by subsequent letters. He says, "In order to convert a solid into a

liquid the *pressure* must be *above* a certain point," and goes on to describe some experiments with ice, implying that ice is in this respect a typical substance. Now our text-books speak of the behaviour of water in freezing and melting as exceptional. For instance, Prof. Balfour Stewart says ("Heat," p. 89): "If a substance expands in congelation, its melting-point is lowered by pressure, but if a substance contracts in congelation, its melting-point is raised by pressure." And (p. 91): "Bunsen found that the melting-points of paraffin and spermaceti, both of which contract when freezing, were raised by the application of pressure."

Do the new results tend to overthrow the generally received opinions on the subject? or is there some way of reconciling these seeming contradictions?

I have more interest in these matters than knowledge of them, and must apologise if I am asking a question which I ought to have been able to answer. C. A. M.

October 2

Mr. Haddon's Marine-Zoology Class

Owing to misconceptions which have arisen from the notice in Nature, vol. xxii. p. 517, relative to my marine zoology class, I should like to state that this class was formed solely for the purpose of the practical study of marine zoology, and without any idea of founding a zoological station. I would also like to take this opportunity of acknowledging my great indebtedness to Prof. Dohrn's magnificent institution at Naples.

Zoological Museum, Cambridge Alfred C. Haddon

Landslips

I read with great interest the article on landslips in Nature, vol. xxii. p. 505. It is no doubt familiar to many that the salt districts of Cheshire, in the neighbourhoods of Northwich and Winsford, are subject to landslips of a peculiar kind. The beds of rock salt occupying the position of the Triassic salt lakes are the centre of an extensive underground drainage. The fresh water on reaching the salt proceeds to dissolve it and becomes brine. This brine is pumped up and manufactured into white salt. As the fresh water keeps constantly dissolving and eating away the solid salt, the superincumbent earths keep sinking, and on the surface deep furrows, like the dried beds of rivers, mark the course of the underground waters. At times enormous masses of earth sink bodily, leaving cavities of a funnel shape. A short time since a mass of at least 60,000 tons of earth suddenly disappeared. When these subsidences are near rivers they become filled with water, and large lakes over 100 acres in extent have been formed. Although houses are not overwhelmed they are very frequently destroyed, and this destruction of property is so serious that the sufferers are now about to appeal to Parliament for assistance.

The district of the salt manufacture presents phenomena both curious and interesting, and is well worth visiting. A fortnight ago the whole of the water in one of these subsidences of over five acres in extent disappeared, leaving a chasm or abyss in many places forty or fifty feet deep. The action of water on soluble rocks can be seen here in great perfection.

LIQUEFACTION OF OZONE

At a recent meeting of the French Academy, MM. Hautefeuille and Chappuis announced that they had liquefied ozone. These chemists have been able to ozonise oxygen to a greater extent than has hitherto been done, by passing the silent discharge through the oxygen at a low temperature. The tube containing oxygen was immersed in liquid methylic chloride, which boils at -23°. After being submitted to the electric discharge for fifteen minutes at this temperature, the oxygen was conducted into the capillary tube of a Cailletet's apparatus, the temperature of which was maintained at -23°.

After a few strokes of the pump the gas in the tube appeared azure blue; as pressure increased the depth of colour likewise increased, until under a pressure of several atmospheres the ozonised oxygen appeared dark indigo blue. The pressure was increased to ninety-five atmospheres, and was then suddenly removed, whereupon a mist, indicating liquefaction, appeared in the capillary tube.

The stability of a mixture of oxygen and ozone rich in ozone appears to be chiefly dependent on the temperature. If such a mixture be rapidly compressed at ordinary temperatures, a considerable amount of heat is evolved and the gas explodes.

Ozone, say MM. Hautefeuille and Chappuis, is therefore to be placed in the category of explosive gases.

Berthelot has shown that the transformation of oxygen into ozone is attended with absorption of heat; the stability of products of endothermic reactions is as a rule increased by decreasing temperature.

Ozone is much more easily liquefied than oxygen; the latter must be compressed under 300 atmospheres at about the temperature of -29° before sudden removal of pressure succeeds in producing liquefaction.

We have thus the existence through a large range of temperature and pressure of two allotropic forms of the same element; each with distinctly marked chemical and physical properties. We know that the molecule of oxygen has a simpler structure than that of ozone; the substance of simpler molecular structure is capable of existing through a much more extended range of temperature and pressure than that of more complex structure. Under special physical conditions it seems possible that new allotropic modifications of various elements might be produced.

The marked differences in colour, and in temperature of liquefaction, between oxygen and ozone, furnish another illustration of the close connection which exists between the "chemical structure" and physical properties of substances; a different "linking," even of similar atoms, being evidently associated with distinctly different physical properties.

MM. Hautefeuille and Chappuis will doubtless soon be able to furnish more details of the properties of this most interesting substance, liquid ozone. M. M. P. M.

THE UNIVERSITY OF NEW ZEALAND

The University of New Zealand, with which, since 1874, the University of Otago has been affiliated, has, we are glad to find, adopted a quite modern schedule of subjects for its degree of B.A.

The subjects of examination for the B.A. degree are:—1. Greek Language and Literature. 2. Latin Language and Literature. 3. English Language and Literature. 4. Modern Languages and Literature. 5. General History and Political Economy. 6. Jurisprudence and Constitutional History. 7. Mathematics. 8. Physical Science, any two of the following branches: (*a*) Sound and Light, (*b*) Heat and Radiant Heat, (*c*) Electricity and Magnetism, (*d*) Astronomy and Meteorology. 9. Chemistry. 10. Natural Science, any one of the following branches: (*a*) Geology and Mineralogy, (*b*) Zoology, (*c*) Anatomy and Physiology, (*d*) Botany. 11. Mental Science. No candidate shall be approved by the examiners unless he show a competent knowledge of at least five of the above subjects of examination, of which two must be Latin and Mathematics. The examination may be passed in two sections. Either two or three subjects of examination, one of which must be either Latin or mathematics, shall constitute the first section, which may be taken at the end of the second or any subsequent year, and the remaining subjects shall constitute the second section, which may be taken at the end of the third or any subsequent year; or, at the option of the candidate, all the subjects may be taken together at the end of the third or any subsequent year.

In this curriculum the physical and natural sciences

seem to have a fair share allotted to them, and the same is also the case in the courses for the senior scholarships and honours—which latter cannot be competed for until the end of one year after the candidate takes his B.A. degree. A Bachelor of Arts obtaining honours can have his M.A. degree without special examination; all others have to pass an M.A. examination.

It is probable that for some time to come there will be great differences of opinion as to how the natural sciences should be taught and examined in in our universities. Some incline to limit the courses in botany and zoology, and to require a good sound knowledge of the prescribed work; others imagine that the effect of limiting a course is to produce a specialist, which, they argue, is to spoil a student; but the mean appears to us to be not so hard to find. A sound general knowledge of development and of physiology might certainly be demanded of all students, and the field of biology being too large for any human being to work over, the student might, as to details of structure, &c., be limited to the study of some defined class. It is in this direction evidently that Prof. Hutton has framed the schedule of zoology and botany, a schedule which, while we acknowledge it to be excellent from a general point of view, is, we are firmly persuaded, longer and more profound than is expedient in a new country, where the teaching power is not great. We are fully aware that there is a tendency in classical and mathematical teachers to believe that the study of natural science is something quite easy; but those able to judge have long agreed that not only does this study call for all the best talents, but that the student too often approaches it long after the impressionable period of his life: a little Latin, perhaps less Greek, a schoolboy knows; arithmetic, algebra, and geometry he is fairly familiar with; but the natural sciences and the how he lives, moves, and has his being, of these he is fain to exclaim, But who are ye? The professors of natural science must bide their time; it is no doubt coming, for biology is now somewhat taught in our schools, and may be will be taught on the mother's knee; but in the meanwhile let them not exact too much from candidates for B.A. degrees or honours; let them progress surely, even though they be accused of progressing slowly. As to the New Zealand University, we shall follow its progress with pleasure, and trust it may soon fulfil the great expectations that we have of it.

DOCTORED WINES

THE French Government have just passed a most salutary measure, which will have for effect the diminution, if not the complete suppression, of the process known as *plâtrage*, now become an almost constant custom through most of the wine districts of France, and which, from having at first been performed on a very moderate scale, has lately enormously increased, till it has developed into a crying abuse. The *plâtrage* is carried on during the fermentation, and consists in merely sprinkling the grapes, as successive baskets of them are emptied into the fermentation vats, with plaster of Paris —calcium sulphate —(French *plâtre*), mineralogically known as gypsum, or selenite, in fine powder. Now the grape-juice contains several salts of potash, among which the most abundant are the tartrate and bi-tartrate, and these decompose when placed in contact with the calcium sulphate, forming calcium tartrate—an insoluble salt—and potassium sulphate.

In the case of potassium bi-tartrate, potassium bi-sulphate is formed. Now besides the salts of potash above named, the juice of the grape contains grape-sugar, a nitrogenous fermenting principle and an astringent principle—to which latter new red wines owe much of their harshness—and also a red colouring-matter, with which the astringent principle is intimately associated. The fermentation splits up the grape-sugar, as it is well known, into carbonic acid, which escapes with effervescence, and alcohol, which remains dissolved. In pure undoctored wines, in proportion to the development of alcoholic strength, and as the wine by age tends to become more acid, potassium bi-tartrate separates as a crystalline precipitate, forming the chief constituent of the deposit in the casks known as *lees*, or, when it forms in bottled wines, as the *crust*.

Now the astringent principle which in the red grape is, as we have explained, intimately combined with the colouring-matter, seems to be held more or less in solution by the tartrates, and as these subside with age the wine grows less harsh, losing at the same time much of its colour, and is said to ripen or grow mellow. As the astringent principle however disappears, the wine, if it be one of the weaker French wines, tends to run to the acetous fermentation, and this is why we frequently find a wine become sour and unpalatable shortly after it has mellowed with age and arrived at its maximum of perfection. Many a bin of valuable claret or Burgundy has thus suddenly surprised and disappointed its possessor, changing in the short space of a few months from fine mellow wine to undrinkable vinegar.

Now, as stated above, calcium sulphate (*plâtre*) decomposes the potassium tartrates, and by withdrawing them and substituting the potassium sulphate, tends to prevent much of the colouring and astringent matter from passing into solution, so that this so-called *plâtrage* is nothing more than a means employed by the Bordelais and Burgundians for giving to their wines a fictitious effect of age, and they naturally defend a practice which enables them to bring their wines sooner into the market, economising their outlay in casks, and diminishing the chances of loss entailed by keeping a large stock of wine on hand. Further the process lends itself to fraud, permitting the wine merchants of Bordeaux and Burgundy to import the strong harsh wines of the north of Spain and the south-east of France, which, when blended with the small, poorer wines of the hill-districts of their own country, and then being *plâtrés* (that is agitated with powdered calcium sulphate), become mild and palatable. Thousands of hogsheads of wines thus blended and doctored are annually sold, and too often at the high rates commanded by pure vintage wines. Under the provisions of the new act no wine is allowed to be brought into commerce if it contains over two grammes of potassium sulphate per litre. Even this proportion is too large, *plâtrage* should be entirely prohibited; but when we consider that wines are now often sold with five or six grammes of this salt to the litre, it was time indeed that some measures should be taken. The merchants defend themselves on the basis of the practice being innocuous, and that while it promotes the keeping qualities of the wine, even four grammes of potassium sulphate could do no harm. It is the greatest possible mistake to fancy that *plâtrage* makes wine keep; for, no the contrary, it withdraws from it the astringent principle, a most potent means of its preservation. For a Bordeaux merchant to contend that forty grains of potassium sulphate to the pint of wine is not or cannot be unwholesome, is a thesis which may be agreeable to his pocket, but certainly ought to be discouraged, for, to say the least, it would surely be prejudicial to the stomachs of delicate or dyspeptic consumers. Not very many years since a case occurred of actual death by poisoning from the administration of a comparatively small dose of potassium sulphate, and this salt is well known in medicine as a drastic and dangerous purgative. We should then be most sincerely grateful to the French Minister of Commerce for the prudent forethought with which he has protected the consumers of French wines from a practice which had grown into a crying abuse, and for giving us one more guarantee for the purity of these wines, justly ranked as the most esteemed that the world produces.

MULTIPLE SPECTRA[1]

III.

I HAVE endeavoured to show in the previous articles that there are many facts which justify the conclusion that the same elementary substance in a state of purity can under different conditions give us spectra different in kind. To those spectra to which special reference is now made the names of *lined* and *fluted* have been given to mark their chief point of difference, which is that in lined spectra we deal with lines distributed irregularly over the spectrum; while in fluted spectra we deal with rythmical systems.

This was the first point, and I showed that the idea was suggested that the lined and fluted spectra, though produced by the same substance, were produced by that substance in a different molecular condition.

I have pointed out that both in lined and fluted spectra taken separately there was evidence of still further complication, that is, that a complete lined spectrum of a substance and a complete fluted spectrum of a substance, was the result of the vibration not of one kind of molecule only, but probably of several.

So that in this view we have to imagine a series, in some cases a long series, of molecular simplifications brought about by the action of heat, and ascribe the spectral changes to these simplifications.

To understand my contention, and one objection which has been taken to it, in the clearest way, let us suppose that there is a substance which gives us, under different conditions, three spectra, which we will term *a*, *b*, and *c*. My view is that these spectra are produced by three distinct molecular groupings brought about by successive dissociations. On the other hand, it is objected that they are produced by *one and the same molecule* struck, as a bell might be struck, *in different ways* by the heat waves or the electric current passing among the molecules.

In my memoir entitled "Discussion of the Working Hypothesis that the so-called Elements are Compound Bodies," I remarked as follows:—

"I was careful at the very commencement of this paper to point out that the conclusions I have advanced are based upon the analogies furnished by those bodies which, by common consent and beyond cavil and discussion, are compound bodies. Indeed, had I not been careful to urge this point, the remark might have been made that the various changes in the spectra to which I shall draw attention are not the results of successive dissociations, but are effects due to putting the same mass into different kinds of vibration or of producing the vibration in different ways. Thus the many high notes, both true and false, which can be produced out of a bell with or without its fundamental one, might have been put forward as analogous with those spectral lines which are produced at different degrees of temperature with or without the line, due to each substance when vibrating visibly with the lowest temperature. To this argument, however, if it it were brought forward, the reply would be that it proves too much. If it demonstrates that the *h* hydrogen line in the sun is produced by the same molecular grouping of hydrogen as that which gives us two green lines only when the weakest possible spark is taken in hydrogen inclosed in a large glass globe, it also proves that calcium is identical with its salts. For we can get the spectrum of any of the salts alone without its common base, calcium, as we can get the green lines of hydrogen without the red one.

"I submit, therefore, that the argument founded on the over-notes of a sounding body, such as a bell, cannot be urged by any one who believes in the existence of any compound bodies at all, because there is no spectroscopic break between acknowledged compounds and the supposed elementary bodies. The spectroscopic differences between calcium itself at different temperatures is, as I shall show, as great as when we pass from known compounds of calcium to calcium itself. There is a perfect continuity of phenomena from one end of the scale of temperature to the other."

Not only is what may be termed the bell hypothesis opposed to the law of continuity, as I endeavoured to show in the last paragraphs quoted, but it appears never to have struck the objectors that it is also opposed to the theory of exchanges as it is generally enunciated, on which the whole of our supposed knowledge of extra-terrestrial matter depends. If vapours, when relatively cool, do not absorb the same wave-lengths which they give out when relatively hot, what becomes of some of the most noted exploits of our nineteenth-century science?

Take the case of sodium. Three distinct spectra have been mapped for it. There is first the yellow line seen in a Bunsen flame, then the green line seen alone in a vacuum tube when the vapour is illuminated by an electric glow, and again there is the fluted absorption spectrum, without any lines, seen when sodium is gently heated in hydrogen in a glass tube. If we have here the same molecule agitated in different ways, I ask which is the true spectrum of sodium? And what right have we to say that sodium exists in the sun because the yellow line is represented? Why do we not rather say that sodium does *not* exist in the sun because the fluted spectrum is *not* represented.

It is not necessary to enlarge upon this point because the difficulty in which the theory of exchanges is thus landed is obvious, while, if we acknowledge different molecular groupings in the vapours of the same chemical substance, and apply the theory of exchanges *to each grouping*, then the teachings of that theory become more numerous and important than before.

It is of course of the highest importance to see whether there is any *experimentum crucis*—any mode of inquiry—by which the theory can be settled one way or the other.

I submit that the results of experiments based on the following considerations ought to be accepted as throwing light on the question.

1. At different temperatures the brilliancy of the spectral lines of the same substances as ordinarily observed changes enormously. See if these changes can be produced *at the same temperature* by employing those experimental conditions which will be most likely to bring about different molecular conditions if such exist.

2. At a low temperature some substances give us few lines while at a high one they give us many. Vapours, therefore, already glowing with few lines at a low temperature, say in a flame, should give us all their lines when the vapour is suddenly subjected to a high one, say by the passage of a high tension spark. On the bell hypothesis the spectrum should change with the mode of striking. On the dissociation hypothesis this should only happen for the lines of those molecular groupings which are *from other considerations* held to be more simple. If the flame has brought the substance to its lowest state, the passage of the most powerful spark should not cause the flame spectrum to vary.

Now what are the "other considerations" above referred to? This necessitates a slight digression.

In the *Phil. Trans.* for 1873[1] I gave an historical account, showing how, when a light source such as a spark or an electric arc is made to throw its image on the slit of a spectroscope, the lines had been seen of different lengths, and I also showed by means of photographs how very definite these phenomena were. It was afterwards demonstrated that for equal temperatures chemical combination or mechanical mixture gradually reduced the

[1] Continued from p. 312.

[1] *Phil. Trans.*, 1873, p. 254.

spectrum by subtracting the shortest lines, and leaving only the long ones.

On the hypothesis that the elements were truly elementary, the explanation generally given and accepted was that the short lines were produced by a more complex vibration imparted to the "atom" in the region of greatest electrical excitement, and that these vibrations were obliterated, or prevented from arising, by cooling or admixture with dissimilar "atoms."

Subsequent work, however, has shown[1] that of these short lines *some* are common to two or more spectra. These lines I have called basic. Among the short lines, then, we have some which are basic, and some which are not.

The different behaviour of these basic lines seemed, therefore, to suggest *that not all of the short lines of spectra were, in reality, true products of high temperature.*

That some would be thus produced and would therefore be common to two or more spectra we could understand by appealing to Newton's rule: "Causas rerum naturalium non plures admitti debere quam quæ et veræ sint et earum phænomenis explicandis sufficiant," and imagining a higher dissociation. It became, however, necessary to see if the others would also be accounted for.

Now if not all but only *some* of the short lines are products of high temperature, we are bound to think that the *others* are remnants of the spectra of those molecular groupings first to disappear on the application of heat.

At any particular heat-level, then, some of the short lines may be due to the vibrations of molecular groupings produced with difficulty by the temperature employed, while others may represent the fading out of the vibrations of other molecular groupings produced on the first application of the heat.

In the line of reasoning which I advanced a year ago,[2] both these results are anticipated, and are easily explained. Slightly varying Fig. 2 of that paper, we may imagine furnace A to represent the temperature of the jar spark, B that of the Bunsen burner, and C a temperature lower than that of the Bunsen burner (Fig. 1).

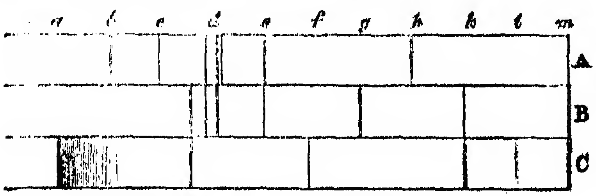

FIG. 1.—A. Highest temperature. C. Lowest temperature.

Then in the light of the paper the lines *b* and *c* would be truly produced by the action of the highest temperature, *c* would be short and might be basic, while of the lines *h* and *m*, *m* would be short and could not be basic, because it is a remnant of the spectrum of a lower temperature.

So much then by way of explanation; it is clear that to make this reasoning valid we must show that the spark, or better still the arc, provides us with a summation of the spectra of various molecular groupings into which *the solid metal which we use as poles* is successively broken up by the action of heat.

We are not limited to solid metals; we may use their salts. In this case it is shown in the paper before referred to[3] that in very many cases the spectrum is one much less rich in lines.

The experimental work has followed two distinct lines. I shall refer somewhat in detail to the results obtained along each. The first relates to the extraordinary and beautiful phenomena and changes observed in the spectra of vapours of the elementary bodies when volatilised at different temperatures in vacuum tubes. Many of the lines thus seen alone and of surpassing brilliancy, are those seen as short and faint in ordinary methods of observation, and the circumstances under which they are seen suggest, if we again apply Newton's rule, that many of them are produced by complex molecules.

In this case the appeal lies to the phenomena produced when organic bodies are distilled at varying temperatures; the simplest bodies in homologous series are those volatilised at the lowest temperatures; so that on subjecting a mixture of two or more liquids to distillation, at the beginning a large proportion of the more volatile body comes over, and so on.

The novelty of the method consists in the use of the luminous electric current as an explorer and not as an agent for the supply of the vapours under examination; that is to say, the vapours are first produced by an external source of heat, and are then rendered luminous by the passage of the current. The length and bore of the tube therefore control the phenomena to a certain extent.

A form of apparatus which I have found to answer very well is shown in the accompanying woodcut (Fig. 2).

A is the tube or retort containing the metal experimented on in its lower extremity, and having a platinum wire sealed into it at a distance of about two inches from the lower end, the other end being drawn out and connected by a mercury joint to an ordinary Geissler tube, which is connected by another mercury joint to the Sprengel pump C.

Another form of tube which I have used is prepared by inserting two platinum poles into a piece of combustion tubing sealed at one end, and after inserting the metal to be experimented on, drawing out the glass between the platinums to a capillary tube.

I have also tried inserting the platinum pole at the end of the retort, so that the spark passes from the surface of the metal, but this arrangement did not answer at all.

Some other modifications have been tried, but the first form I have described is that which I have found to answer best, so far as the trials have yet gone.

D is the spectroscope.

E is the lens used for focussing the image of the Geissler tube on the slit.

F is the spirit lamp for heating the retort.

H is the battery.

K and L are the wires connected with the coil.

In the second cut (Fig. 3) the method of observing the spectrum of the vapours close to the surface of the metal is indicated; the same letters apply, D' being, however, in this case a direct-vision spectroscope, which was sometimes employed for convenience.

For determining the exact positions of the lines in the spectrum of the vapour in any part of the retort, a larger spectroscope, with its illuminated scale, was used in the place of the direct-vision spectroscope.

The secondary wires of the coil were connected, one with the pole in the upper bulb at B, and the other with the platinum at A.

B is an ordinary Geissler tube with two bulbs separated by a capillary tube. The great advantage of this arrangement is that this capillary portion can be used for ascertaining what gases or vapours are carried over by the pump without any interference with the retort, both wires being connected with the Geissler tube. If, for example, we are working with sodium which contains an impurity of hydrocarbon, the moment at which it begins or ceases to come off can be found by examining the spectrum of this capillary tube.

I now give an account of the phenomena observed when we were working with sodium, in order to show the kind of phenomena and the changes observed.

After a vacuum has been obtained the retort is heated gradually. The pump almost immediately stops clicking,

[1] *Proc. R.S.*, vol. xxviii. p. 159. [2] *Proc. R.S.*, vol. xxviii. p. 162. [3] *Phil. Trans.*, 1873, p. 238.

and in a short time becomes nearly full of hydrogen. The spectrum of the capillary then shows the hydrogen lines intensely bright. After some time the gas comes off far less freely, and an approach to a vacuum is again obtained. Another phenomenon now begins to show itself: on passing the current a yellow glow is seen, which gradually fills the whole space between the pole in the retort and the metal; its spectrum consists of the lines of hydrogen and the yellow line of sodium, the red and green line being both absent until the experiment has gone on for some time.

As the distillation goes on, the yellow glow increases in brilliancy, and extends to a greater distance above the pole, and the red and green lines presently make their appearance as very faint lines.

The upper boundary of the yellow is quite sharp, the lines and fluted spectrum of hydrogen appearing above it.

After the yellow glow-giving vapour (which does not attack the glass) has been visible for some time, the pump is stopped and the metal *heated more strongly*. On passing the current a little while afterwards, a very brilliant leaf-green vapour is seen underlying the yellow one, and connected with it by a sap-green vapour. The spectra then visible in the tube at the same time are—

Leaf-green	...	Green and red lines of sodium and C of hydrogen; D absent.
Sap-green ...	...	Green, red, and yellow sodium lines of equal brilliancy and C of hydrogen.
Yellow ...	...	D alone and C.
Bluish-green	...	C and F and hydrogen structure.

To observe the green sodium line alone it is necessary to point the direct-vision spectroscope just above the surface of the metal where the green is strongest. It is also necessary to guard against internal reflections from the glass, as this may sometimes cause the D line to be seen by reflection from the surface.

This method of inquiry has been tried also with potassium, calcium, and some other metals, and with metallic salts.

With potassium and calcium we get the same inversion of phenomena, the yellow-green lines of potassium being

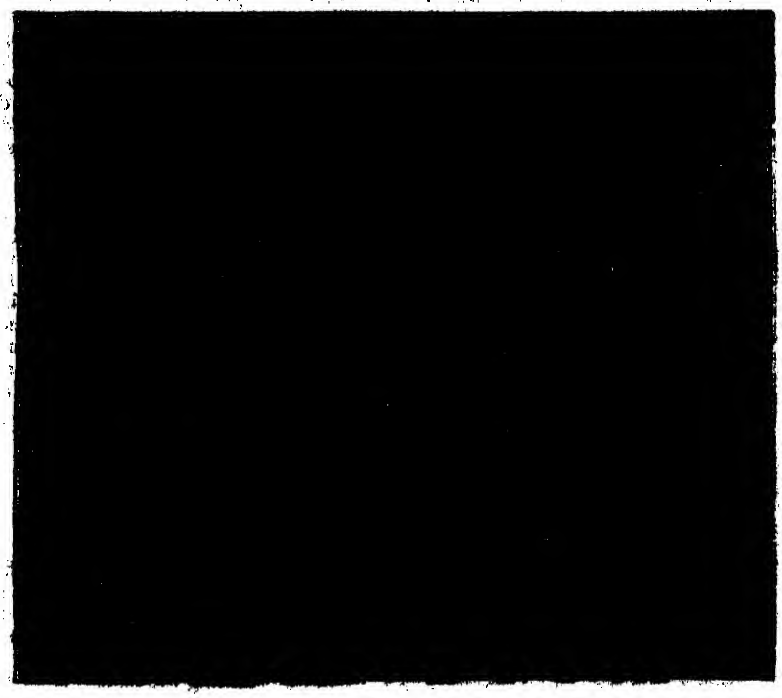

Fig. 2.—Distillation Apparatus.

seen without the red; while in the case of calcium the blue line alone was seen.

The fact that in these experiments we get, as before mentioned, vapours which at one and the same time exhibit different colours and different spectra at different levels in the tube, at once suggests the phenomena of fractional distillation.

It is also suggested, as a result of the application of this new method, that in the case of a considerable number of chemical substances not only the line spectrum is compound in its origin, as I suggested many years ago, but that a large number of the lines is due to molecular groupings of considerable complexity, which can be kept out of the reaction by careful low temperature distillation.

So much then for one method. Now for the other.

In this I have attempted to gain new evidence in the required direction by adopting a method of work with a spark and a Bunsen flame, which Col. Donnelly suggested I should use with a spark and an electric arc. This consists in volatilising those substances which give us flame spectra in a Bunsen flame and passing a strong spark through the flame, first during the process of volatilisation, and then after the temperature of the flame has produced all the simplification it is capable of producing.

The results have been very striking; the puzzles which a comparison of flame spectra and the Fraunhofer lines has set us find, I think, a solution; while the genesis of spectra is made much more clear.[1]

To take an instance, the flame spectrum of sodium gives us, as its brightest, a yellow line, which is also of marked importance in the solar spectrum. The flame spectra of lithium and potassium give us, as their brightest, lines in the red which have not any representatives among the Fraunhofer lines, although other lines seen with higher temperatures are present.

Whence arises this marked difference of behaviour?

[1] I allude more especially to the production of triplets, their change into quartets, and in all probability into flutings, and to the vanishing of flutings into lines, by increasing the rate of dissociation.

From the similarity of the flame spectrum to that of the sun in one case, and from the dissimilarity in the other, we may imagine that in the former case—that of sodium—we are dealing with a body easily broken up, while lithium and potassium are more resistant; in other words, in the case of sodium, and dealing only with lines recognised generally as sodium lines, the flame has done the work of dissociation as completely as the sun itself. Now it is easy to test this point by the method now under consideration, for if this be so then (1) the chief lines and flutings of sodium should be seen in the flame itself, and (2) the spark should pass through the vapour after complete volatilisation has been effected without any visible effect.

Observation and experiment have largely confirmed these predictions. Using two prisms of 60° and a high-power eyepiece to enfeeble the continuous spectrum *of the densest vapour produced at a high temperature*, the green lines, the flutings recorded by Roscoe and Schuster, and another coarser system of flutings, so far as I know not yet described, are beautifully seen. I say largely, and not completely, because the double red line and the lines in the blue have not yet been seen in the flame, either with one, two, or four prisms of 60°, though

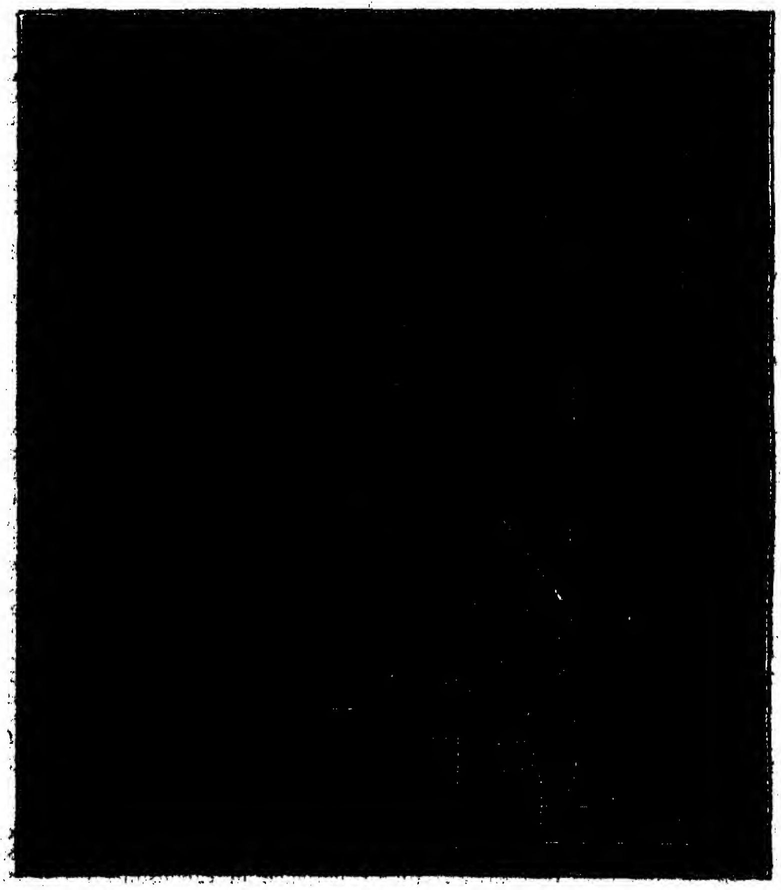

Fig. 3.—Position of Spectroscope for discovering Vapours close to the Metal.

the lines are seen *during volatilisation* if a spark be passed through the flame. Subsequent inquiry may perhaps show that this is due to the sharp boundary of the heated region, and to the fact that the lines in question represent the vibrations of molecular groupings more complex than those which give us the yellow and green lines. The visibility of the green lines, *which are short*, in the flame, taken in connection with the fact that they have been seen alone in a vacuum tube, is enough for my present purpose.

With regard to the second point, the passage from the heat-level of the flame to that of the spark after volatilisation is complete, produces no visible effect, indicating that in all probability the effects heretofore ascribed to *quantity* have been due to the presence of the molecular groupings of greater complexity. *The more there is to dissociate, the more time is required to run through the series, and the better the first stages are seen.*

J. Norman Lockyer

(To be continued.)

WILLIAM LASSELL, LL.D., F.R.S.[1]

THE scientific world will receive with deep regret the intelligence of the death of this distinguished astronomer. The smaller circle of those who knew Mr. Lassell personally will deplore the loss of a friend of rare worth. Mr. Lassell passed away without suffering soon after five o'clock on the morning of Tuesday, October 5, in the eighty-second year of his age, full of years and greatly honoured and respected.

In the words of Sir John Herschel, Mr. Lassell "belonged to that class of observers who have created their own instrumental means, who have felt their own wants and supplied them in their own way." The qualities which enabled Mr. Lassell to do all this made him what he

[1] Based on an obituary notice written by the present writer for the *Times*.

was. The work was the revelation of the man. He felt precisely where lay the difficulties and wants which met him in his work, because he was sensitive and sympathetic. He could deal successfully with these difficulties, and supply these wants, often in a masterly and original way, because he could think for himself cautiously and yet boldly. He could work out his conceptions in new and difficult directions to a successful issue, because the constancy of his character showed itself here in concentration of thought and perseverance of action. These qualities, sensitive sympathy, wise prudence, constancy, were those which pre-eminently characterised him as a man and a friend.

In the history of science Mr. Lassell's name must rank with those of Herschel and the late Lord Rosse in connection with that essentially British instrument, the reflecting telescope, whether we consider the genius and perseverance displayed in the construction of these instruments, or the important discoveries which have resulted from their use. About 1820 Mr. Lassell, then in his twenty-first year, began to construct reflecting telescopes for himself. It is perhaps to circumstances which Mr. Lassell at the time considered most unfavourable that science is indebted for much that Mr. Lassell has accomplished. At that time he did not possess sufficient means to enable him to purchase expensive instruments, and besides "his business avocations were such as most men consider of an engrossing nature." The value to him in his subsequent work of the energy and power of resource which were in this way so strongly developed in his character at an early age it is difficult to appraise. His success with the two first instruments which he attempted simultaneously, a Newtonian of 7-inch diameter and a Gregorian of the same size, encouraged him to make a Newtonian of 9-inches aperture. The several mirrors made for this instrument were of great excellence. The observatory note-books of the late Mr. Dawes, which are in the writer's possession, bear record to the delicate tests for figure to which these mirrors were put on the occasions of the visits of Mr. Dawes to the observatory of his friend at Starfield, near Liverpool, where the instrument was erected.

The instrument may be said to form an epoch in the history of the reflecting telescope, in consequence of the successful way in which Mr. Lassell, on a plan of his own, secured to it the inestimable advantage of the equatorial movement.

About 1844 Mr. Lassell conceived the bold idea of constructing a reflector of 2 feet aperture and 20 feet focal length, to be mounted equatorially on the same principle. Mr. Lassell spared neither pains nor cost to make this instrument as perfect as possible, both optically and for the mechanical side. As a preliminary step he visited the late Earl of Rosse at Birr Castle, and commenced the specula for this instrument with a machine similar in construction to that employed by that nobleman. After some months work he was not satisfied with this apparatus, and was led, in consequence, to contrive a machine for imitating as closely as possible those motions of the hand by which he had been accustomed to produce perfect surfaces on smaller specula. "The essential difference of these constructions," to use the words of Sir George Airy, "as regards the movements of the grinder is this: that in Lord Rosse's apparatus every stroke is very nearly straight, while in Mr. Lassell's apparatus there is no resemblance to a straight movement at any part of the stroke." This is not the place to describe the many new contrivances in the mode of support of the mirror, in the equatorial mounting, and in the polishing machine, which enabled Mr. Lassell to bring this instrument to a high degree of perfection. I must not omit to notice, to use Sir John Herschel's words, "that in Mr. Nasmyth he was fortunate to find a mechanist capable of executing in the highest perfection all his conceptions, and prepared by his own love of astronomy and practical acquaintance with astronomical observation, and with the construction of specula, to give them their full effect." Mr. Lassell was very successful in the great brilliancy and permanency of polish of his metal. Within the last few years the writer has been shown specula by Mr. Lassell which had not been polished for more than twenty years, and which appeared as bright as if but just removed from the polishing machine.

With this fine instrument he discovered the satellite of Neptune. This minute body was first seen on October 10, 1846, but it was not until the next year that it could be satisfactorily followed and its existence fully confirmed.

The superiority of the telescope and the vigilance and skill of the observer were further shown by the discovery in 1848, simultaneously with Prof. Bond in America, of an eighth satellite of Saturn, of extreme minuteness, which was named Hyperion.

In 1851, after long and careful search, he discovered two additional satellites of the planet Uranus (Umbriel and Ariel), anterior to the two discovered by Sir W. Herschel in 1787. In the autumn of 1852 he took his 20-foot telescope to Malta, and observed through the winter of that year.

A most careful drawing of the nebula of Orion and drawings of several planetary nebula will be found in vol. xxiii. of the *Memoirs* of the Royal Astronomical Society. With respect to the planets, to use his own words, "his discoveries were rather negative than otherwise," for he was satisfied that without great increase of optical power no other satellite of Neptune could be detected. With regard to Uranus he says, "I am fully persuaded that either he has no other satellites than the four, or if he has they remain yet to be discovered."

Mr. Lassell's energy and zeal in the cause of science did not permit him to remain content with this magnificent instrument. His last work was a much larger telescope, four feet in aperture and thirty-seven feet focus, mounted equatorially. This grand instrument was erected at Malta in 1861, and the work done with it, with Mr. Marsh's assistance during the next four years, is fully described in vol. xxxvi. of the *Memoirs*. This work consists of numerous observations of nebulæ and planets and a catalogue of the places of 600 new nebulæ discovered at Malta. It is not possible to suppress a feeling of regret that this magnificent instrument no longer exists.

After his return from Malta Mr. Lassell purchased an estate near Maidenhead, and erected in an observatory his equatorial telescope of 2-feet aperture. Mr. Lassell's experience in repolishing his 4-feet mirrors suggested to him some alterations in his polishing machine. After his return he was able to carry out these experiments in a workshop erected at Maidenhead, and succeeded in constructing an improved form of polishing machine, which is described in the *Transactions* of the Royal Society for 1874. In 1839 Mr. Lassell was elected a Fellow of the Royal Astronomical Society, received its gold medal in 1849, and in 1870 was elected its president, which office he held for two years. He became a Fellow of the Royal Society in 1849, and received one of its gold medals in 1858. Among other honours conferred upon him may be mentioned an honorary degree from the University of Cambridge, and the honorary Fellowships of the Royal Societies of Edinburgh and Upsala.

The numerous papers by Mr. Lassell to be found in the *Monthly Notices* and the *Memoirs* of the Royal Astronomical Society bear abundant record to his industry and skill, and make us feel that in Mr. Lassell's death we have to deplore the loss of one who contributed largely to the advancement of the science of his age.

WILLIAM HUGGINS

NOTES

ANOTHER brilliant synthesis has recently been accomplished in the domain of organic chemistry; Messrs. Grimaux and Adam have succeeded in building up citric acid from glycerin. We shall give full details next week. Curiously enough, in the last number of the Berlin *Berichte*, Kekulé announces that he has been working at the same subject, but by a totally different method. Kekulé's work is not sufficiently advanced for him to say positively that his method of synthesis is successful, but he feels justified in saying that very probably the process adopted by him has resulted in the formation of citric acid.

THE death is announced of Dr. Hofrath von Wagner, Professor of Technological Chemistry in the University of Würzburg, and the author of several works on that science, chief of which is "Jahresberichte über Chemische Technologie" and "Handbuch der chemischen Technologie," translated into English by Mr. Crookes. He was born at Leipsic in 1823, and first taught in Nüremberg.

THE credit of the invention of binocular glasses has usually been assigned to a certain Bohemian friar, Father de Rheita, who died at Ravenna in 1660. His treatise, which bears the quaint title of "Oculus Enochi et Eliæ," was published at Antwerp in 1645. In 1677 there appeared at Paris a volume entitled "La Vision parfaite," by another ecclesiastic, Père Cherubin of Orleans, which contained an account of some improvements on de Rheita's discovery, illustrated by excellent copper-plate engravings. Lately however Signor Govi has unearthed in the Bibliothèque nationale a printed document which proves the antiquity of binocular glasses to be a little more remote. This document is a placard by one D. Chorez of Paris, who lived on the island of Nôtre-Dâme, at the sign of the "Compas." The placard is in old French, and is headed "Av Roy"; it states that the "admirable lunettes" it describes, and which are represented by accompanying figures, were invented by Chorez and dedicated to the king in 1625.

IN the placard of the optician Chorez referred to, the address actually printed was "la ruë de Perigneur aux Marais du Temple"; but these words have been struck out with a pen, and above is written "Lisle nostre Dame." The incident is curious as showing that two centuries and a half ago the same quarters of Paris were frequented as now by the instrument-maker. M. Salleron is in the Rue Parée du Marais; M. Lemaire a little farther north, just out of the *Quartier du Temple*, in the Rue Oberkampf. On the island of Nôtre-Dâme the opticians elbow one another in shoals, not to omit M. Breguet's modest shop. The only district of Paris which can, indeed, compete with these being the *Quartier Latin*, where instrument-makers of all kinds abound.

WITH regard to the announcement in an enterprising provincial contemporary of a projected "Natural History Survey of India," the general conduct of which is to be intrusted to Dr. George King of the Botanical Gardens, Calcutta, we believe that those most concerned know nothing which affords any foundation for the statement. The notion is intrinsically improbable, inasmuch as the "Flora of British India," which is in process of preparation at Kew, and of which the third volume is now in course of publication, covers the same ground. It would be inexpedient for the Government to take any step of the kind as far as botany is concerned till the material collected by Indian botanists since the beginning of the century has been fully worked up, and this is being rapidly proceeded with under the direction of Sir Joseph Hooker, assisted by Mr. C. B. Clarke of the Bengal Education Department, who has been detached on duty at Kew for the purpose.

THE case recently reported in the newspapers of poisoning by American tinned beef is calculated to arouse much alarm in the minds of those who use tinned meats. According to the newspaper report of the inquest, no direct evidence was given that poisoning was actually due to zinc or other metallic poison; in the present state of knowledge the explanation referred to by Mr. Dyer in his letter to the *Daily News*, viz., that it was due to the unwholesome state of the meat itself, and not to metallic poison absorbed from the tin, seems the most probable. Nevertheless, a series of well-conducted experiments, undertaken by some of the companies whose trade in these meats is so large, on the action of meat juices on tin and on solder, might do much to allay suspicion, and at the same time to advance our knowledge of natural facts.

IN the last session of the United States Congress at Washington, May 24, 1880, the "Committee on Naval Affairs" reported a bill in support of a proposed International Commission to agree upon standard tests for colour-blindness and visual power in navies and merchant marines, and standard requirements of these faculties. Resolutions in recommendation of this Commission have been passed by the American Ophthalmological Society at their Newport meeting, the Ophthalmological Section of the British Medical Association at Cambridge, and the International Congress of Ophthalmology at Milan. The next United States Congress will act on this bill to initiate the Commission. Dr. R. Joy Jeffries, 15, Chestnut Street (Beacon Hill), Boston, Mass., U.S. America, intimates that he will be greatly indebted for any public or private statistics or information in relation to this subject which any one can send him.

MR. ADAM SEDGWICK, who was elected a Fellow of Trinity College, Cambridge, on Saturday last, the 9th inst., graduated in the First Class of the Natural Sciences Tripos of 1877, when he was especially distinguished for his knowledge of zoology and comparative anatomy, human anatomy and physiology. Those of our readers who are interested in the study of the principle of heredity may be glad to know that this gentleman is the great-nephew and eldest male representative of the illustrious geologist whose name he bears.

IN reference to our note (NATURE, vol. xxii. p. 541) upon the awards of the juries of the Exhibition of Agriculture and Insectology at Paris, wherein we observed that a suggestion had been put forward to arrange the electric light as an insect-catcher, a correspondent writes that in experimenting for other purposes with a Browning electric light upon a roof at Charing Cross, besides innumerable flies and moths, single individuals of two species of sphinxes were attracted, probably from considerable distances.

THE Freedom of the City of London was conferred on Sir Henry Bessemer on Wednesday last week. Sir Henry in his address indicated the vast improvements which his process had introduced in the manufacture of steel, and at the dinner in the evening he sketched the early progress of iron manufacture.

THE French Minister of Public Instruction has caused an edition of Mr. Herbert Spencer's work on Education to be published for gratuitous distribution in France.

A PRACTICAL experiment was, on Wednesday last week, tried with the air-engine at Woolwich, designed by Col. Beaumont, Royal Engineers, and which has been for some time running on the short lines of the Royal Arsenal. Although weighing but 10 tons, it has proved capable of hauling a burden of 16 tons up a fair incline, and arrangements were made to try its powers in a more extended run, such as engines of the kind would have to encounter on the London railways and tramways. The air-reservoir, which contains only 100 cubic feet of air, was charged at the torpedo pumping-house, up to pressure of 1,000 lb. to

the square inch, and with this store of energy it was proposed to run to and from Dartford, about 16 miles. The chief feature of Col. Beaumont's method is the introduction of an almost imperceptible supply of steam, by which the air, as it is admitted to the cylinder from the reservoir, is largely heated, and thereby greatly increased in force. The engine is driven by six cylinders and a double set of machinery at one end, and, having no smoke-stack, resembles in appearance a locomotive tender rather than a locomotive. It runs on four wheels, and in size is less than that of an ordinary omnibus. It left the Royal Arsenal at Plumstead Station at 12.22 p.m., with a full charge of 1,000 lb. to the inch, passed Abbey Wood Station at 12.27 with 940 lb. on the guage; Belvedere at 12.33, with 8.60 lb.; and Erith at 12.36, with 760 lb., arriving at Dartford at 12.50, with a remaining energy of 540 lb. on the square inch. Shunting about at the station reduced this pressure somewhat, and at 1·35 the return journey commenced with a store of 510 feet. Although the minimum for effective working is considered to be a pressure of 200 feet, Plumstead station was reached again at 2.10, but the engine was nearly pumped out, having a pressure of barely 80 lb. remaining. It was stated that another engine was being constructed, much more powerful; capable, in fact, of travelling double the distance with a single charge. The operation of pumping in the compressed air occupies about fifteen minutes, and it is calculated that an air engine on this principle as large as the usual steam locomotive of 50 tons weight would be considerably more powerful than any locomotive yet made. The objection to steam, that it frightens horses, cannot apply to this system, as there is no escape of steam visible or audible, and the only noise to be distinguished is a rumbling sound like the rattle of the street traffic.

ONE of the most satisfactory reports on the progress of cinchona cultivation and the harvesting of bark in the Government plantations in Bengal, has just been issued by Dr. King. A summary of the work of the year 1879-80 shows that the plantation was extended by about three-quarters of a million of young trees, a crop of 361,590 lbs. of dry bark was harvested, a new kind of cinchona, namely, that which yields the Carthagena bark of commerce, was brought into cultivation, and the nursery stock was maintained at a sufficiently high level for the supply of young plants for the present year. In the details of the year's planting it is shown that as in former years the species most largely planted was *C. succirubra*, and of this as many as 644,222 were put out. Of the valuable *C. calisaya* and hybrid plants a comparatively large number has been planted; of the hybrid species as many as 39,400 at Mungpoo, and 36,680 at Sittong, and of *C. calisaya* 12,782 at Sittong. The yield of bark during the year amounted to 361,590 lbs. of dry bark. Dr. King further reports that in accordance with the orders of Government arrangements were made towards the end of the year for sending a quantity of the Calisaya bark, which had accumulated in the factory store-room, to London for sale, and since the expiry of the year, part of this bark has actually been despatched: further it is stated that the amount of febrifuge used in substitution of quinine in Government hospitals and dispensaries during the past year was 5,400 lbs. Taking the average price in Calcutta of quinine for the year at Rs. 90 per lb. (a low estimate), the saving effected by this substitution has been ery nearly four lakhs of rupees. The saving in former years from the substitution of the febrifuge having amounted to seven and three quarter lakhs of rupees, the total saving up to the end of last year therefore reaches eleven and three quarter lakhs, which is quite a lakh and a half more than the plantations (including compound interest at 4 per cent.) have cost since their commencement. This is a most satisfactory statement, added to which the introduction through Kew of the valuable species of cinchona, yielding Carthagena or Columbian bark, and the prospect of its successful propagation, makes Dr. King's present report one of very great interest and satisfaction.

WE have received several numbers for the current year (vol. v.) of the *Botanical Gazette*, a Paper of Botanical Notes published at Crawfordsville, Indiana. The *Gazette* appears to have a large circulation in Western America, which, as far as we can judge from the specimens before us, it well deserves. We quote the following interesting and sensible remarks from the editorial notes:—"A new school of botanists is rapidly gaining ground in this country, and we are glad to see it. While the country was new and its flora but little known, it was very natural for systematic botany to be in the ascendency. It is a very attractive thing to most men to discover new species; but when the chance for such discovery becomes much lessened, there is a turning to the inexhaustible field of physiological botany. Systematists are necessary, but a great number of them is not an essential thing, and it is even better to have but a few entitled to rank as authorities in systematic work. But in studying the life-histories of plants or their anatomical structure, we cannot have too many careful observers. This, at the present day, seems to be the most promising field, and one botanist after another is coming to appreciate it. As microscopes are becoming cheaper, and hence commoner, the workers in the histology of plants are becoming more numerous, and it is to such that the *Gazette* would now address itself." We noticed especially some remarkable observations by a correspondent of the *Gazette* on the carnivorous habits of the honey-bee of South America. These would appear, however, to require confirmation before they can be accepted without hesitation.

THE *Valley Naturalist* is the title of a small monthly journal published in St. Louis, U.S. It contains contributions in various departments of natural science; it would be of more value, we think, if it confined itself more strictly to contributions on local natural history, and had fewer miscellaneous items from foreign journals.

WE noticed a few months ago that an international metrological office had been established at Breteuil (near St. Cloud) at the expense of all the civilised nations except England. A part of the duties of this office is to deliver to the associated nations approved standard metres and kilograms for the ulterior construction of other standards, and practical verification of the usual metres and kilograms. The standards intended for France being ready, the Minister of Public Instruction appointed the French national committee, which is composed of MM. Dumas, St.-Claire Deville, Hervé-Mangon, Mascart, and a few others. It may be noted that M. Tresca, who designed the pattern of the international metre adopted by the International Commission, is not one of the new committee.

THE Nineteenth Century Building Society has done a commendable thing in resolving, that as, in their opinion a course of lectures at the Parkes Museum of Hygiene on House Sanitation would be most valuable to the members of building societies (who to a very large extent own the house they live in), the secretary of the society be requested to ask the Committee of the Museum whether such a course of lectures could not be given gratuitously during the ensuing winter.

THE Municipal Council of St. Petersburg is at present deliberating on a proposition made by the Electrotechnik, a Russian society recently established, for illuminating with Siemens lamps the Newsky Prospect, whose length is 7,000 metres.

THE Algerian *Akhbar* says, in one of its last numbers, that the corpses of two European travellers, who according to all probability have died from want of water, have been discovered lying in the desert fifty miles southward of Wargla, the most remote oasis occupied by the French in the Algerian Sahara.

The names and nationality of these two unfortunate travellers have not been ascertained yet, according to our contemporary.

From a Japan paper we learn that at the Botanical Garden in Aichi *ken*, an Indian tea-plant, has been planted as an experiment. The leaves have lately been gathered and treated in the same manner as the Uji tea, and it has been found that the product of dried tea is greater in proportion to the quantity of leaves used than in the case of Japanese plants. Tea-growers are, in consequence, said to be devoting their attention to the new plant.

The additions to the Zoological Society's Gardens during the past week include a Plantain Squirrel (*Sciurus plantani*) from Java, a Smooth Snake (*Coronella lævis*) from Hampshire, presented by Mr. D. Tober; a Plantain Squirrel (*Sciurus plantani*) from Java, presented by Mrs. Elliot; a Common Spoonbill (*Platalea leucorodia*), European, presented by Mr. W. H. St. Quintin; a Common Kestrel (*Tinnunculus alaudarius*), European, presented by Mr. J. Young; two Central American Agoutis (*Dasyprocta isthmica*) from Central America, a Variable Squirrel (*Sciurus variabilis*), a Common Boa (*Boa constrictor*) from South America, two West African Pythons (*Python sebæ*) from West Africa, a European Pond Tortoise (*Emys europæus*), European, two Glass Snakes (*Pseudopus pallasi*), a Lacertine Snake (*Coelopeltis lacertina*), a Common Snake (*Tropidonotus natrix—var.*), South European, deposited; a Fraser's Squirrel (*Sciurus stramineus*) from Ecuador, a Ring-tailed Coati (*Nasua rufa*), a Cayenne Lapwing (*Vanellus cayennensis*) from South America, three Californian Quails (*Callipepla californica*), purchased; two Gayals (*Bibos frontalis*) from Assam, two Sumatran Porcupines (*Hystrix longicauda*) from Sumatra, an Indian Crocodile (*Crocodilus palustris*) from India, received in exchange.

OUR ASTRONOMICAL COLUMN

Hartwig's Comet.—Prof. Winnecke, in a circular issued from Strassburg on October 5, expresses the opinion that it is highly probable the comet discovered by Dr. Hartwig on September 29 was observed in the year 1506, and at his request Dr. Hartwig has submitted the point to calculation, using the first approximation to the orbit which we gave last week. Laugier computed elements of the comet of 1506, from the rough accounts left by European chroniclers and one in the Chinese annals, but his places were necessarily very arbitrarily fixed in this case, as may be seen on referring to his communication presented to the Academy of Sciences at Paris on January 26, 1846. It has not been consequently from any striking similarity between the orbits that Prof. Winnecke has been led to conjecture the identity of the comets, but rather, it would appear, from a general resemblance of track, allowance being made for the somewhat later appearance in the year of the comet of 1880. The Chinese observations do certainly in some cases enable us to make reliable approximations to the orbits of comets, as, for instance, in 568 and 1337; indeed for the latter comet they furnish a remarkably good outline of its apparent path, considering the difficulties which in many cases attend the interpretation of the Chinese accounts: nevertheless for the great majority of comets recorded in their annals the descriptions are unfortunately totally insufficient for this purpose, one very common failing being the omission of dates corresponding to the positions given, as for the comet of A.D. 178, which must have passed very near the earth from the long track it described in the heavens.

As regards European observations of the comet of 1506, Pingré tells us (on the authority of the Chronicles which, according to his excellent custom, are named in his margins), that a comet was seen in the month of August in the north, or between the north and east, or lastly between the west and north, and as the comet was not distant from the Pole, so that it appeared in the evening after sunset, and in the morning before sunrise, it may have had at different hours of the night the various positions mentioned by the historians. It had a long and bright tail which extended "between the fore and hind-wheels of the chariot." On August 8 a Polish historian, an eye-witness, says it was seen near the Pole above "the seven stars or the stars of the great chariot;" on the following night it was situated amongst the same stars, and later, on several nights, it was seen below them; declining by the signs Cancer, Leo, and Virgo, it attained the northern part of the horizon and disappeared on August 14. Some writers limit its appearance to eight days; others say it was visible for three weeks, or even a month.

With respect to Chinese observations, Pingré quotes from Gaubil's manuscript, of which he made so much use, which was preserved in the Dépôt de la Marine at Paris in his time, but since understood to be lost, and from Mailla and Couplet. We have now the fuller translations by Biot and Williams. We read that in the first year of the epoch Ching Tih, in the reign of Woo Tsung, on the day Ke Chow of the 7th moon (1506, July 31), a star was seen to the west without the boundary of Tsze Wei (the circle of perpetual apparition). . . . After some days it had a short tail. It was seen between the sidereal divisions Tsan (determined by δ Orionis) and Tsing (by μ Geminorum), the Chinese sidereal divisions, it must be remembered, being intervals of right ascension with wide limits of declination reckoned from the determining star of the division, which we have here taken from Biot. It gradually lengthened, extending in a north-westerly direction towards or to Wan Chang (θ, υ, φ Ursæ Majoris). On August 10 it was bright, and moved to the south-east, it lengthened to about 5° and swept the upper of the stars Hea Tae (ν, ξ, Ursæ Majoris), and entered within the space Tae Wei Yuen (Biot's *Thai-Wei*), a space between stars in Leo and Virgo, to which, as also to Tsze Wei, the circle of perpetual apparition mentioned above, constant reference is made in the Chinese cometary observations. For the limits of this space Williams may be consulted. Biot and he substantially agree in their translations. Dr. Hartwig assumes the perihelion passage in 1506 to have occurred on July 1, old style, and with the elements of 1880 finds a track of which it is remarked, "Die Uebereinstimmung des so gefundenen Laufes mit dem wirklich beobachteten ist eine vollständige." The track is thus given:—

	R.A.	Decl.		R.A.	Decl.
	°	°			°
July 19 ...	97·1 ...	+39·3	Aug. 18 ...	250·1 ...	+54·5
29 ...	106·6 ...	61·3	28 ...	258·1 ...	37·0
Aug. 8 ...	201·9 ...	77·9			

We should incline to characterise the presumed identity of the comets of 1506 and 1880 as one rather of possibility than of high probability.

From observations at Strassburg on September 29 and October 1, and one at Leipzic on October 3, Mr. Hind has deduced the following elements:—

Perihelion passage, September 6·9182 G.M.T.

	° ′ ″	
Longitude of perihelion	81 1 37	App. Eq.
„ ascending node ...	44 19 47	Oct. 1.
Inclination of orbit	38 28 11	
Logarithm of perihelion distance ...	9·558048	

Motion—retrograde.

As regards position the comet may be observed for many weeks, but the brightness will be rapidly declining. Since it was not detected till three weeks after perihelion passage, it is desirable that observations should be continued as long as practicable, if the character of the orbit is to be decided at this appearance.

GEOGRAPHICAL NOTES

The newly-published volume of the Geographical Society's *Journal* contains some useful and even valuable contributions to geography. The veteran traveller, Capt. R. F. Burton, furnishes a memoir respecting the new map of Midian constructed by the officers of the Egyptian General Staff. Capt. Burton however, as might be expected, supplies geographical information beyond that given by the Egyptian officers. He also contributes a second paper of a different character on the subject of a visit to Lissa and Pelagosa. Even more valuable than Capt. Burton's first paper is Lieut. R. C. Temple's account of the country traversed by the second column of the Tal-Chotiali field-force in the spring of 1879, with his sketch-map of part of the country passed over by it between Candahar and India. This memoir has evidently been drawn up with elaborate care, and embodies a mass of important information. The notes upon some astronomical observations made in Kordofan and Darfur

by Major H. G. Prout of the Egyptian Staff are also of value, and are accompanied by a map of routes in the two provinces, constructed by the Society's draughtsman from the reconnaissances of various officers in the service of the Khedive. Mr. E. Colborne Baber, lately our Consular representative at Chungking in Western China, also communicates through the Foreign Office some brief remarks under the heading of "Approximate Determination of Positions in South-Western China," to which are appended a number of tables of observations for latitude, &c.

IN the middle of last January Mr. W. S. Jerdan and a small party started from the Elderslie station on the Diamantina River, in Western Queensland, for the purpose of exploring the Mackinlay Ranges for gold. Leaving the Booker-Booker Mountain, with its dark fringe of gidya scrub, on their left, and Mount Munro on the right, they travelled up the Diamantina over splendidly grassed downs, and as they advanced up the river they found that the grasses became even finer and herbs more plentiful. After eight days' marching the party reached the neighbourhood of the Mackinlay River, and they report that the country passed over for some time previously was principally level plain, and just at that season perfectly bare, with the exception of a few tussocks. After about another week they got out of the low country and obtained their first good view of the Mackinlay Ranges, which they describe as presenting a very picturesque appearance in the distance, with their numerous pinnacles, peaks, and flat-topped mountains. The country along the ranges is covered with granite boulders, or else consists of decomposed granite flats infested with spinifex, with numerous sandy creeks running through it in all directions. The party spent about two months in searching for gold, but met with little success.

SIGNOR BIANCHI has reported to the Milan Society, which sent him out to Shoa and other parts of North-Eastern Africa for the purpose of making commercial explorations, that he has been able to make some corrections in the position of places as given in our existing maps. Antotto he places in 8° 53′ N. lat., 36° 15′ E. long., instead of its present position further north. Fanfinni is really north-north-east and not south of Antotto, while the Salala Mountains are fifty kilometres from Fanfinni, and not close to it. Lake Zouay he has not met with, though his route ought to have taken him to it, according to the map.

THE United States Navy Department have received through the Russian Government a letter from the Captain of the Arctic Exploration steamer *Jeannette*, dated from Cape Serdze Kamen, August 29, 1879, which reports the arrival of the *Jeannette* at that place on the afternoon of the above date. The letter states that the members of the expedition were all well, and that they expected to sail that night for Wrangell Land, by way of Kaliutchin Bay. This news has taken more than a year to reach America. The *Corwin* has arrived at San Francisco, and is reported to have searched all the region between Point Barrow and Herald Island, without finding any trace of the expedition. Still he thinks there is no reason yet to give up hope.

The new number of *L'Exploration* is an improvement on previous ones. We have a good article on the commercial relations between France and Russia; information as to the progress to their destination of MM. Revoil and Crevaux; an interesting analysis of an article on Ausland, on the country of Muata Yanvo, a letter from Dr. Quintin on a former expedition to the Upper Niger, and letters from Matteucci on the progress of his expedition in the Sudan. The notes are also much better edited.

CAPELLO and Ivens have furnished to the Portuguese Government a detailed account of their African explorations, a great number of drawings, and a comprehensive map containing an important part of Portuguese Africa, and also the adjacent territories. Next year Capello and Ivens will return to Africa to finish their explorations, and make a complete chart of the province of Angola.

THE death has just taken place at Pitminster, near Taunton, of Capt. Hobson, of the Royal Navy, who in his earlier days took an active part in the search for the remains of the late Sir John Franklin, and was the discoverer of the records which afforded the clue to the lamented explorer's fate. He was second in command, then holding the position of lieutenant to Capt. McClintock, who, in the year 1845, sailed in the *Fox* to search for the Franklin Expedition. Hobson was the leader of one of the parties which went in search of traces of Franklin, and he succeeded in finding the brief record which only too clearly set at rest the conjectures which the public entertained as to Sir John Franklin's fate.

THE expedition which left France on October 5 for the exploration of the country between the Upper Senegal and the Niger, though mainly for military and commercial purposes, is likely, if successful, to add greatly to the fulness and precision of our knowledge of that region of Africa. Astronomical, geodetical, and topographical officers accompany the expedition, so that we may expect important scientific results. The terminus on the Niger will be either Bamakou or Dina, above Yanina and Segon.

COL. FLATTERS has returned from his explorations in the Touareg region.

THE Wellington correspondent of the *Colonies and India* states that the area of the Crown forest lands in New Zealand in 1879 was estimated at 10,158,870 acres, but it has been proved that some of the most valuable kinds of timber have been recklessly used, and it is said that at the present rate of consumption all the splendid *kauri* forests will be exhausted in twenty-one years, and that the value of the timber will be about 11,000,000*l.* He does not however appear to have taken into consideration the very serious effect which this wholesale destruction of forests will have upon the climate of New Zealand.

PROF. ASAPH HALL ON THE PROGRESS OF ASTRONOMY[1]

ASTRONOMY, in some of its forms, reaches back to the most distant historical epochs, and the changes that it has undergone during this long lapse of time give to this science a peculiar interest. In no other branch of human knowledge have we such a long and continuous history of the search after truth, of the painful struggle through which men have passed in freeing themselves from theories approved by the wise of their own times, and in overthrowing beliefs which had become incorporated into the life and culture of those times. Perhaps the grand array of the heavens, and the vast phenomena which they display, naturally led men to the invention of complicated theories; but these passed away at last before the test of observation and the criticism of sceptical men; and the Copernican theory of our solar system, Kepler's laws of elliptical motion, and the Newtonian law of gravitation, gave to astronomy a real scientific character.

The discovery of the laws that govern the motions of the heavenly bodies, and the construction of the theory of these motions, demanded from practical astronomy better observations and a more accurate determination of the orbits of the planets and the moon, or of the constants that enter into the problems of celestial mechanics; and this demand led to an improvement in the instruments, and in the art of observing. The astronomers and instrument-makers of England and France led the way in these improvements. The great national observatories of those countries were established, and in England, Flamsteed and Sharp, Bird and Bradley, were foremost in raising practical astronomy to the condition of satisfying the demands of theory. But theoretical astronomy was soon to receive a wonderful advancement. Perhaps no one contributed more powerfully to this progress than Lagrange. The writings of this man are models of simplicity and elegance; and yet so complete and general are his investigations, that they contain the fundamental theorems of celestial mechanics. By the invention and perfection of the method of the variation of the arbitrary constants of a problem, and by the establishment of the differential equations of a planetary orbit depending on the partial differential coefficients of a single function, Lagrange reduced the question of perturbations to its simplest form, and gave the means of deducing easily the most interesting conclusions on the past and future condition of our solar system. To supplement this great theorist there was needed another kind of genius. Combining the highest mathematical skill with unequalled sagacity and common sense in its application, Laplace gathered up and presented in a complete and practical form the whole theory of celestial mechanics. Besides his numerous and brilliant discoveries in theoretical astronomy, Laplace gave us some of the finest chapters ever written on the theory of attraction,[2] and a complete treatise on the calculus of probability.

[1] Address as Vice-President of Section A, at the Boston meeting of the American Association.

[2] "Ein schönes Document der feinsten analytischen Kunst."—GAUSS.

By such labours as these the questions of astronomy were brought into order and classified, and the attention of astronomers was directed better than ever before to the determination of the quantities which must be found from observation. Moreover, the refinement of analysis and the completion of theory brought out new and more delicate questions, not less interesting, and requiring more complete investigation and more powerful instruments. The careful examination and study of the instruments and methods of observation became necessary, as well as complete and rigorous methods of reduction; and finally there was needed a critical and satisfactory method for the discussion of observations. For these last improvements in astronomy we are indebted chiefly to the astronomers and mechanics of Germany.

Among those who contributed by means of their optical and mechanical skill to furnish astronomy with the instruments necessary for its further advancement, no one holds a more honourable place than Joseph Frauenhofer. This man began his scientific work at the age of twenty-two, and died at thirty-nine, and yet in those seventeen years he gave to astronomy great improvements in the manufacture of optical glass, driving clocks for equatorials, and telescopes and micrometers, that in the hand of Bessel and Struve gave to observations a degree of accuracy hardly thought of before. To such men as Frauenhofer and his co-workers, who have carried on and improved the construction of instruments of precision, practical astronomy owes much; and yet, after all, the principal thing in a science is the man himself. No matter how excellent the instruments may be, the question whether they shall be used for the advancement of the science, and shall contribute the full value of their peculiarities to help towards increasing the accuracy of astronomical determinations, depends wholly on the astronomer. Again, astronomy is now so completely a science, and all its operations are so closely connected with theory, that no one is fit to have charge of an extended series of astronomical observations who has not a fair amount of theoretical knowledge. Without such knowledge his labour is apt to be thrown away, and is never so effective.

As a good example of what the modern astronomer should aim to be, we may take Bessel. To this man we owe a large part of our best methods for the examination and determination of the errors of our instruments and the introduction of complete and rigorous methods for the reduction of observations. Bessel's reduction and discussion of Bradley's observations was a masterpiece of its kind, bringing out the value of Bradley's work, which had lain unnoticed for more than half a century, and forming a starting-point for sidereal astronomy. This work was continued and perfected in his tables for the reduction of astronomical observations, published twelve years afterwards, a work that has done more than anything else to introduce order and system into practical astronomy. In the discussion of instruments and the determination of their errors, Bessel's conception of an instrument was that of a geometrical figure, and the positions of the lines and divisions of this instrument were considered with corresponding rigour. Although devoted almost entirely to astronomy, yet Bessel was an able mathematician, and of this he has left abundant proof. It seems to be necessary that a man should die and be forgotten personally before his work can be fairly estimated; but time adjusts these matters at last, and I know of no astronomer whose work promises to endure the judgment of the future better than that of F. W. Bessel.

It has been said that for producing the most puzzling compound of metaphysics and mathematics something which has neither height nor depth, nor length nor breadth, and which no one can understand, the German mathematician is unequalled. And at the same time it must be said that, for clearness of conception and beauty and precision of expression, Germany has produced in Gauss a mathematician who is unsurpassed, and who is worthy a place by the side of Lagrange. Omitting all reference to the works of Gauss in theoretical astronomy and in geodesy, which are many and important, I refer here only to his method for the discussion of observations and of deducing the most probable values of our constants. Almost the entire work of astronomy is a vast system of numerical approximation, in which the first steps are obvious and easy, but where the theory soon becomes complicated and the labour enormous. Thus the calculation of the approximate orbit of a planet or of a comet is the work of only a few hours; but the computation of the perturbations and the correction of the elements from all the observations may be the work of months and years. It is therefore of the highest importance that we should have a method for the discussion of observations that will give us the best result, and which will introduce order and system into this department of astronomy. Such a method is that of least squares. For the complete theory of this method and for nearly all the arrangements and algorithms necessary for its practical application, we are indebted to Gauss. The invention and application of this method to the discussion of observations of all kinds seems to me one of the greatest improvements of modern times, and its proper use will lead to a steady progress in astronomy. We must remember, however, that this method does not undertake the improvement of the observations themselves, as some have seemed to think; but, when rightly used, it produces simply the best result we can hope for from a given series of observations. It does not therefore dispense with skill and judgment on the part of the astronomer, but one is tempted to say that, if he has not these prime qualities, then the next best thing for him to have is the method of least squares. The use of this method has become one of the chief characteristics of modern astronomy, and if we compare the results of its application with those of the older methods, we shall see its superiority. Thus, for example, no astronomer of to-day who is accustomed to the modern methods of discussion, would be satisfied with the manner in which Bouvard represents in his tables the observations of Jupiter and Saturn, but would suspect at once some error in his theory of the motions of these planets.

The present condition of astronomy is the result of the continued labours of our predecessors for many generations; and to this result the lapse of time itself has largely contributed. For the full development of the secular changes of our solar system, for an accurate knowledge of the proper-motions of the stars of our sidereal universe, and of the great changes of light and heat that are going on among them, the astronomer must wait until future ages. It is his present duty to prepare for that future by making the observations and investigations of his own day in the best manner possible; and to do this needs a careful consideration of the present condition of the science. Although the objects for observation have become so numerous, and the range of investigation so wide, that there is room for the most varied talent and skill, yet there is danger that there may be a waste of labour either in duplicating work, or in doing it in an improper manner. Especially may this happen in observations of the principal planets of our system, and of the fixed stars. In the case of the planets the observations are abundant, and the orbits are already well determined, except that of Neptune, for which, on account of its slow motion, we must of necessity wait for time to develop its small peculiarities, if such there be. For all these planets the observations at one or two observatories are amply sufficient, and even then the observations ought to be confined to a short time near the opposition, or at quadrature, and so made that they may be easily combined into a single normal position, which will suffice for the theoretical astronomer. To scatter such observations over a period of several months is to throw away one's labour, and to leave to the computer the disagreeable duty of rejecting a part of the observations as useless. It seems to me, therefore, unwise for several observatories to continue heaping up observations of the four outer planets of our system, when ten observations a year of each planet will give all the data that are needed. Again, for all the principal planets, observation is now in advance of theory, except, perhaps, in the case of one or two of them. Thus, for Saturn, all the tables are decidedly in error, and, although an attempt has been made to accuse the observations of this planet, it is quite certain that the trouble lies in the theory; for in the case of Jupiter and Saturn we have the most complicated planetary theory of our system, and one that has not yet been completely developed. It seems to me, also, that observations of our moon might well be confined to one or two observatories. Here again observation is far in advance of theory, if indeed there be now in use anywhere a pure lunar theory. All the lunar ephemerides that we have are affected with empirical terms, and the lunar theory itself remains an unsolved mystery. In this case there is no attempt to impeach the observations. The trouble seems to be with the perturbations of long period, and this does not call for numerous observations during each lunation. By a proper consideration of these matters astronomers may, I think, save themselves much useless labour.

Observations of the fixed stars are of the utmost importance in astronomy, since the positions of the stars are of the fundamental points on which depends our knowledge of the motions of the planets, the moon, and of the stars themselves; and it is

on account of this fact that Bessel's tables, published in 1830, were of such great service, since they introduced correct and elegant methods of reduction, and clearly defined all the constants and epochs. We now have the positions of several hundred stars so well known that they may be safely used in the reduction of observations; and for these accurate positions we are largely indebted to the astronomers of the Pulkowa Observatory, who have made such absolute determinations a special work. There is still an opportunity for the improvement of these positions, and every well-executed determination will be of value; but it is doubtful if crude and irregular observations can add anything to our knowledge of the positions of these stars. Neither can the routine, mechanical style of observing, that is apt to prevail in large observatories, be of much use here. It would be better in most cases for such observatories to assume the positions of the fundamental stars, and to leave the further improvement of their places to skilful astronomers who understand the theory of such work, and who carefully study and become masters of their instruments. In these refined observations the refraction of light by our atmosphere also plays an important part, and this question will need to be examined at every observatory that undertakes to do independent work. It is true that every new and good meridian instrument may, and perhaps ought, to contribute something towards removing constant errors, and giving us a more accurate knowledge of a star's position; but when this position is very well known, the only way for further improvement is through complete and careful observations, and their thorough reduction and discussion.

In the observations of double stars but little had been done before the present century, and the labours of W. Struve form the real starting-point in this branch of astronomy. These labours have been ably continued by his son, the present director of the Pulkowa Observatory, and the observations of these two astronomers, extending over a period of nearly sixty years, are of the greatest value for our knowledge of the motions of the double stars. This is a branch of the science into which irregular workers are apt to enter, and where some of them have done good service; but if any amateur astronomer will compare his own work with that of the Struves, and will study the methods followed by them in determining their personal and instrumental errors, and will emulate the steadiness with which they have followed out their purpose, he can do much to enhance the value of his labour. Here the observations are simple, and easily reduced, and the chief requisites are skill and patience on the part of the observer. He should not be discouraged because he obtains no immediate or great reward for his work, or public notice, or because some one who rants about the nebular hypothesis and kindred subjects of which he knows nothing is for a time the great astronomer of the day. The observer will learn finally that a good observation of the smallest double star, or of the faintest comet or asteroid, is worth more than all such vague talk. The observation has a positive value, however small, but the physical theories of the universe, of which modern popular science is so productive, are generally worse than useless.

The first step towards a rational and trustworthy knowledge of our sidereal universe must come from a determination of the distances of the stars. The solution of this problem was attempted soon after the Copernican theory of our solar system was established, when it was seen that we have a long base line for our measures, or the diameter of the earth's orbit, and it was supposed that the solution would be easy. These early trials were all failures, but they led to some very interesting and important discoveries, such as Bradley's discovery of the aberration of light; to the knowledge of the fact that the determination of the parallaxes, or the distances of the stars, although simple in theory, is practically a difficult question; and then to an improvement in the instrumental means of observation, to a careful study of the methods of observation and the instruments, and to a recognition of the necessity of a complete and rigorous reduction of the observations. An examination of these early attempts is an instructive study. It is only about forty years ago that the solution of this problem was at last attained, and then only by the application of the most powerful instruments, and the best observing skill. An interesting result of the determinations of stellar parallax is obtained at once in the check it puts on speculations concerning the structure of the sidereal universe. The first astronomers who considered the parallaxes of the stars very naturally assumed that the bright stars are nearer to us than the faint ones, and therefore they observed the bright stars for parallax. Now, while this assumption may be true as a general statement, the actual determinations of parallax show that some of the faint stars which are not visible to the naked eye are much nearer to us than the brightest stars of our northern sky. Again it was assumed that a large proper motion is a certain index of a star's nearness to us; but observation shows that this also may be an erroneous assumption. This is a problem whose solution is only just begun, but already we know enough of its difficulties to see that we need the most powerful micrometrical apparatus that can be brought into use. The invention of some micrometer that, while as accurate as the present filar micrometer, would give the observer a much greater range of observation, and enable him to select suitable stars of comparison, is something much to be desired. At present the heliometer seems to be the best instrument for observations of this kind. Formerly it was thought that photography would furnish a good method for such delicate determinations; but so far the photographic methods have not given the necessary degree of accuracy in the measurements, and the astronomical use of photography is confined mostly to descriptive astronomy, where, especially in solar eclipses, it has rendered excellent service. Closely connected with the parallaxes of the stars and their proper motions is the interesting question of determining their motions to or from our sun according to the theory of Doppler. Here likewise the numerical determinations are so discordant, that we cannot have much confidence in the results. In both these cases we need more powerful apparatus, and a complete and thorough investigation of the methods of observation. Perhaps some of the large instruments now constructing may be employed in these methods, and we may soon have better results.

A great advance has been made in cataloguing the fainter stars. This work was begun by the French astronomers nearly a century ago, and was continued by Bessel, Argelander, and others. An important step towards the completion of this work was taken by Argelander and his assistants in their great catalogue of the approximate positions of 324,198 stars, which was finished in 1861. This census of the stars will soon be extended, we hope, over the whole heavens; and it already forms the groundwork for the great zone observations of stars now going on in Europe and in this country, and which must be nearly finished. These observations will doubtless reveal many interesting cases of the proper motion of the stars, and will certainly form the basis for a knowledge of the motion of our solar system in space, and for sidereal astronomy generally, such as we have never had before. Our American observatories can render a good service by observing stars of southern declination, since our observatories are ten or twelve degrees farther south than those of Europe, and thus have an advantage of position which ought to be made use of; and which may serve to unite into a harmonious system the observations made in the northern and southern hemispheres. The work of mapping the very faint stars near the ecliptic has also been greatly extended, and it is to this extension that we owe the rapid increase in the number of the small planets between Mars and Jupiter. But besides aiding in the discovery of the asteroids, accurate charts of the small stars have a permanent value in giving us a knowledge of the heavens at their epoch, and also some idea of the distribution of the stars in space.

It is an interesting question whether, among the thousands of nebulæ that are scattered over the heavens, any of them show changes of form or of brightness. These objects seem to be at least as distant as the stars, and as they have sometimes an area of several degrees, they must be bodies of an enormous extent. That changes are going on in these bodies seems probable, but to be visible at such distances the changes must be very great. In this case there is need of much caution in the discussion of the drawings made at different epochs, and by different astronomers with telescopes of different power; since the nebulæ change their appearance with the telescope used, with different conditions of the air, and with a variation of their altitude above the horizon. Here the excellent photometers that have been recently invented, and which are being so well applied to the determination of the brightness of the stars, may give us assistance. Perhaps also new drawings of the nebulæ, and their criticism and discussion, and a full recognition of the difficulties of making such drawings, will soon lead to a decision of the question of their change of form. Since the study of the light of the stars with new and improved photometers has now become a specialty, we may look for more exact and continued observations of the variable stars. This is a matter of which we know but little, and it is one where a persevering observer may do good service. Although he may not find any immediate encouragement in the discovery of remarkable relations among

these stars, or the probable cause of their variability, he will be collecting observations that must form the test of every theory. As examples of the result of intelligent and persevering observation, we have the case of the sun-spots, which led directly to the discovery of their period, and its singular variability; and that of the shooting stars, which has shown us a very curious relation between these meteors and the comets, and one which may open to us the most extensive views of the relations between our own solar system and other systems in space.

The present condition of astronomy, with its vast and rapidly increasing store of accurate observations, offers many interesting subjects to the theoretical astronomer. The observations of the stars are now so numerous, and have been so fully reduced and criticised, and the time during which the observations have been made is so extended, that we shall soon have excellent data for a new and very exact determination of the constant of precession. The orbits of the planets and the moon, and their masses, are now so well known, that little uncertainty can arise from this source; and by taking into the calculation a great number of stars in different parts of the heavens, we may be able to determine the motion of the solar system in space, as well as the constant of precession. The constant of aberration also needs a new determination, and since this constant is so closely connected with the theory of light and its velocity, and the methods of its determination are still under discussion, it would be well if several astronomers could determine this constant independently. The value we now use was found by W. Struve from prime-vertical observations, and is apparently very accurate; but no astronomical constant should depend on the work of a single astronomer with a single instrument, when it can be determined so easily and by other methods. The old method of finding the value of this constant from the eclipses of Jupiter's satellites may yet give us a trustworthy value. The value of the other constant necessary for the reduction of observations, that of nutation, must be nearly that found by Peters in his well-known investigation of this question. This value may be verified by a new series of observations of Polaris, or of the declinations of stars situated so that this constant has its full influence on the reductions.

There are many subjects in astronomy that need investigation, but in most cases the labour required is very great, and the completion of the work would occupy a long time. This follows of course from the fact that, with the refinement of observations and their exact reduction, many small terms must be considered which formerly could be neglected. The lunar theory has been a vexed question for the last two centuries, and may remain so for a long time to come. This will no doubt be the case until some able astronomer, with the will and perseverance of Delaunay, shall undertake its complete revision. This question should now be looked on as a purely scientific one, and its definite solution should be undertaken. The theory should not be patched up by guesswork to fit the observations, but should be carried out with the utmost rigour. This is a problem to which a young and able mathematician may well devote his life, and we must expect its solution from some such clear-headed devotee of science. Several of the planetary theories need a new investigation, and some of them are already in the hands of able astronomers. That of mercury is especially interesting in connection with the intra-Mercurial planets, and it is to be hoped that Leverrier's theory of this planet may soon have a careful revision.

Again, among the secondary systems, the satellites of Jupiter and Saturn offer many interesting questions to the astronomer. At present the satellites of Jupiter demand a more complete theory and new tables of their motions. Corrected elements of these satellites may be required for reducing observations of their eclipses, and for deriving a new value of the constant of aberration. These satellites form a peculiar and interesting system, and their theory is so complicated that the labour of correcting their elements and forming new tables would be great, but still within the power of a persevering astronomer. The recent discovery of the connection of comets with streams of meteors has given additional interest to cometary astronomy, and there is plenty of hard work to be done in reducing observations, in computing perturbations, and in deducing the best orbits of the comets. The periodical comets have another interest, since they may give us information concerning the matter filling space. It seems to be probable from different reasons, such as the consideration of the light of the stars, that there must be matter spread throughout the celestial spaces; but the only heavenly body, that has directly given us information on this subject is Encke's comet, which has a period of three years and a third. For a long time the motion of this comet was very completely computed by Encke, whose calculations show very strong proof of a resisting medium. These calculations were continued by Von Asten, whose early death prevented him from finishing his work, and the theory of this comet is left in an unsatisfactory condition. It is very desirable that the motion of this comet should be completely investigated, and although the method of the special perturbations of the elements followed by Encke is probably the best that can be used, still in such a case it would be well to apply various methods. Here again, on account of the frequent returns of the comet, the labour of computation is very great, and probably would be enough fully to occupy the time of one astronomer. The interesting questions connected with the motion of this comet ought to induce some one to undertake this laborious work, and these questions are so important that two or three astronomers might well be employed on its theory.

The methods of astronomy have now become so well established that the future advancement of the science is assured, especially since long intervals of time give an increased value to observations. Yet we may hope for improvement in instruments, for the introduction of new methods of observing, for better trained and more efficient astronomers; and perhaps also the rapid advancement of the physical sciences may furnish us with new and more powerful methods of investigation. There is an intimate relation between the instrument-maker and the astronomer, and they should understand each other better than is generally the case. It may seem a small matter that the divisions of a circle, or of a scale, should not be too finely or too coarsely cut; that the reading scale should not be placed in an inconvenient position, and that the illumination of the instrument should be carefully studied, and brought under the control of the astronomer; but these are really essential points, and, if not rightly arranged, are certain to weary the observer and to impair the quality of his work. Such mistakes will not be remedied until the makers better understand the uses of an astronomical instrument, and have correct ideas of the end to be attained. Since our American opticians have placed themselves at the head of their craft, we may hope that our instrument-makers will do likewise, and that they will soon be able to furnish us with the best instruments of precision.

There is one point to which astronomers should give more attention, and from which we may reasonably hope that great advantages to astronomy may come; and that is to the selection of sites for new observatories. It is possible, perhaps probable, that our instruments may be greatly enlarged and improved, and that important discoveries and improvements in the manufacture of optical glass may be made; but it seems certain that we have within easy reach very decided advantages for astronomical work by the choice of better positions for our instruments. Very few American observatories have been established for the purpose of doing scientific work, or with much thought or care for their future condition; but generally they are built in connection with some college or academy, and are the product of local and temporary enthusiasm, which builds an observatory, equips it with instruments, and then leaves it helpless. The atmosphere that surrounds us, and its sudden changes of temperature, are the great obstacles to the good performance of a telescope; and the larger the instrument, and the higher the magnifying power, the more serious are these hindrances. Now, with our present means of travel, we can easily place our instruments at an altitude of eight or ten thousand feet, and above a large part of the atmosphere. In this way we may be able to do with small instruments what at common altitudes can be done only with large ones; and when possible it is always better to use small instruments, since they are more easily handled, and are relatively stronger and better than large ones. Uniformity of temperature may be secured by seeking locations in the tropical islands, or on coasts like that of California, where the ocean winds keep the temperature nearly uniform throughout the year. At great altitudes we may secure a clearness of vision that would be of the greatest value in the examination of faint objects, and by this means, and by persevering and continuous observation, interesting discoveries may be made. It is a matter of course that, except in the case of comets, the future discoveries in astronomy will belong to faint and delicate objects; but these are interesting, and should not be neglected. A uniform temperature, which secures good definition, and steady images of the stars, is necessary for accurate determinations of position, and for all measurements of pre-

cision. This condition is especially important in such work as that of stellar parallax, the determination of the constant of aberration, and wherever the yearly change of temperature may act injuriously. In the selection of better sites for observatories I think we have an easy means of advancing astronomy.

As this science grows and expands, it will become more and more necessary to study the economy of its work, in order that astronomers may bestow their labours in the most advantageous methods, and may rid themselves of all cumbersome and time-consuming processes. The manner of publishing observations has already been much abbreviated, and improved I think, by some of the European astronomers, and this change seems destined to become universal. As the positions of many objects are now well known, the need of printing all the details of the observation, such as the transits of the wires, the readings of the micrometers, &c., is very slight; and this printing may be safely abandoned. Even this change will lead to a great saving in the time and cost of printing. But this will necessitate a more complete discussion of the work, and a more careful examination of the instruments; things to be desired, since they tend to lift the observer out of his routine, and make him a master of his business. There are objections to this change, and some of them are real, such as the importance of publishing a complete record; but this is overestimated, I think, since the original records ought always to be referred to in case of doubt; and other objections are factitious, such as the need of publishing a large and showy book in order to impose on the public.

We may hope also for improvements in theoretical astronomy, and for the better training and preparation of students of this science. I know that it is sometimes said that theoretical astronomy is finished, and that nothing more can be done. Such assertions come from professors who are old and weary, or from those young men who tire out early in life; but they are wrong. The improvements that Hansen has made in the theory of perturbations, and Poinsot's study of the theory of rotation, show what careful investigation may do, and assure us of further progress. It must be confessed that some of the astronomical work done in our country bears evidence that the astronomers did not understand the correct methods of reduction, and much of it shows evidence of hasty and ill-considered plans. This is perhaps a natural condition for beginners, but we trust that it has been outgrown. An actual need for the astronomical students of our country is a good book on theoretical astronomy, similar to Pontécoulant's work, in which the whole subject shall be presented in a complete form, such as we find in the "Mécanique Céleste," together with an account of the improvements made by Gauss, Poisson, Hansen, and others. There is no American book of this kind, and the English works are too partial, designed apparently to fit the student for college examinations, and not to give him a complete knowledge of the science. Such a book has hardly been attempted in our language, unless that of Woodhouse may be an exception, and it may be a long time in coming, since it requires a man qualified to do the work, and will involve an expense of labour in the preparation and of cost in publishing such as few are willing to incur. In the mean time it is far better for the student to go directly to the writings of Lagrange and Laplace, of Gauss and Poisson and other masters, rather than to spend time in reading second-rate authors who endeavour to explain them. And generally this will be found the easier way also, since the student avoids the confused notions and symbols, and the grotesque expressions and egotism of small men, and is lifted into the region of ideas and invention.

In presenting his exposition of the nebular hypothesis, which has since become so celebrated, Laplace says: "I present this hypothesis with the distrust which everything ought to inspire that is not a result of observation or of calculation." It is a singular fact that, among all the writings on the nebular hypothesis, I have never seen a reference to this presentation of it by its most distinguished advocate; and yet this is the true spirit of scientific astronomy. Laplace did not wish to exempt his own theories from criticism, and neither should any one. In astronomy there is no final human authority, no synod or council, but simply an appeal to reason and observation. If a theory or a discovery be true, it will stand the test of observation and of calculation; if false, it must pass away to that Miltonian limbo where so many things have gone and are going. The question is sometimes asked, Of what use is astronomy? and the reply generally made is that it has conferred great benefits on navigation and on commerce, since it is by means of his astronomical knowledge that the sailor determines the position of his ship on the ocean. There is a truth in this reply, but it is only partial. The great value of astronomy is that it is really a science and that it has broken the path and led the way through which all branches of science must pass if they ever become scientific. It is the spirit of honest, unrelenting criticism, and of impartial examination, that finally eliminates error and awards to every one his just due, that makes astronomy honourable and attractive; and it is by cultivating this spirit that astronomy confers its chief benefit, for it is this that shall break in pieces and destroy all false assumptions in science and in philosophy.

SCIENCE IN NORWAY

We have received several publications from Norway of scientific interest.

Nyt Magazin for Naturvidenskaberne. B. 25, H. 4. (Kristiania, 1880.)

In this number of the Norwegian "New Magazine for Natural Sciences" Herr Hansen continues his description of the annelids yielded by the Norwegian North Sea Expedition of 1878, to which he appends drawings of his own of all the rarer forms.—Herr L. Schmelck gives the results of his analysis of sea-water obtained in the same voyage within and near the Polar circle. The water was taken at various depths, and was obtained from a stratum intermediate between the surface and the bottom by means of an apparatus devised for the purpose by Herr Tornöe.—Herr Brögger and Reusch's observations on the character and localities of Norwegian apatite, which originally appeared in 1875 in the *Zeitschrift d. deutschen geologischen Gesellschaft*, are here translated into Norwegian by the authors, who have made various additions to their paper, which is illustrated with numerous drawings.—In a paper on the Lepidoptera of Norway by W. M. Schöyen the author draws attention to the number of new forms added to this branch of the Norwegian fauna since the publication, in 1876, of Siebke's list of the insects of Norway. The number given at that time for the lepidoptera was 934; it is now raised to 1,019. The writer's own contribution to these is 38 hitherto undetected Norwegian species, the habitats and characters of which he describes.

Kort Fremstilling af de Norske Kursteders Udvikling, &c. Ved Axel Lund, M.D. (Kristiania, 1880.)—In this *brochure* we are reminded that Norway, from her geognostic character, is naturally deficient in thermic springs, and we are shown that till recently the *water-cure*—taking the words in a comprehensive sense to include the use of waters internally and externally—was unknown in the country. In fact even now the Norwegians stand exceptionally low in the scale of water-using nations, although an encouraging change in this respect has been manifested of late years by the establishment of mineral and sea-bathing places in various parts of the kingdom. These Dr. Lund describes at great length, giving the analysis of the waters yielded by the few springs that have been opened, and the amount of salt present in the sea-water at the various marine stations, with the medical reports of each and the mode of treatment adopted. In the last respect the only difference that we observe from the system generally followed at German baths is that at the sea-bathing establishment in the Sandefjord, a small species of Medusa is used to excite local irritation in cases of cerebro-spinal, rheumatic, or neuralgic affections, by passing the animals rapidly over the parts affected. To Dr. Thaulow, the founder of the baths at the Sandefjord and at Modum, the Norwegians owe a large debt of gratitude as the first of their countrymen who drew public attention to the paramount importance of baths as a hygienic agent. Sweden has long been in advance of Norway in its appreciative comprehension of the curative value of mineral and sea-waters; and from Dr. Lund the reader will learn all that there is to learn in regard to the water-establishments, springs, and baths of the sister kingdom, while he may also gather some information respecting similar institutions in the Danish dominions. In conclusion, we may observe that some of the newly-opened Norwegian water-cure establishments, as that of Modum, lying in the midst of pine-woods, and the sea-bathing places on the Sandefjord and Kristianiafjord, offer numerous attractions to foreigners in respect to salubrity of air, beauty of position, and moderate cost of living.

Knudshö, eller Fjeldfloraen. J. B. Barth. (Kristiania, 1880.)—Herr Barth, who is well known for his animated descriptions of the natural scenery of his country, and his lively narrative of

the adventures of a sportsman in Norway, supplies us in the present sketch with a comprehensive *résumé* of the flora of the Fjelds. The spot he has chosen for his point of observation is the double-topped hill Knudshö, near Kongsvold, well known to the botanists of other countries, as well as to those of Norway, for its exceptionally rich and varied Alpine flora. Here may be gathered the rare *Artemisia norvegica;* the gentians, *nivalis* and *glacialis;* some of the less common saxifrages, numerous species of *Carex* and *Salix;* and some Alpine forms, as *Kobresia caricina, Chamærops alpina,* which are not found elsewhere so low down; while here, too, the collector will find close at hand a number of sub-Alpine and south-Norwegian plants of rare occurrence in other parts of the country. Herr Barth, himself an enthusiastic botanist and a practised collector, never fails to give the local and ordinary Norwegian name of the plant he describes, in addition to its scientific designation; and thus supplies foreigners with very valuable and much-needed information, the want of which often proves to be a matter of great inconvenience in studying the flora of a foreign country.

Om Grantörken og Barkbillen. J. B. Barth.—In this little pamphlet the author, who is one of the first authorities in Norway on questions of forestry and arboriculture generally, explains his reasons for differing from the opinion commonly received, that the desiccation and ultimate death of the Norwegian spruce (*Abies excelsa*) are due to the attacks of *Tomicus typographus* (*Bostrychus typographus*), which is usually regarded as the most pernicious of all the insect-enemies of the Coniferæ. Herr Barth does not dispute the fact that this beetle is to be found often in large numbers on trees affected by abnormal drying up, whether still standing or cut down; but, in his opinion, although disease in the tree may be the cause, it is not the result of the presence of the Tomicus, which he believes to have absolutely no effect on the condition of the bark. According to this view the numerous agents employed in Germany and elsewhere to eradicate this beetle have no result but waste of labour and money; the only remedy against the drying up of the bark being a more scientific mode of clearing forests, in which the trees often perish either through overcrowding, or more frequently through reckless felling, by which cold blasts are allowed to fall directly on the interior. Herr Barth's views are in opposition to those of the majority of the working foresters of Germany and Scandinavia, but his extensive acquaintance with home and foreign forests, his great practical experience, and his reputation as a naturalist, entitle them to all possible respect, although it is not to be supposed that his plea for the innocuousness of the *Bostrychus typographus* will be admitted without much sifting of the evidence, seeing that this insect is generally believed by German foresters to have been the cause of the destruction of the forests of the Harz Mountains, when between 1780 and 1790 two million trees died of desiccation.

SPECTROSCOPIC INVESTIGATIONS[1]

As I have stated in my former communication,[2] all chemically related elements exhibit a homology of spectra, the various spectra of the elements of a group differing solely in the manner in which their groups of lines are shifted towards one end or other of the spectrum.

In a comparative investigation on the alkaline earths, I have arrived at conclusions which may explain these remarkable analogies in chemically-related elements.

I have now the honour of laying before the Academy a brief account of my investigations; on another occasion I shall report on this subject more fully.

If the spectra of the alkaline earths are produced by a jar-spark in a hydrogen-atmosphere,[3] spectra are obtained which show the homology of the spectral lines very beautifully. The spectrum of magnesium cannot be compared with the spectra obtained in this manner, because it does not contain the less refrangible lines. However, without the jar, or employing a smaller battery and a smaller induction-coil, it appears that in the spectra of calcium and strontium all lines in the red and yellow disappear, and the spectra which become visible are remarkably similar to those of magnesium.

[1] By G. Ciamician, in *Sitz. Ber. der k. Akad. der Wiss.*, Vienna, Vol. lxxiv. Heft i.

[2] "Ueber die Spectren der chemischen Elemente und ihrer Verbindungen" (vol. lxxvi. chapter ii., October, 1877). "Ueber den Einfluss der Dichte und der Temperatur auf die Spectren von Dämpfen und Gasen." (vol. lxxviii. chapter ii., October, 1878.)

[3] With four of six medium Bunsen's elements and a great Gaiffe's induction coil giving a spark of 10 centimetres.

Comparing the less refrangible part of the spectrum of the alkaline earths, which are only rendered visible by increased temperature with the less refrangible half of the entire oxygen spectrum, we find the remarkable fact that these two halves of the spectra show a decided resemblance or homology. From this we may conclude that *the spectrum of the groups of the earth-alkali metals is composed of the spectrum of magnesium and of that of the less refrangible parts of oxygen.*

In order to determine the real importance of these remarkable analogies—it being known that the atomic weights of baryum, strontium, and calcium are capable of being composed of the atomic weights of magnesium and oxygen[1]—I found it necessary to analyse the spectra of combinations, which are not saturated, but behave as compound radicals, and thus most resemble in chemical behaviour the simple radicals or elements.

Hitherto I have analysed cyanogen and carbonic oxide. The cyanogen spectrum comprises two portions, one of which is the homologue of the nitrogen spectrum, the other the homologue of the less refrangible part of the carbon spectrum.

Also in the carbonic oxide spectrum there are present the well-known groups of carbon appearing as bands, and displaced in the red field there are several lines homologous to those of oxygen. Therefore the same relation exists between the spectra of nitrogen and carbon, and between the spectra of cyanogen, carbon, and oxygen, and carbon oxide spectrum, which prevails between the spectra of magnesium and oxygen and the spectra of the earth-alkali metals.

One can go further and say that in general the homology of the spectral lines of chemically-related elements is in all probability based upon the circumstance that the elements of such natural groups conform to the laws of Mendelejeff on atom-weights, and consist of identical components.

[1] It is, namely, $24 + 16 = 40$ (calcium), $24 + 4 \times 16 = 88$ (strontium), and $24 + 17 \times 16 = 136$ (barium).

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Science Lectures at Cambridge this term include Prof. Liveing on the General Principles of Chemistry, and on Spectroscopic Analysis; and Prof. Dewar on Physical Chemistry. One of the demonstrators will give demonstrations in Volumetric Analysis; and Mr. Scott, assistant to Prof. Dewar, will give a course of demonstrations in Elementary Organic Chemistry. For permission to carry out special investigations in the University laboratories application should be made to one of the Professors.

Lord Rayleigh will lecture on Galvanic Electricity and Electro-Magnetism in the Cavendish Laboratory; Dr. Schuster will lecture weekly on Radiation; Mr. Glazebrook will give an elementary course of demonstrations in Electricity and Magnetism; and Mr. Shaw will give demonstrations on the Principles of Measurement and the Physical Properties of Bodies. Courses of demonstrations are announced for the Lent Term on Heat and Advanced Electricity and Magnetism; and for the Easter Term on Light, Elasticity, and Sound.

Mr. W. J. Lewis will lecture on the Silicates, in the Mineralogical Lecture-room.

Mr. F. M. Balfour will give elementary and advanced courses on the Morphology of Invertebrata, with practical work. Prof. Humphry will lecture on the Osseous System; Prof. Hughes on the Principles of Geology, with Field Lectures; Prof. Latham on Therapeutics; Prof. Newton on Invertebrata; Prof. Stuart on Mechanism.

It is to be hoped that something may be done this term to relieve science students in the matter of Greek, and to encourage French and German studies, for want of which there is so much hindrance to science, as well as literature. The Sedgwick Geological Museum, with money accumulating, must still wait, we suppose. Will the Museum be ready for 1900?

Mr. Sedley Taylor will lecture on the Acoustics of Music in the Cavendish Laboratory.

SCIENTIFIC SERIALS

Bulletins de la Société d'Anthropologie de Paris, tome iii. fasc. 2 (1880).—M. Robin, Inspecteur primaire du Département de Loir-et-Cher, has laid before the Society his scheme for obtaining important anthropological measurements by the help of teachers of schools. The proposed questions, with a full description of the various appliances by which such measurements could be

taken, have been submitted to the consideration of a special commission.—M. J. Parrot's paper on the development of the brain in infants, considers the subject chiefly in reference to the modifications of colour which the medullary substance undergoes. —The present number of these *Bulletins* gives M. P. Broca's remarks on his "goniomètre flexible," of the various parts of which drawings are appended.—M. Harmand makes the interesting communication that some Cambodian inscriptions, hitherto undeciphered, have been found by Prof. Kern, of Leyden, to be Sanskrit, written in Kawi and Kalinga characters.—M. Vinson suggested that fixed rules should be drawn up for the transcription of foreign words, and should form part of the official anthropological instructions provided for travellers and explorers in savage countries. His suggestion has been accepted. —In addition to the article already referred to on the flexible goniometer, these *Bulletins* contain several papers from the pen of the late M. Paul Broca, which will be read with the more interest as being among the last of his communications to the Society; these are his post-mortem reports of the appearances presented in the thorax of a young Zulu girl, with his remarks on a retrogressive anomaly in the aorta of this girl; a description of the appearances of the cranium of the assassin Prévost, more especially with reference to the assumed importance of the protuberance between the occipital and parietal, to which Gratiolet applies the term *calotte*, and which he regards as a simian character. M. Broca considered that in the interests of physical science it would be desirable that greater facilities should be afforded to scientific men for obtaining the heads of those who die in public prisons, asylums, &c. Finally we have the report of M. Broca's remarks on the case of an illiterate boy of eleven, possessed of extraordinary powers of calculation, and evincing surprising facility in extracting cube-roots. The consideration of this case gave additional interest to the discussion that had been raised at an earlier meeting, in regard to Galton's observations on the vision of serial numbers.—M. Moudière has drawn up a monograph on the women of Cochin-china, in which he has embodied the results of six years' laborious anthropological researches. The three races of Annamites, Cambodians, and Chinese, of which the Cochin-china population is composed, were severally studied.—M. Bertillon gives the results of his comparative analysis of the statistical tables of suicides for France and Sweden. The results show singular accord between the two countries, and the author considers himself justified in maintaining that they establish the two following laws:—1. That widowers commit suicide more frequently than married men. 2. That the existence and presence in the house of children diminishes the inclination to suicide both in men and women.—M. René de Semallé gives a comparative table of the mean length of the generations of mankind, based on the genealogy of the reigning and other princely families in Europe. From these it would seem that the period of thirty years, which in common parlance is accepted as that of a generation, very closely corresponds with the means obtained from these genealogical data.—M. Fourdrignier gives the result of his exploration of the double tumuli found at Thuizy, near Rheims, among a large number of other graves in which only one individual had been interred. Where these graves have escaped earlier spoliation, the human remains and the broken fragments of ornaments found in them would appear to show that the individuals buried together were of different sex. M. Fourdrignier has made an interesting discovery of the several parts of two conical casques. The fragments of these singular head-coverings were extracted from two of the double graves, and, according to their discoverer, they belong to a Gallic race of the pre-Roman period, and must in form have closely resembled the modern German "Pickelhaube."

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, October 4.—M. Wurtz in the chair. M. Perrier presented a *Compte rendu* of the determinations of longitudes, latitudes, and azimuths in Africa under his direction, at Géryville, Laghouat, Biskra, and Carthage in 1877 and 1878, with a description of instruments and methods. In the exchange of signals it was possible to calculate the mean retardation of transmission of a signal along an aërial conductor, from chronograph to chronograph, for distances comprised between 414 km. and 1,236 km. The mean velocity of propagation was found about 40,000 km. At this rate an electric signal would go round the earth in a second.—Military and geographical exploration of the region comprised between the Upper Senegal and the Niger, by M. Perrier. A Government expedition under Commandant Desbordes was to start on the 5th, Commandant Derrien having charge of the topographical department. They go to St. Louis, and make their way to Bafoulabé, at the confluence of the Bafing and the Bakhoy. Here they construct their first fort, and organise escorts and convoy, with a view to a general triangulation of the region between Bafoulabé on the Senegal, and Dina and Bamakou on the Niger. The railway contemplated would run from Medina, by Bafoulabé and Fangalla, to the Niger.—Order of appearance of the first vessels in the spike of *Lepturus subulatus*, by M. Trécul.—M. de Lesseps presented the "Bimensual bulletin of the Inter-oceanic Canal" for September.—On utilisation of the crystals of lead-chambers, by MM. Girard and Pabst. The crystals offer an abundant and economical source of nitrous acid, and the authors have been able to prepare on a large scale, the dinitric bodies, amidoazobenzol and nitroalizarine, by making the nitroso-sulphuric acid act on the corresponding amidised derivatives, or aniline and alizarine. But the crystals can only be employed in presence of a quantity of sulphuric or nitric acid (preferably the former) sufficient to prevent their decomposition by water.—Observations of Faye's comet made at the Observatory of Florence-Arcetri, by M. Tempel.—On some thermometric questions, by M. Crafts. It is very probable that the least change of volume of a thermometer is accompanied by a change of the coefficient of dilatation.—On the decomposition of salts by liquids, by M. Ditte. The laws of dissociation by heat which apply to decomposition of salts by pure water and by saline or acid solutions, apply also to decomposition by alcohols, and probably in general to decompositions of salts by the wet way, whatever the solvent.—On the physiological action of *Conium maculatum*, by M. Bochefontaine. Conine diminishes or abolishes the physiological properties of the nervous centres before acting like curare on the "nervo-muscular junctive substance" (Vulpian). In the dog and frog it at length abolishes the nervous excito-motricity if given in sufficient quantity, and it is fatal for batrachians as well as for mammalia. Hemlock then may act like curare, but it has additional physiological effects.—Floral dimorphism and staminal petalody observed in *Convolvulus arvensis*, L.; artificial production of this latter monstrosity, by M. Heckel. Petalody is the effect of direct fertilisation long continued. The autogamic process in plants as in animals (but in a longer period with the former) has the result of altering the organs of reproduction and leading to absolute infertility.

SCIENTIFIC WORTHIES

XVI.—RICHARD OWEN

AMONG time-honoured sayings there is none the truth of which comes more frequently home to the scientific worker than that which reminds him that a prophet is not without honour save in his own country and among his own kin. Its very truth would seem to make it short of impossible for us to take full cognisance of our own Scientific Worthies. The subject of this notice, still in hale strength, though now in full years and full of honours, is however in a very great measure an exception to the above proverb. Foreign men of science and foreign countries when they came to offer him their rewards found him already decorated. That a life abounding in labour, some of the results of which will remain as the heritage of mankind, was not undeserving of human recompense the following lines will abundantly show.

Richard Owen was born on July 20, 1804. He matriculated in the University of Edinburgh in 1824. Entering Bartholomew's Hospital the following year, he took the diploma of the Royal College of Surgeons in 1826. In 1825 he visited Paris, making the acquaintance of Baron Cuvier. On the completion of his medical studies Mr. Owen settled down to practise in Serle Street, Lincoln's Inn Fields. While at Bartholomew's Hospital he had been one of Dr. Abernethy's dissectors, and in 1828, on Dr. Abernethy's suggestion, he was employed at the College of Surgeons to make the catalogue of the Hunterian Collection in that institution. Mr. Clift was the Conservator of the College Museum at this time. The first catalogue of the invertebrate animals in spirits was published by the College in 1830, and in the following year appeared the memoir on the Pearly Nautilus (*Nautilus pompilius*), with some excellent drawings from the author's pencil.

The Zoological Society of London had been at this time in existence for some years, but up to 1830 it can scarcely be said to have had any scientific life. Some few of the then Fellows determined it should be otherwise, and after some little opposition the Council of the Society allowed the formation of a committee of science, who were further permitted to publish their own *Proceedings*. The first meeting of this committee was held on November 9, 1830, at which Owen read a paper on the anatomy of the Orang-Utan. It is not without interest to note that at the next meeting, held December 28, 1830, a letter was read from Vaughan Thompson, mentioning his discovery of a metamorphosis in Crustacea. From 1830 to the present date the contributions to the *Transactions* and the *Proceedings* of the Zoological Society of Mr. Owen have been both numerous and important, and for many years he was the unpaid prosector to the Society. He also at this period read several papers on pathological subjects before the Medical Society of St. Bartholomew's and the Medical and Chirurgical Society of London, one of the most remarkable of which was that describing the anatomical results of the ligature of the internal iliac artery, by Dr. Stevens, at Santa Cruz in 1812.

In 1834 a Chair of Comparative Anatomy was founded for Mr. Owen at St. Bartholomew's Hospital. In the year 1835 he published an account of a remarkable nematoid worm found living in the muscles of the human body (*Trichina spiralis*), and giving rise to a serious and often fatal disease called trichinosis, since, unfortunately, too well known. In 1834 he was elected a Fellow of the Royal Society, and in the same year was appointed the first Hunterian Professor at the Royal College of Surgeons. This chair he continued to fill until 1855. Mr. Owen, on succeeding his father-in-law, Mr. Clift, as Conservator of the Museum of the College of Surgeons, gradually retired from professional practice, and after a short time devoted himself exclusively to scientific pursuits. Of the thirty years during which he worked at Lincoln's Inn Fields, the last twenty were mainly spent in the study of comparative anatomy. A very rapid survey of the immense amount of work accomplished by him during this period will not be without interest. The catalogue of the physiological specimens in the Hunterian Collection consists of five quarto volumes, which were published by the Council of the College of Surgeons between 1833 and 1840. The catalogue of osteological specimens is contained in two quarto volumes published in 1853, and that of the Fossil Vertebrates and Cephalopods in three quarto volumes published in 1855.

The great work on the study of teeth was issued between 1840–1845. In preparing the drawings for this work Prof. Owen was threatened with an attack of retinitis, and was compelled to commit the further preparation of the illustrations to the excellent artists Lens Aldous and Erxleben.

The well-known Lectures on Comparative Anatomy and Physiology appeared between 1843 and 1846. After a one-and-twenty years' study of the homologies of the vertebrate skeleton, Prof. Owen's era-marking work on the "Archetype and Homologies of the Vertebrate Skeleton" was published. After having made a certain progress in comparative anatomy the evidences of a greater conformity to type, especially in the bones of the head of the vertebrate animals, than the immortal Cuvier had been willing to admit, began to enforce on Prof. Owen a re-consideration of Cuvier's conclusions to which for long he had yielded implicit assent. The results of these reconsiderations were successively communicated to the Royal College of Surgeons of England in the Course of Hunterian Lectures for 1844-45, and a sketch of his general views on the subject was laid before the British Association at Southampton in 1846. In 1849 were published the memoirs "On the Nature of Limbs," and "On Parthenogenesis." The term "parthenogenesis" was devised to replace a phrase somewhat cumbrous and incorrect, which was to this time applied to designate a phenomenon as interesting as strange.

Nor was all this sufficient for the superabundant energy of the Hunterian professor. The Palæontological Society succeeded in enlisting his services for a series of monographs of British fossil vertebrates, and during this period were published a memoir on the "Fossil Chelonian Reptiles of the Purbeck Limestones and Wealden Clays" (1853), the various supplements to which date from 1859 to 1879; "On the Fossil Reptiles of the London Clay" (1849, 1850), the portion of this memoir relating to the Chelonia was in part written by the late Prof. Bell; "On

the Fossil Reptiles of the Cretaceous Formations" (1851). A remarkable series of papers on the Fossil Birds of New Zealand and on some Fossil Mammals of Australia also about this date appeared in the *Transactions* of the Zoological Society, and a very elaborate memoir on the great American Megatherium in the *Philosophical Transactions*.

But even amid a scientific activity that rivalled that of his great friend Baron Cuvier, Prof. Owen had the energy to devote some time during these thirty years to the more direct benefit of his fellow men. He was appointed one of the Commissioners to inquire into the Health of Towns. This Commission sat during 1843 and 1846. A special report from his pen on the sanitary state of his native town, Lancaster, appeared in 1848, and the improved sewage of that town with a new water supply on the unintermittent system followed. He was appointed as one of the Commissioners on the Health of the Metropolis, 1846, 1848, and again on the Commission on the Meat Supply in 1849; as the result of this latter Commission it will be remembered that the famous market at Smithfield was suppressed, and the large Cattle Market was transferred to Islington.

Prof. Owen was also one of the Commissioners for the Great Exhibition of 1851; Chairman of the Jury on Raw Animal Products applied to Food and Manufactures, and Vice-Chairman of the Jury for "Les Substances Alimentaires" in the Great Exhibition of Paris in 1855. Labours so abundant were not without reward. In 1842 the Royal Society conferred on him the Royal Medal for his memoirs on the General Economy of the Monotremes and Marsupials. In 1846 the same society decreed to him the Copley Medal. In 1851 the King of Prussia sent to him the "Ordre pour le Mérite." In 1852 her Most Gracious Majesty assigned to him a residence in Richmond Park, and in 1855 the Emperor of the French bestowed on him the cross of the "Légion d'Honneur." The old Universities of Oxford, Cambridge, and Dublin conferred on him honorary degrees. The Royal College of Surgeons of Ireland made him an Honorary Fellow, and most of the learned societies of Europe and America numbered his name on their lists of Honorary or Corresponding Members.

John Hunter had left behind him a very abiding monument of his labours, some idea of which could now be obtained from the patient labours of the first Hunterian professor; but on terminating those labours Prof. Owen bethought him of yet another way in which he could make known the thoughts and works of the founder of philosophical surgery, which was, by the publication of Hunter's original papers. Between 1793 and 1800 Mr. Clift, F.R.S., had sole charge of the Hunterian collection and manuscripts, and during this period he had copied some proportion of the latter before they were removed from the Museum in Castle Street, Leicester Square, by the executor, Sir Everard Home. A short time previous to Mr. Clift's death he placed in Prof. Owen's hands the whole of his transcripts of the Hunterian manuscripts, with an autograph statement of the important fact. These were published in two volumes in 1861, and thus, after an entombment of nearly seventy years, were added "to the common intellectual property of mankind."

Prof. Owen's connection with the Royal College of Surgeons ceased in 1856, when he was appointed Superintendent of the Department of Natural History in the British Museum. He was the Lecturer on Palæontology at the School of Mines in Jermyn Street in 1856, and Fullerian Professor of Physiology in the Royal Institution of Great Britain in 1858.

When Prof. Owen entered on his duties at the British Museum his attention was at once called to the subject of the want of space wherein to stow the rapidly-increasing natural history collections. For several years already had Dr. Gray, to whom this Museum owes so much, urgently demanded additional space. In 1851, in 1854, and again in 1856, Dr. Gray implored for more room; scarcely half of the zoological collections was exhibited to the public, and their due display, he declared, would require more than twice the space devoted to them. Numerous suggestions were made to remedy this state of things, but without avail. Even such distinguished trustees as the late Sir Roderick Murchison and Sir Philip Grey Egerton, backed though they were by a large and most influential body of scientific memorialists, were powerless to obtain the least of the additions to the British Museum which they had recommended—additions which long ere this date would have been overcrowded in their turn. The Government declined to carry into effect any alterations in the present building in Great Russell Street, preferring the alternative of a severance of the Natural History Department from the British Museum. At this juncture it seemed to Prof. Owen to be unwise and indeed even wrong to hazard the safety and utility of these collections by persisting in the advocacy of a course which was futile, and having satisfied the then Chancellor of the Exchequer of the exigencies of the case, plans were obtained for a large new museum at South Kensington which would afford a superficial space for display of the collections, systematically arranged, of about five acres. Prof. Owen's report (1859) was approved of, but a vote on account of the new building was negatived by the House of Commons. This led to the publication of a pamphlet by Prof. Owen, "On the Extent and Aims of a National Museum of Natural History," in 1862, and as a final result the Government obtained the sanction of Parliament in 1872 to the erection at South Kensington of the magnificent range of buildings there just completed, in which in process of time the whole of the natural history treasures of the British Museum will be systematically arranged.

For long the propriety of moving this collection from Great Russell Street was hotly contested, and as in other great questions the weight of authority could at one time be quoted as against the move. Scientific men are however as a rule not often to be unduly swayed even by authority and they are generally philosophical enough to accept accomplished facts. In this immense building the State has provided ample accommodation, so far as space is concerned, for the present collections and for the probable increase of these for another generation; and not content with this, there is in addition room enough for future generations if they feel inclined, to nearly double the available space, and thereby even add to the beauty and completeness of the whole structure. In the obtaining of this splendid casket in which to display Nature's gems, Prof. Owen has seen accomplished one great object of

his life; and even those who think it might have been better for science] had their own peculiar plans been carried into effect, will hardly grudge Prof. Owen the palm of victory which he may have won from them.

The necessary and often arduous routine work required of Prof. Owen as head of so large a department did not in any great measure diminish the extraordinary activity with which he from time to time published original works. Nearly a quarter of a century has elapsed since he entered on his duty at the British Museum, and the record of his contributions to science during this period equals, if it does not surpass, that of the previous thirty years period. Among the more important of these we must notice: Memoir on the British Fossil Reptiles of the Mesozoic Formations—Pterodactyles, 1873-1877; on the British Fossil Reptiles of the Liassic Formations—Icthyosaurs and Plesiosaurs, 1865-1870; on the British Fossil Cetacea of the Red Crag, 1870; on the Fossil Reptiles of South Africa, 1876; on the Classification and Geographical Distribution of Mammals, 1859; a Manual of Palæontology, 1861. The long list of papers published in the *Proceedings* of learned societies, to be found in the Royal Society's invaluable Catalogue (numbering over 360), includes many, the scientific value of most of which would have given an abiding fame to their author. It would be impossible here to give even a tithe of their titles, but we quote a few to show that Prof. Owen left few of the classes of the animal kingdom unnoticed:—On the Andaman Islanders; on the Anthropoid Apes; on the Aye-Aye; on the Giraffe; on the Great Anteater; on the Great Auk; on the Dodo; on the *Apteryx australis*; on *Lepidosiren annectens*; on the *Argonauta argo*; on *Spirula australis*; on Clavagella; on *Limulus polyphemus*; on Entozoa; on *Euplectella cucumer* and *E. aspergillum*.

In 1857 he was elected president of the British Association for the Advancement of Science. In 1859 he was chosen one of the eight Foreign Associates of the Institute of France (in succession to Robert Brown). The King of Italy conferred on him the "Ordre de St. Maurice and St. Lazare" in 1862. The Emperor of Brazil in 1873 gave him the Imperial Order of the Rose, while in the same year the Queen conferred on him the Order of the Bath. In 1874 the Academy of Medicine, Paris, elected him as one of their Foreign Associates in succession to Baron Liebig.

At an age when most men have to cease from their labours, the subject of this necessarily brief notice works on. No better proof could there be of a spirit still young, than to witness the energy with which he has entered on the occupation of the new home for natural history at South Kensington; and who will not join in the hope that he may live to see its treasures arranged in an orderly sequence. In this sketch we have presented Prof. Owen as one eminently qualified to take high rank among our Scientific Worthies. What niche in the temple of fame he may permanently occupy is perhaps better left to a generation removed from our own to determine. To us it would seem as if a double portion of the spirit of Cuvier had without doubt fallen upon Owen, who has raised for himself a monument of work that is truly stupendous.

INSECT VARIETY

Insect Variety: its Propagation and Distribution. Treating of the Odours, Dances, Colours, and Music in all Grasshoppers, Cicadæ, and Moths; Beetles, Leaf-Insects, Bees, and Butterflies; Bugs, Flies, and Ephemeræ; and Exhibiting the Bearing of the Science of Entomology on Geology. By A. H. Swinton, Member of the Entomological Society of London. (London, Paris, and New York: Cassell, Petter, Galpin and Co. No date.)

WHEN Mr. Darwin published his "Descent of Man" in 1871 non-entomological readers were first made acquainted with a host of interesting facts connected with the various sounds produced by insects, the different colours in the two sexes, with their corresponding senses, emotions, and habits, so far as these bore upon the question of sexual selection. As in so many other cases Mr. Darwin's volume was the means of attracting the attention of working entomologists to this interesting field of observation, which has since been assiduously worked by Dr. Fritz Müller in Brazil, while in this country Mr. Swinton has for many years devoted himself to its study, both by personal observation and by collecting together the scattered observations spread over the entire literature of entomology, the result of his labours being embodied in the present volume.

No more interesting or instructive subject could be found for a great entomological work. The author appears to have spared no pains in the collection and elaboration of his materials. The book is full of original observations, and carefully drawn tabular statements of facts. It is copiously illustrated with roughly executed but characteristic figures; and the writer is evidently a man of wide information and some literary skill. But notwithstanding all these points in its favour, the book—except as a mere collection of facts—is a disappointing one. The arrangement is frequently defective; the style is often so vague and high-flown as to be actually unintelligible; while whenever an attempt is made to generalise the facts adduced, the writer appears to have no definite views of his own, or if he has is quite unable to convey them to the reader. A few examples will serve to illustrate the several merits and defects here pointed out.

In discussing the combats of male insects as tending towards a selection of powerful males from which to continue the race, our author well remarks that the law of the prior appearance of the males subjects them also to all atmospheric and other influences, "rendering them inured to manifold terrestrial strife previous to propagating their kind." This is a good observation; but what is probably a more important function of the early appearance of the males is, that the females should not have to wait long in order to be impregnated and thus be exposed to the dangers of destruction, owing to their usually slower flight and consequent defencelessness, before their great duty of oviposition has been safely performed.

The remarkable discovery by Dr. Fritz Müller of scent-producing organs in a variety of Brazilian butterflies, is here supplemented by an account of the numerous cases in which analogous organs, often of very varied kinds, have been found in moths, though in comparatively few instances has any odour been actually detected. It may

however very possibly exist even though quite imperceptible to us. Most of these organs occur in male insects only, whereas it is undoubtedly the case that the males discover the females at great distances, and we should therefore anticipate that the latter would have the scent-producing organs, the former the sense-organ capable of perceiving the odour. The investigation of this obscure subject is however still in its infancy.

Whether the antennæ are organs of touch only or of some other sense is yet undecided, but the question might probably be solved by an experimenter as ingenious and persevering as Sir John Lubbock. Mr. Swinton speaks of the male butterfly or moth "running over his partner with snuffing antennæ," but this is begging the question; and the following observation, though interesting, does not throw much additional light on the subject: "One dull afternoon on the 4th of September during the wet season of 1879 my eye was arrested by the pretty dappled wings of a female of the large Magpie Moth who was flying most purposely from leaf to leaf along a hedgerow. She successively visited a reddening bramble, a hawthorn, clematis, and guelder-rose, fruitlessly touching over their glandular surfaces with a quick alternate vibration of her black antennæ, in search, as I at first supposed, of honey-dew. The crisping foliage of a thorny sloe finally arrested her, and seemed to confer satisfaction on her tactile perception; for raising simultaneously her feelers and crawling on to the centre of a leaf, she hung on at its upper surface, elevated her wings, and by curling her abdomen round its apex, began to methodically attach her oval and shagreened eggs to the underside close to the midrib. She could distinguish Souchong from Pekoe."

The account of light-giving insects is very unsatisfactory, the old theory of the light serving as a guide and attraction to the male being the only one given. Yet in the list of luminous insects appended to the chapter we find no less than six cases recorded in which larvæ or pupæ are luminous, a fact which might surely have suggested a doubt as to the use of luminosity as a sexual attraction in the case of the glowworm and fireflies. There being so many luminous larvæ, taken in connection with the fact (not mentioned by Mr. Swinton) that glowworms are distasteful to birds, renders it almost certain that Mr. Belt's explanation is the true one, and that luminosity is, primarily, a warning of uneatableness, and is therefore a protective character, though it may of course, like colours, serve the purpose of aiding discovery and recognition by the opposite sex.

The whole subject of colour is treated with vagueness and indecision, and we find no systematic grouping of the facts nor any firm grasp of a principle by which to interpret them. The following characteristic passage will illustrate these deficiencies:—"The attractive quality of insects' colours from the foregoing appears nearly that presented to the human eye, and, utilised in sedentary or aërial display, originates phenomena of love and rivalry, battles, dances, and gregariousness in evident parallelism with those evoked by music. But this attractive virtue, which must be considered as stimulative, does not reside especially in either sex, as some at first sight might be inclined to assert; for we find conspicuous colorisation, though for the most part distinguishing the males, sometimes by a species of inversion appearing in the females; the sexes also are often very similar in hue. And the reason of this is that the females very generally attract the eager males by sedentary display, of which the moth kind affords notable instance. Here we may remark the paler hues of many heavy Bombycina females who exhibit on herbage, and the grey, white, or satiny shades of moths that repose on tree-trunks, sexually marked in the Gipsy Moth, who is rendered in measure terrestrial by her limp wings. Others more or less apterous, like the Vapourers and Psychidæ, owe what little chromatic attraction they possess to their conspicuous cocoons."

There is hardly a sentence in this paragraph that is not open to discussion or that is not more or less inconsistent with some other sentence; while the whole is completely neutralised by the succeeding paragraph which goes on to describe how the male moths are evidently attracted to their partners by odour, and not by sight at all!

The chapter on the sounds produced by insects is crowded with interesting observations and is certainly of great value, yet here too we meet with the same looseness of remark and incapacity to see the importance of certain facts. Thus, we find the strange, and in the present state of our knowledge altogether unproved statement, that—"In Lepidoptera music is in direct relation to colour, sound to beauty;" while the fact that the *pupal* form of some Hemiptera stridulate, taken in connection with many proofs that the sound is produced under the influence of *fear*, shows that in some cases at all events these sounds are protective rather than sexual; and this opens up a field of inquiry analogous to that of the diverse uses of colour, but which our author passes over almost without remark.

Among the smaller errors and misconceptions in the volume we must note the statement that Darwin adopts the pressure theory of the formation of the bee's cell (p. 58); the total misconception of the theory of mimicry (at p. 81); and the extraordinary account of tropical colour, certainly evolved out of the writer's own consciousness. He says:—"In the Brazils, for example, all colours, whether of birds, insects, or flowers, are brilliant in the extreme. Blue, violet, orange, scarlet, and yellow are found in the richest profusion, and no pale faint tints are to be seen"! In the matters of Palæontology and glacial epochs the author's authority is Mr. Page; but the subject is evidently beyond him, for he confounds the precession of the equinoxes with the obliquity of the ecliptic, and winds up with "glacial phenomena at the poles now exposed to the continuous action of cold interstellar space, with a collapsing in the earth's superficies, giving birth to the ensuing wrinkling marked by earthquakes, volcanic action, and land depression, or *vice versâ*."

We also notice many errata, indicating some carelessness in passing the volume through the press. Dr. Falconer is called "Faulkener" (p. 15); anthropods is written for arthropods (p. 86); Leucanidæ for Lucanidæ (p. 99); Grophilus for Geophilus (p. 101); and Libuella for Libellula (p. 311); but the chief fault of the volume is a constant effort at fine writing, which, combined with an inveterate obscurity of style, often renders it utterly impossible to comprehend what is meant. Scores of passages might be quoted illustrative of this peculiarity, but the following will serve our purpose:—

"Dealing with geological chronology, the phenomena

of generic and specific variation should also be applicable in explanation of certain plants and insects of constant character, being discovered confined to various geological soils within the radius of their distribution, or to favourite haunts postulating more than simple dispersion from a centre. And the pale blue of butterflies frequenting limestone and chalky downs need evoke no interference in the law of albinism if the honeyed cowslips and downy oxlips over whose leaves they flutter are, as reputed by Linnæus and Prof. Henslow, specifically identical with the shadow-seeking primrose, and may be raised from the same root. So likewise the local feature of melanism may be regarded as not only manufacturing annual varieties, but as pervading the black, brown, and drab tribes of the Alpine, Arctic, and woodland faunas, and may give a reason for their dark trait of beauty."

We give up the above in despair of extracting its meaning, if it has any; and cannot but regret that a book so full of valuable facts and good observations should be spoilt by constant efforts at philosophical disquisition, for which the tone of mind of the writer quits unfits him.

WEAPONS AND POLITICS OF THE ANCIENT HINDUS

On the Weapons, Army Organisation and Political Maxims of the Ancient Hindus, with Special Reference to Gunpowder and Firearms. By Gustav Oppert. (Madras: Higginbotham and Co.; London: Trübner and Co., 1880.)

"WHILE pursuing my researches into ancient Indian history," says Dr. Oppert, "I lighted upon two ancient Sanskrit manuscripts containing interesting information on many new and important topics. One of them, the Nītiprakā'sikā, has been, I believe, up to now utterly unknown, and the other, the 'Sukranīti, though known to exist, has never been described and published." The manuscripts relate to the weapons and military organisation of ancient India, a subject upon which fresh light was much needed. If for no other reason, therefore, they deserved to be edited and translated. But one of them at least also contains statements sufficiently novel and startling to claim for them a special hearing. If we may believe it, not only was gunpowder invented in India long before the days of Berthold Schwarz or Roger Bacon, but firearms, including both cannon and guns, were known and used. The guns were even provided with sights and flints. "The tube" of one of them, it is said in the 'Sukranīti, "is five spans long, its breech has a perpendicular and horizontal hole, at the breech and muzzle is always fixed a sesame-bead for aligning the sights. The breech has at the vent a mechanism which, carrying stone and powder, makes fire by striking. Its breech is well-wooded at the side, in the middle is a hole, an *angula* broad; after the gunpowder is placed inside, it is firmly pressed down with a ramrod. This is the small gun which ought to be carried by foot-soldiers. . . . A big gun is called (that gun) which obtains the direction of the aim by moving the breech with a wedge; its end is without wood; but it is to be drawn on cars. . . . The ball is made of iron, and has either small balls in its inside or is empty." Dr. Oppert believes that the Nītiprakā'sikā also contains references to firearms, though the passages he quotes seem rather to refer to supernatural weapons or to fire-machines like those used by the Greeks of the Eastern Empire. A work, too, which mentions the Hūnās ("Huns," or Europeans) cannot be of the antiquity to which he would assign it.

Dr. Oppert seeks further support for the early use of firearms in India in a passage from a portion of the Atharvaṇarahasya, which he renders: "the fire prepared by the combination of charcoal, sulphur, and other material depends upon the skill of its maker." It is plain, however, that there is no necessary allusion to gunpowder in these words, much less to firearms. A quotation from Manu, in which fighting with "darts kindled by fire" is forbidden, is equally inconclusive.

The statements of the 'Sukranīti must therefore stand by themselves. In spite of Dr. Oppert's arguments to the contrary, it is difficult to admit that in its present form it can be earlier than the thirteenth century. The prohibition to use firearms in "fair" fighting would not account for the total absence of any reference to them in the law-books and epics and other literature of ancient India, and had they existed in the seventh century, or had the Hindus been acquainted with gunpowder at that time, we can hardly suppose that the fact would have remained unknown to the inquisitive Buddhist pilgrims from China who have left us accounts of their travels in the Peninsula. The Greek fire had nothing to do with gunpowder, and we do not therefore see why Dr. Oppert introduces it into the discussion, while there is no proof that the *manjanik* or machine employed by Mohammed Kasim at the siege of Daibal (A.D. 711) was propelled by gunpowder. The flaming thunderbolts launched by the Indians against the army of Alexander, according to the pseudo-Aristotle, belong to the region of myth, like the storms of lightning with which Herakles and Dionysos were received when they invaded India, as related in the romance of Philostratos. Gunpowder may indeed have been invented in India, as Beckmann believed, but if so we want further evidence before we can admit that the invention was earlier than the twelfth or thirteenth century of our era.

Among other interesting points noticed by Dr. Oppert are the (ideal) rate of pay received by the officers and privates of a Hindu army at the time the Nītiprakā'sikā was composed, and the identification of Manipura, the capital of the Pāndya kings, with the modern Madura. He also points out that the boomerang is well known in many parts of India, especially in the south, and that he himself possesses four wooden ones, besides an iron one, which he obtained from Pudukoṭa. Two ivory ones, from the armoury of the late Rajah of Tanjore, are preserved in the Madras Museum. The Tamil name of the boomerang is *valai taḍai*, or "bent stick," and it is employed in hunting deer. It is one of the weapons described in the Nītiprakā'sikā under the name of *āstara* or "scatterer."

OUR BOOK SHELF

Lehrbuch der organischen Qualitativen Analyse. Von Dr. Chr. Th. Barfoed. (Kopenhagen: Andr. Frest und Sohn, 1880.)

THERE is no branch of qualitative chemical analysis in such an unsatisfactory condition as that which deals with organic acids and bases. The plans on which examina-

tions in practical chemistry are generally conducted are probably largely to blame for this unsatisfactoriness. Examiners require a knowledge of the separation and identification of organic acids, in addition to the ordinary power of analysing a mixture of inorganic substances; one day is probably considered sufficient time to devote to the examination. Candidates must make themselves acquainted with a few of the tests for organic acids; they find these in all the text-books of analysis; they repeat the tests, and manage to stumble through the examination. The truth is that the detection of organic compounds, even when but a few of these are present, is far too complex and difficult a process for repetition in the hurry and bustle of the examination-room. Were all organic compounds omitted from the examinations in practical chemistry at the leading schools of medicine and science, we have no doubt that in a few years the processes for detecting these compounds would be largely improved.

We should strongly advise all students who wish to acquire just that amount of knowledge of organic analysis which may perhaps enable them to pass an examination *not* to procure Dr. Barfoed's book, and as strongly advise all who wish to study this branch of analysis in a thorough and accurate manner to procure the book, or rather that part of it which is now published, at once. The publishers of this work announce that the book will be completed in three parts; if the second and third are as fully and accurately compiled as the first, the book will undoubtedly be the standard work of reference in the department of organic qualitative analysis.

The first part, extending to 192 pp., contains the more important acids, cellulose and starch. A full account is given of the properties and reactions of each compound so far as these are of value in qualitative analysis; methods of separation, varying according to the conditions of complexity of mixtures, are also given. The book is not arranged after the ordinary plan of the text-books of inorganic analysis; it is rather a full and accurate store of information regarding the reactions of organic compounds from which the student may select materials according to the special conditions of the problem presented to him.

The work contains no preface or indication of the ground to be covered by the completed book; judging however from the scope of the first part, the author would seem to aim at presenting a complete account of the reactions of all those commonly occurring organic compounds which can, with a fair degree of certainty, be identified by qualitative analysis.

A Synopsis of Elementary Results in Pure and Applied Mathematics; containing Propositions, Formulæ, and Methods of Analysis, with Abridged Demonstrations. By G. S. Carr, B.A. Vol. i. Pp. xxiv. 256. (London: C. Hodgson and Son, 1880.)

WE shall not enter upon any discussion as to the utility or inutility of such a work as the present, but simply confine ourselves to an account of its contents. It is not a work of yesterday, for the author tells us that it is compiled from notes "made at various periods of the last fourteen years, and chiefly during the engagements of teaching." Mr. Carr's chief aim has been so to arrange his matter that the student may be assisted in the revision of bookwork, hence he generally confines himself to indicating the main features of a proof or to a mere reference to the theorems by which the proposition is proved. To aid in this end he has employed a system of cross-references, each article being numbered progressively in "large clarendon figures." A feature to which the author rightly draws attention is the compression he has attained without sacrificing clearness in his "last section, in which in the space of twenty-four pages are contained more than the number of propositions usually given in treatises on geometrical conics," together with clear large figures, and in most cases the demonstrations. This, we think, he has done well. This first part he divides into seven sections. The first contains a large collection of mathematical tables (Factor Tables, Values of the Gamma-function, and many other useful and frequently-recurring constants), in addition to an introduction on the C.G.S. system of units. Algebra is treated of in articles 1-380; Theory of Equations, 400-593; Plane Trigonometry, 600-859; Spherical Trigonometry, 870-910; Elementary Geometry, 920-1099; Geometrical Conics, 1151-1267. It will be seen from the above numbering that there are breaks; these have been "purposely made in order to leave room for the insertion of additional matter, if it should be required in a future edition, without disturbing the original numbers and references." It is obvious to object here that the new matter may not fit into the plan adopted in this edition.

Owing to causes which Mr. Carr names, the earlier part of his work contains a rather long list of errata; most of these are pointed out, but not all. The utility of such a work greatly depends upon its reliability for purposes of reference, and our confidence is somewhat shaken when, on opening the work casually, as we did at p. 6, we find "$\log_{10}\pi = 1{\cdot}4971499$, $\log_e\pi = 0{\cdot}6679358$," and this not corrected elsewhere.

Having carefully read the whole of the text, we can say that Mr. Carr has embodied in his book all the most useful propositions in the above subjects, and besides has given many others which do not so frequently turn up in the course of study. The work is printed in a good bold type on good paper, and the figures are admirably drawn.

Estudio Micrográfico ne Algunos Basaltos de Cuidad-Real. Par Don Francisco Quiroga. (Madrid, 1880.)

IN this memoir the author gives an account of the microscopic characters exhibited by the basalts of the volcanic district of the Campos de Calatrava, which basalts he shows to have been erupted in Tertiary times. These rocks appear to belong to Dr. Boricky's classes of the Nepheline-basalts and the Nephelinitoid-basalts, in the former of which the nepheline is fully crystallised, while in the latter it exists as a glassy base in which crystals are beginning to make their appearance. The primary minerals of these rocks are nepheline, augite, magnetite, and olivine, which may be regarded as their essential constituents, and apatite and hornblende, which the author regards as accessory or accidental constituents. The secondary or derivative minerals are kaholite, hinsuite, and hematite, magnetite, serpentine, and aragonite. The memoir is illustrated by a coloured plate of rock-sections.

Il Binomio di Newton. Per Ignazio Cameletti. 7 pp. (Genova, 1880.)

BY performing the successive multiplications and writing, after the following fashion—

$$\begin{array}{rll} (1+x)^m = & 1 + x & (m = 1 \\ & \overline{x + x^2} & m = 2 \\ & \overline{x + x^2} & \\ & x^2 + x^3 & m = 3, \end{array}$$

and so on, the author succeeds in an ingenious manner, by summation of simple series, in getting the successive coefficients of the general expansion, and so proves his theorem, which is—

$$(a+b)^m = a^m + \Sigma_{p=1}^{p=m} \frac{m(m-1)\ldots(m-p+1)}{1 \cdot 2 \cdot \ldots \cdot p} a^{m-p} b^p$$

or the Binomial Theorem of Newton without having recourse to the doctrine of combinations.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.]

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Photograph of the Nebula in Orion

DURING the night of September 30 I succeeded in photographing the bright part of the nebula in Orion in the vicinity of the trapezium. The photographs show the mottled appearance of this region distinctly. I intend shortly to publish a detailed description of the negatives. They were taken by the aid of a triple objective of eleven inches aperture made by Alvan Clark and Sons, and corrected especially for the photographic rays. The equatorial stand and driving-clock I constructed myself. The exposure was fifty minutes. HENRY DRAPER

New York, October 2

An Annelidan Entozoon

WHILE examining the intestinal tract of *Megaderma frons* from the Gold Coast, I found coiled up spirally and adhering to the wall of the lower part of the ileum a small parasite about half an inch in length. On placing this under the microscope I was much surprised to find that it belonged to a class of worms (*Annelida*), none of the species of which have hitherto been known as Entozoa, and further that I was unable to refer it to any of the orders of that class.

On showing it to Dr. J. D. Macdonald, F.R.S., he quite agreed with my opinion that it represents a new order of Annelids, and is moreover disposed to consider it as a connecting-link, hitherto wanting, between the *Chætopoda* and the true leeches.

The specimen in question is about half an inch in length without distinct segmentation, except what is indicated by the perfectly regular disposition of the cephalo-somatic appendages—seventy-three pairs, extending from the anterior almost to the posterior extremity of the body—whereof those occupying the anterior attenuated fourth of the body are fin-like lamellæ, apparently branchial, with a single unarmed mouth not provided with a proboscis, with the intestine spirally coiled round the ovarian tube and terminating inferiorly at the posterior extremity of the body.

Megaderma frons, the host of this remarkable annelid, is a species of bat of very peculiar aspect, which is apparently widely distributed throughout and restricted to the tropical parts of the Ethiopian region. It belongs to a genus whereof one of the species at least is known to suck the blood of smaller bats, which it captures on the wing (see my "Monograph of the Asiatic Chiroptera," p. 77), and as all the species closely resemble one another in structure, it is exceedingly probable that they have all much the same habits.

Although I found remains of insects in the intestinal canal of the specimen from which the above-noticed parasite was taken, yet there was also mixed up with them a large quantity of hair, not from its own body, but evidently (judging from its microscopic structure) that of some other bat on which very likely it had been feeding. It is also worthy of notice that the intestine of the parasite is filled with a reddish matter like the remains of blood.

I have handed over this very interesting specimen to Dr. Macdonald, who will shortly publish a full description of it with figures. G. E. DOBSON

Royal Victoria Hospital, Netley, October 7

Sounds made by Ants

FROM the very interesting remarks lately made by Sir John Lubbock regarding the habits and capabilities of ants, I gather that he seems to consider them as a silent group. The modes of producing sounds among insects are as various as beautiful, whether by internal or external agency. As a rule the larger animals produce sound by internal means, *i.e.* voice, and insects by some external means.

Among ants I know of two varieties or distinct kinds, a black and brown, that make a concerted noise loud enough to be heard by a human being at twenty or thirty feet distance, and which sound is produced by each ant scraping the horny apex of the abdomen three times in rapid succession on the dry crisp leaves of which the nest is usually composed.

The noise made by a single ant is sufficiently loud to be heard on a very dry leaf if attention is directed to it, and no doubt by this means of a vibrating medium they can without special auditory organs communicate with each other. I had the honour of first discovering that the great *Mygale stridulans* made a noise; the apparatus by which it was produced was discovered and fully described by Mr. J. Wood Mason of the Indian Museum, and I should be glad if I am the means of making a similar discovery regarding ants. White ants (so-called) make a noise which is audible—if put on crisp paper—by suddenly shaking the whole body, and seem to warn each other by this means.

Sapakati, Sibsagor, Asam, August 20 S. E. PEAL

Faraday Exhibiting Ghosts

MR. J. INNES ROGERS' communication on a "Spectre of the Brocken at home" reminds me of a passage in Dr. Bence Jones's "Memoir of Faraday," vol. i. p. 422.

Faraday's niece, Miss Reid, thus writes: "One evening a thick white mist rose and completely hid everything before us. About ten o'clock my uncle called me into his room to see a spectre. He placed the candle behind us as we stood at the window, and there, opposite to us, appeared two gigantic shadowy beings, who imitated every movement that we made."

Ardchapel, N.B., October 16 W. S.

Ice under Pressure

IN reply to C. A. M.'s letter of last week I would make the following remarks:—Ice is not an exceptional substance, for mercuric chloride has also given experimentally the same results, and though I have not yet had the opportunity of submitting other substances to the same conditions, yet I conclude from other experiments that all the bodies which I have so far investigated, and which are of the most varied description, will also exhibit the same phenomenon. As I have not yet published my detailed results, I do not wish at present to enter more fully into the subject, but I may say that the influence of pressure in the present case is not of the same kind as that referred to by C. A. M. as occurring in the text-book named, for the following amongst other reasons. From Prof. Thompson's prediction and Sir Wm. Thomson's experiments it resulted that the melting-point of ice is lowered by pressure, and lowered in proportion to the pressure, whereas in my experiments, at any rate so far as I have at present seen, we do not *vary* the melting-point by diminishing the pressure, but we prevent the substance from melting at all. If the pressure be increased even but slightly above the critical pressure, the ice melts at its ordinary melting-point. The influence of pressure in this case is not one of degree varying with the amount by which the pressure is reduced. The two cases are, I consider, entirely different, and are not contradictions. Similar remarks would probably apply to paraffin and spermaceti, though these are bodies which have not come within the range of my experiments.

Firth College, Sheffield, October 6 THOS. CARNELLEY

A Peat Bed in the Drift at Oldham

IN NATURE, vol. xxii. p. 460, there is a letter by Mr. Jas. Nield, giving an interesting description of unique, or nearly unique, appearances in the boulder clay near Oldham. It appears that this glacial deposit has one or more beds of peat, or fragments of peat, intercalated along with it at various depths, leading to the inference that the clay had been stirred up and the fragments of peat had in some manner been mixed with it. That peat bogs, or surface black peaty mould, had existed at no great distance is a conclusion forced upon us, and that the action of ice and snow, probably during a submergence, had mashed up the clay and distributed the peat amongst it. The boulder clay, and the scratched mountain sides, and the travelled fragments of rock, do not extend over the whole of England. It used to be said by geologists that the effects of a severe Arctic climate could not be detected south of a line drawn across the country from London to Bristol; by which it was inferred that all the land north of that line had been under water, subject to the influences of snow

and floating icebergs, and all the country south of it above water and clear of those influences. Since then the large granite boulder on the shore of Barnstaple Bay, estimated to weigh ten tons, has been brought more prominently under our notice by Mr. W. Pengelly (*Trans.* Dev. Assoc. vi. 211), and several others by Mr. T. M. Hall (*Id.* xi. 429), discovered by excavation. All these are travelled blocks, and probably ice-borne. Many attempts have been made by ardent and intelligent students of late years to detect proofs of glacial action further south, and even to the shores of the British Channel, but hitherto with doubtful success. There lies on the greensand of Haldon, near Exeter, and on the Blackdown Hills, stretching away towards the south-east corner of the county of Devon, a stratum of tough yellow clay full of white flints, mostly angular. About Haldon and eastward over Pitminster and Churchstanton, many white quartz rounded pebbles, foreign to the accompanying beds, are met with. Farther south, between Honiton and the sea, this stratum of flints and clay in some places is seen to be from forty to fifty feet thick, and the best section of it is in the gravel pits near the cliff on Peak Hill, on the west of Sidmouth. By some persons this deposit has been regarded as the thinned-out edge of the plastic clay formation, containing the remaining flints of the washed-out chalk, still found more perfect at Beer Head, a few miles east. Whether it was this, or whether it was a boulder clay, so called, it is well to remark that, though thickest on the flat tops of the hills, it seems to lap down over their sides, as if it had been deposited after the valleys and the elevations had come to their present conformation; and at two places at least to be visible in the valley of Sidmouth—one under the great blocks of breccia in the orchard near the brook on the Boomer or Boughmoor Estate, and the other on a subordinate hill in a grass field, at about 200 yards from Jenny Pine's Corner, walking down the new road towards Cotmaton, and on the right-hand side. Most of this latter patch of clay and flints was dug away two or three years ago to assist in forming the new road.

When engaged in making certain trenches and excavations on the top of Salcombe Hill in 1879 for archæological purposes (see *Proceedings* Soc. Antiq. Lon. viii. 209) it appeared that the yellow clay, to the depth of two or three feet, was not so much encumbered with flints as deeper down. But whilst thus engaged, what struck me as rather strange was that numerous fragments of black peat were more or less generally but irregularly distributed through the upper two feet; and bearing in mind Mr. Nield's letter, I have in my foregoing remarks been trying to lead up to this point. The cases may not be similar, but they are worth comparing. The land on the top of the hill at this place still bears its wild growth of heath and furze, and has never been subjected to the plough or to cultivation of any sort; so that the clay has not been disturbed by the hand of man. It is too soon to say that this capping of clay and flints is of glacial origin; but some of the indications that have suggested the idea may be observed in the section in the gravel pits on Peak Hill, especially when fresh dug down. They are: (1) that no horizontal bedding is visible, as there would be if the deposit had been made in a large body of undisturbed water; (2) That, on the contrary, waving and distorted lines are sometimes very plain, one instance of which I carefully sketched and coloured in January, 1875; (3) and that the long axes of the embedded flints do not as a rule lie horizontally, as they would necessarily do if they had settled at the bottom of a sea or pond, just as an egg will lie on its side, and not on its point, but they are distributed through the soft mass at all angles, as raisins lie in a pudding that has been kneaded up together.

My object in this communication has been merely to compare the case of the peat mixed with the clay on Salcombe Hill with the somewhat similar case occurring near Oldham.

P. O. HUTCHINSON

Old Chancel, Sidmouth, Devon, October 4

IN NATURE, vol. xxii. p. 511, I find a letter from Mr. G. H. Morton, in which he expresses an opinion contrary to that expressed by me (vol. xxii. p. 460), as to the age of the "peat bed in the drift of Oldham." The section therein alluded to is fairly described by him, but I am surprised that he should for an instant entertain the belief that the clay "has simply slipped down off the sand on to the surface of the peat at a lower level." Had the clay slipped down we ought to have been able to see some indications of the conjectured displacement. Let me say, however, that during my repeated visits to the place and my examinations of the section I have utterly failed to perceive any trace of such indications, and, moreover, I do not remember that one person out of some scores who have in presence of the section pointed out to me the slightest appearance of disturbance. There is not a broken or crumpled line in the whole section.

The peat bed, and indeed the whole of the section, is now, I am sorry to say, covered up; but in and about Oldham we have a large area covered by what I believe to be typical beds of the "Middle" and the bottom of the Upper Drift—alternations of gravel, pebbles, fine and coarse sand, the latter showing lines of "current bedding," and occasionally clay with boulders—in which many similar sections, but wanting in the peat, of course, may be seen, and in which the position and surroundings of the beds quite forbid the possibility of "slipping." The idea of the upper clay "having been excavated and thrown down" is, I think, too improbable to be seriously entertained, seeing that the surface-soil and subsoil on the top of it are of the usual thickness common to the neighbourhood.

The "blue silt" alluded to by Mr. Morton as giving strength to his suspicions, I can assure him is one of the supports upon which I rest my opinion that there has been no disturbance. Do I understand him to mean that the silt is the result of the washings of some passing stream? If so, let me recommend him to visit the railway cutting across the large peat bog a few miles from here, and known as the "Ashton Moss," where he will find, at the bottom of a bed of recent peat, of from two to three yards in thickness, a thicker, but in every other respect a similar band of blue silt, upon which the peat rests throughout the length of the whole cutting. This silt seems to have its equivalent in the "floor clay" which accompanies our seams of coal. I believe that the removal of so much of the peat bed and drift deposits from the face of the excavation as has already taken place has served all the purposes of the "few hours digging at a right angle to the present exposure," suggested by Mr. Morton.

Perhaps a more complete acquaintance with the Oldham drift beds would bring Mr. Morton nearer to my way of thinking. I shall be glad to see him here again, and to assist him in making a wider, and more thorough examination of them.

29, Radclyffe Street, Oldham, October 7 JAMES NIELD

Temperature of the Breath

MR. MCNALLY has, it appears to me, missed the point of my observations on this subject.

His own experiments, though they show a temperature obtained by breathing on a thermometer through silk, wool, and linen, considerably above the accepted temperature of the breath, are by no means an exact repetition of mine. He only breathed through four folds of the material for three minutes. I breathed through a much greater amount of material and for a longer time, viz., twenty to thirty folds tightly encircling the thermometer bulb for five minutes.

The temperatures I obtained were very much higher than those observed by your correspondent. Thus on a warm summer day the temperature obtained on rising in the morning before dressing and before eating was 106°. In the afternoon, after playing a game of golf, when returning home by rail with all the windows open, the temperature observed was 107°. The same day, after dinner (without alcoholic stimulants), the thermometer rose to 108° when breathed on in the way described. The temperature of the air that day averaged 70°. Since then I have not obtained a higher temperature than 107°·5.

These temperatures were obtained by breathing through a silk pocket-handkerchief tightly rolled round the thermometer, but I have obtained temperatures nearly as high when the thermometer was wrapped up in cotton or woollen stuff.

Mr. McNally asserts that the explanation suggested by my friend that the high temperature thus obtained was owing to the heat evolved by the condensation of the aqueous vapour contained in the breath is "undoubtedly correct," but he gives no answer to the obvious objection to this explanation, viz., that if the real temperature of the breath be, as stated in physiological works, 95° to 97°, condensation of the aqueous vapour in it would only take place as long as the material through which it is propelled was of lower temperature than the breath. When the material attained a higher temperature than 97° the aqueous vapour, in place of being condensed, and thus evolving heat, would be still further evaporated, and hence be a cause of reduction of temperature.

The fact that woollen clothing prevents chill after exercise has

no bearing on the subject of the high temperatures obtained by breathing through woven material on the bulb of a thermometer, for no one has yet observed that woollen clothing will develop a heat greater than that of the body it covers, viz., 98°·5.

The hygroscopic properties of different materials afford no explanation of the phenomena, for the power of materials to imbibe moisture will not account for an increase of their temperature by breathing through them.

My speculations may be right or wrong; Mr. McNally has not shown them to be either. My facts are not the less true from being incompatible with "ascertained physiological truths," for ascertained physiological truths are only true so long as they are not controverted by other ascertained physiological truths.

My experiments show that the temperature obtained by breathing on the thermometer in the manner described is higher when less caloric is abstracted from the surface of the body, lower when the surface of the body is losing more caloric. Thus on a warm summer day my breath raised the thermometer to 108°, whereas to-day (a cold wet day) it only raised the thermometer up to 103°. Does not this seem to show that respiration is a means of getting rid of the superfluous caloric generated in the body, and that when this excess of caloric cannot be got rid of by the skin it passes off by the breath? R. E. DUDGEON

October 9

Selenium

As the only chance of being able to transmit images of reflection through a conducting wire, in the way sound is repeated to a distance by telephone, appears to lie in the preparation of a fairly transparent sheet of metallic selenium; it may tend to advance the subject if the difficulties experienced in dealing with this substance are mentioned.

Selenium in its vitreous condition melts about 220° Fahrenheit, and can be drawn out between mica plates over a lamp, to a thin transparent red film. But heated for some time it turns black and granular, apparently absorbing hydrogen, then melts only at 423° F., and is brittle and intractable. Unfortunately it is only in this crystalline state that its power of conducting electricity appears, and varies with the light under which the selenium is placed.

Prepared in the mass, electrically conducting selenium is as compact as the hardest gas carbon, with the shiny appearance and surface of graphite. How to reduce such a substance to any degree of transparency is perplexing. By reducing it to fine powder, and subjecting the black selenium to severe hydraulic pressure between hot polished steel plates, the desired effect might be produced. Selenium also dissolves freely in chloride of selenium, Se_2Cl_2, and precipitates slowly in a botyroidal mass of black selenium. It also separates in the crystalline form from concentrated solutions of selenide of potassium or sodium.

There is some uncertainty as to whether a transparent sheet could be more easily obtained by the method of precipitation, than by mere mechanical treatment. But the investigation is one that requires to be carried out with the aid of a fully equipped laboratory, and is beyond the power of an ordinary experimentalist.

To devise a successful mode of making a black substance like graphite at all translucent, requires a distinct understanding of the reason why bodies are opaque. Something more than an explanation in general terms is needed before camera pictures can be resolved into electric currents, and again integrated upon a receiving plate.

Perhaps some of the readers of NATURE may be able to suggest a method of dealing with selenium that will produce thin transparent sheets capable of conducting electricity.

London, October 16 A. T. F.

Dynastes Hercules

THE reviewer of Ober's "Camps in the Caribbees" (NATURE, vol. xxii. p. 216) appears to doubt the story of the habits of the large Hercules beetle, *Dynastes hercules*, given by Ober on the authority of his guide. It is nevertheless perfectly true, and I have myself witnessed the occurrence twice in this neighbourhood, where the beetle is not uncommon. In the first instance I noticed it on a branch of *Ochroma lagopus*, and the second time on a species of *Bombax*, both very soft-wooded trees. The branches in each case were about three-quarters of an inch in diameter, half an inch being formed by the wood. In both cases I saw the performance of the animal most distinctly, just as described by Ober's guide, and I took not only a piece of the severed branch with me, but secured also the second animal. The noise is not so much produced by the cutting of the branch as by the open wings passing rapidly through the air during the rotation of the beetle. I do not believe there is anything of a sexual call in the manœuvre. The beetle wants to get at the abundant juice of the young branches. It is called in this country *aserrador*, *i.e.* *sawyer*. *Golofa porteri*, an allied insect of the same family as Lamellicornes, behaves in a similar way, but chooses of course thinner branches. A. ERNST

Carácas September 9

What is Alrese?

IN the large *Encyclopédie* published by Diderot and d'Alembert, vol. xii. p. 224 (edit. in folio) there is mentioned amongst the substances used for poisoning water to catch the fish, *l'herbe qu'on appelle l'*ALRESE. Littré has no such word, nor anything like it, nor indeed any other lexicographer I am able to consult here. I should be much obliged for any information on this name, or the plant referred to. A. ERNST

Carácas, September 9

Rainfall of Sierra Leone

As I believe there is little account taken of this climate at home, and as perhaps it might interest you, I send you an account of one day's rainfall this month, which is an excessive amount even for Freetown, and equal to one-third the whole year's rainfall for Dublin, I believe:—

Rainfall registered in the Colonial Hospital, Freetown, 50 feet above Sea-level

	Inches.
From 6 a.m. to 4 p.m. September 11	6·35
From 4 p.m. to 6 a.m. September 12	4·05
Total in 24 hours	10·4

Garrison House, Freetown, September 16 W. HUME HART, Colonial Surgeon

An Octopus

I INCLOSE an account of an enormous octopus which was thrown on the shore at Kilkee, Co. Clare, in the last great storm. As strangers find my uncle's hand very hard to read, I have copied his letter.

Ardanoir Foynes C. G. O'BRIEN

"*Saturday, October* 9, 1880

"I am sorry you were not at Kilkee when a great octopus was stranded on the side of the Duggerna reef on Thursday last. Its arms had been partially broken: there were eight of them, each as thick as a strong man's upper arm, and beneath each were two rows of suckers like cupping-glasses, more than a shilling size in circuit. When perfect, each of these arms must have been from twelve to fifteen feet long, and from the point of one arm to that of its opposite was a length of nearly thirty feet. The animal's length from the insertion of its suckers to the end of its body must have been nearly twenty feet, perhaps more. Its mouth, like a parrot's beak, was as large as two joined hands of a large man with the fingers outstretched. It weighed about 4 cwt. Its head was $1\frac{1}{2}$ inch in diameter, about three feet long; its eyes of the size of the inner circuit of a breakfast-plate. A monster. The under colour that of the under side of a turbot." —(*From a letter of the* Rev. R. J. GABBETT.)

SYNTHESIS OF CITRIC ACID

AS we intimated last week, another brilliant synthesis has recently been accomplished in the domain of organic chemistry. Messrs. Grimaux and Adam have succeeded in building up the characteristic acid of lemons from glycerin. Glycerin may be regarded as trihydroxypropane, $C_3H_5(OH)_3$, and citric acid as hydroxypropanetricarboxyllic acid, $C_3H_4(OH)(CO_2H)_3$. To convert glycerin into citric acid it was therefore necessary to replace two hydroxyl groups, and one hydrogen atom, by the group CO_2H (carboxyl). This was done as follows:—By the action of hydrochloric acid on glycerin, dichlorhydrin,

$$CH_2Cl-CH(OH)-CH_2Cl$$

was produced; this was oxidised by potassium dichromate and sulphuric acid, to dichloracetone,

$$CH_2Cl-CO-CH_2Cl,$$

which, when acted on by concentrated hydrocyanic acid, yielded dichloracetone cyanhydrin,

$$CH_2Cl-\underset{\displaystyle OH}{\underset{|}{C}}{<}\begin{array}{l}CN\\ CH_2Cl\end{array}$$

The acid corresponding to this cyanhydrin having been produced by saponifying with hydrochloric acid, the sodium salt of this acid, viz.,

$$CH_2Cl-\underset{\displaystyle OH}{\underset{|}{C}}{<}\begin{array}{l}CO_2H\\ CH_2Cl,\end{array}$$

was treated with potassium cyanide, whereby a dicyanide,

$$CH_2CN-\underset{\displaystyle OH}{\underset{|}{C}}{<}\begin{array}{l}CO_2H\\ CH_2.CN\end{array}$$

was produced. When decomposed by hydrochloric acid, this dicyanide yielded citric acid, in all respects identical with that obtained from the lemon and other fruits. The generally accepted structural formula for citric acid, viz.,

$$CH_2.CO_2H-\underset{\displaystyle OH}{\underset{|}{C}}{<}\begin{array}{l}CO_2H\\ CH_2.CO_2H\end{array}$$

is confirmed by the synthesis of Grimaux and Adam. Glycerin may be prepared from trichlorhydrin,

$$CH_2Cl-CHCl-CH_2Cl,$$

which is itself obtained by the action of chlorine in daylight on propylenic chloride,

$$CH_3-CHCl-CH_2Cl,$$

one of the products of the chlorination of propylene, C_3H_6. Finally this hydrocarbon, propylene, may be produced by passing a mixture of carbon monoxide and marsh gas through a red-hot tube. Inasmuch as carbon monoxide and marsh gas are easily built up from carbon, hydrogen, and oxygen, the synthesis of citric acid from these three elements is now an accomplished fact.

In connection with this synthesis, it is worthy of remark that in the last number of the Berlin *Berichte*, Kekulé announces that he has been working at the same subject, but by a totally different method. Kekulé's work is not sufficiently advanced for him to say positively that his method of synthesis is successful, but he feels justified in saying that very probably the process adopted by him has resulted in the formation of citric acid.

M. M. P. M.

PLANTS FROM LAKE NYASSA AND LAKE TANGANYIKA

MR. THOMSON, who has recently returned from the expedition of the Royal Geographical Society to Central Africa, has brought to Kew a considerable collection of plants from the plateaux round Lake Nyassa and Lake Tanganyika. The plants from an elevation of 6,000 to 8,000 feet above sea-level contain a large proportion of Cape and characteristically temperate types. Amongst the former are the well-known *Dierama* (*Sparaxis*) *pendula*, *Scilla rigidifolia*, *Buphane toxicaria* (the great poison bulb of Natal and the Transvaal), a fine *Moræa* with a long tube and bright purple flowers as large as those of *Iris fœtidissima*, a *Gladiolus*, a *Pelargonium*, more than one species of *Gnidia* and *Helichrysum*, and a proteaceous shrub (probably *Faurea*, which extends to Abyssynia) with large heads of flowers. Of characteristically temperate types there are species of *Geranium*, *Rumex*, *Cerastium*, *Coalamintha*, and a *Scabiosa*, perhaps identical with our European and English *S. Columbaria*. Upon the plateaux below 6,000 feet the vegetation assumes a sub-tropical character. Here he met with a tree-fern of the genus *Cyathea*, *Agauria salicifolia*, Hook, fil, an ericaceous shrub common to Bourbon, Madagascar, and the Cameroons, representatives of *Mimulopsis*, *Hibiscus*, *Clematis*, *Phyllanthus*, *Gerbera*, *Smithia*, *Acalypha*, *Pentas*, *Thunbergia*, *Buchnera*, *Striga*, a shrubby *Spermacoce*, a curious *Loranthus* with broad leaves and tubular flowers densely clothed with yellow hairs, *Hypoxis Villosa*, several fine Dombeyas, Vernonias, and Combretums, a genus of *Hedysareæ* with flowers in heads like those of the hop, and a curious broad-leaved *Euphorbia*, with very large hand-like glands to the involucre. The specimens are well selected and excellently dried. It is probable that nearly all of them are in a condition in which their botanical position can be settled, and that although upon a hasty glance there do not seem to be any strongly-marked new generic types, a good many of the species will prove new to science. The marked northern extension of the Cape flora at comparatively high elevations in Central Africa is a fact of importance. It quite supports the theory that that flora is of great antiquity, and that what exists of it at the Cape is only a survival from a period when it was probably far more extensively diffused, though perhaps less highly specialised. It is much to be desired that travellers in Central Africa would do all in their power to collect dried specimens of the vegetation of elevations above 6,000 feet.

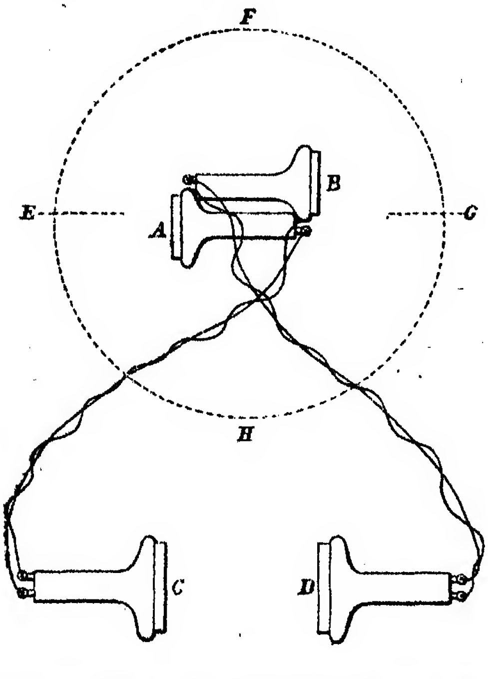
GRAHAM BELL'S EXPERIMENTS IN BINAURAL AUDITION

PROF. GRAHAM BELL has published in the *American* (quarterly) *Journal of Otology* a memoir on some experiments relating to binaural audition, read by him last autumn at the session of the American Association for the Advancement of Science. Some of his observations confirm the work of previous observers, but are of additional value in affording a more systematic examination of some of the phenomena than has hitherto been attempted. The following summary of the results obtained by him will therefore be of some interest.

When we close one ear and listen to sounds through the other only, there seems to be a onesidedness about them, as there is about objects perceived by one eye. When both ears are employed simultaneously a sort of stereoscopic effect of audition is perceived. Sounds assume a "solidity" which was not perceptible so long as one ear alone was employed. The difference between *monaural* and *binaural* audition is especially well marked when we attempt to decide by ear the *locality* of a particular sound. Whatever power a single ear may possess of determining the direction of a source of sound, both ears are certainly much more effective for this purpose.

The following experiment, designed to produce artificially the stereophonic phenomena of binaural audition, was therefore devised by Prof. Bell while in this country in 1878. Four telephones were arranged, as in the figure. The telephones A and B in one room; C and D in another. The mouthpieces of A and B were turned away from one another like the auricles of a person's ears, and the diaphragms were about as far apart as the tympana of the two ears. The expectation was that a person holding C and D to his ears should not simply hear speech when any one was talking near A and B, but that he should be able to perceive the *direction* of the speaker's voice relatively to A and B. In fact, the listener's ears were, as it were, electrically prolonged to A and B respectively. The sensations produced were decidedly novel; but not exactly such as had been expected. Using various sources of sound—speaking, ringing a loud dinner-bell in various parts of the room, &c.—it was found that the location of the sound could be determined to a limited extent. The

general result was as follows: imagine a globe, E, F, G, H, in the interior of which are the telephones A and B; let E and G be the two poles, and imagine the usual meridian lines and parallels of latitude. It was found as the result of the experiments that the observer at C, D could determine with tolerable accuracy the *latitude* of a sound made near A, B, but that *he had no idea whatever of its longitude.* In a later experiment two Blake transmitters were employed. They were placed back to back at about five feet from the ground in the open air. The receiving telephones were indoors, whence the speaker could be observed. The results of observation coincided with those already described. In order more closely to imitate the natural arrangement of the ears the transmitters were then set so that the diaphragms were at 45° to each other. A sound made at H here produced a feebler effect than one made at F; and *after a few experiments* the ear seemed to be able to distinguish whether the speaker were in front of, or behind the transmitters. Unfortunately the two transmitters were not equally sensitive, and the ear had to get accustomed to the slight inequality in the intensity



of the transmitted sounds. Prof. Bell suggests that the sensations experienced by deaf persons might be studied by persons possessed of normal hearing powers by purposely using transmitters of unequal power, or by introducing artificial resistances into the circuits.

It also occurred to Prof. Bell that the telephone might afford a means of ascertaining to what degree the human ear normally has the power of appreciating the *direction* of sound. For this purpose a number of telephones were hung up in different parts of a summer-house, and were connected with a switch-board so that an interrupted current from a rheotome in a distant place could be sent through any one at will. A person stationed at the middle of the summer-house, with his eyes closed, and holding his head perfectly still, was required to indicate the point from which the sound seemed to emanate. The indicated direction usually differed considerably from the true direction, and it was found that the observer soon came to recognise each individual telephone by its particular timbre. To obviate this a single telephone was hung up in different parts of the summer-house during the absence of the observer. This was very laborious; nevertheless a long series of experiments were carried out, and their results carefully set down in a series of eight tables. Five young men were employed as observers, the power of each of their ears being previously ascertained by an independent test. The experiments thus carefully made and tabulated are still too few, and in Prof. Bell's opinion too imperfect in several respects, to admit of accurate generalisation; but some deductions are unmistakable. The tables establish beyond dispute (*a*) that the perception of the direction of a source of sound is less perfect by a single ear than by both ears; (*b*) they disprove the idea that direction cannot be appreciated by monaural observation; (*c*) they show that the direction of sound is more accurately defined as it approximates to the axial line of the ears [this entirely negatives Steinhäuser's theory of binaural audition]; (*d*) that the indications are proportionately at fault as the true source is in any other direction, the angular error sometimes amounting to 180° when the source is 90° from the axial line! (*e*) the perception of direction is absolutely unreliable when the source of sound is at the nadir with respect to the observer. It should however be remembered that in experiments thus made in an apartment reflexion of the sound comes into play, and partially vitiates any general deductions by introducing slight though unknown complications.

The method adopted by Prof. Bell to measure the relative hearing power of the separate ears was as follows:—Two flat coils of wire were placed upon a long wooden rod which passed through their centres. One of these coils, the "primary," was a fixture, and was put in circuit with a battery and a vibrating interrupter in a distant room. The other coil, the "secondary," was joined up to a telephone. When placed close to the primary the induced current produced loud sounds; the observer, holding the telephone to his ear, was then directed to slide the secondary coil away from the primary until he ceased to hear anything. The distance between the two coils was then measured. It will be seen that this arrangement anticipated to some extent the sonometer of Prof. Hughes.

We venture to hope that Prof. Bell will continue these interesting researches in this promising, and hitherto almost unexplored field. S. P. T.

THE GEOLOGY OF THE LIBYAN DESERT[1]

In his very interesting anniversary address before the Academy of Sciences in Munich Dr. Zittel has brought together all the known facts concerning the geology of the northern districts of Africa, in a manner which is calculated to render the greatest service to his fellow-workers in science. The address, with its accompanying map and numerous explanatory notes, constitutes indeed by far the best monograph on North African geology which has yet appeared. The author not only reviews the works of the various travellers who have furnished materials bearing upon the question, from Browne and Hornemann to Fraas, Rohlfs, and Schweinfurth, but what is of far more importance, gives the results of his own accurate study of the rocks and fossils collected and brought home by recent investigators. The general results arrived at by Dr. Zittel are as follows.

To the east of the Nile rises a mountain range composed of highly crystalline rocks—granite, diorite, and hornblendic gneiss. The peaks of this range rise to heights varying from 5,000 to 8,000 feet.

The oldest stratified rocks of the district appear to be of Cretaceous age. Lying upon the axis of crystalline rocks, and also covering wide tracts of country to the south of the Great Desert, is found the Nubian sandstone

[1] "Ueber den geologischen Bau der libyschen Wüste. (Festrede gehalten in der öffentlichen Sitzung der k. b. Akademie der Wissenschaften zu München zur Feier ihres einhundert und einundzwanzigsten Stiftungstages.) Von Dr. Karl A. Zittel.

formation. Concerning the age of these sandstone rocks a considerable amount of controversy has taken place in recent years, and they have been referred by different authors to the Triassic, the Jurassic, and the Neocomian systems. The fossils found by Overweg and others, however, seem to leave no room for doubt that the real age of the Nubian sandstone is the Cenomanian, or lower portion of the Upper Cretaceous.

Lying upon these sandstones are found great deposits over 600 feet in thickness, consisting of dark green and grey, finely-laminated marls in their lower, and of white, earthy limestones in their upper part. These rocks contain many characteristic Upper Cretaceous fossils, such as *Ananchytes ovatus*, *Ventriculites*, and *Rudistes*. These Upper Cretaceous rocks have been found not only forming the whole southern margin of the Desert, but also rising above the sandy wastes in the hilly masses which form the oases.

The deposits which underlie the greater part of the Sahara appear to be of Tertiary age and referable to the Nummulitic and Miocene periods. There would seem to be no sharp line of demarcation between the Cretaceous and the Tertiary deposits in this area, and in this, as in many other particulars, which are pointed out by Prof. Zittel, the North African formations of these periods remind us of those of the Rocky-Mountain regions of North America.

The older Tertiary deposits of Northern Africa are divided by Dr. Zittel into two members, which he designates the "Lybysche Stufe" and the "Mokattam Stufe." In the lowest of these (the Libysche Stufe) a widely-spread and very characteristic fossil is the Belemnite-like *Graphularia desertorum*, Zitt.; many nummulites and other well-marked Eocene fossils also occur.

There appears to be still some doubt as to whether the "Mokattam Stufe" of Dr. Zittel should be classed as Eocene or Oligocene.

In the northern part of the area various freshwater and marine deposits are found which are now referred to the Miocene. No less than sixty-eight forms of marine mollusca have been determined by Dr. Theodor Fuchs as occurring in these beds, and he is led to regard them as indicating a horizon not far removed from that of the Leitha-kalke of the Vienna basin.

The several formations described succeed one another from south to north, this being the direction of the dip of the beds; their relations to one another are well illustrated in the map and sections which accompany the work.

In the midst of the Beharieh oasis a mass of igneous rock is found rising through the midst of the Upper Cretaceous limestones. This rock has been studied by Prof. Zirkel of Leipzic, who pronounces it to be an ordinary plagioclase basalt, very similar in character to that of the Giant's Causeway in Ireland.

Over the whole of these formations the great mass of sands of the Desert is spread, and rises in places into hills several hundreds of feet in height.

In reading this address we cannot but feel that Dr. Zirkel has made admirable use of the collections which Dr. Schweinfurth and others have placed in the museum at Munich; and that by their careful study he has been enabled to clear up many of the difficulties which every one must have felt who has endeavoured to understand the geological structure of the great African continent.

PHYSICS WITHOUT APPARATUS[1]

VIII.

IN the preceding articles of this series we have shown how in every department of physics a large number of instructive experiments may be performed without the aid of any more formal apparatus than the usual domestic appliances of an ordinary household. There remain to be described a few miscellaneous experiments before concluding the subject.

FIG. 25.

Many years ago Prof. Faraday observed that if two pieces of ice are pressed against one another they freeze

FIG. 26.

firmly together at the point of contact, even though they may themselves be thawing at the surface. To this

[1] Continued from p. 538.

peculiar property of ice he gave the name of *regelation.* The true explanation of this property was not at once arrived at. From theoretical considerations Prof. James Thomson was led to predict that the application of pressure to ice would lower the temperature of its melting-

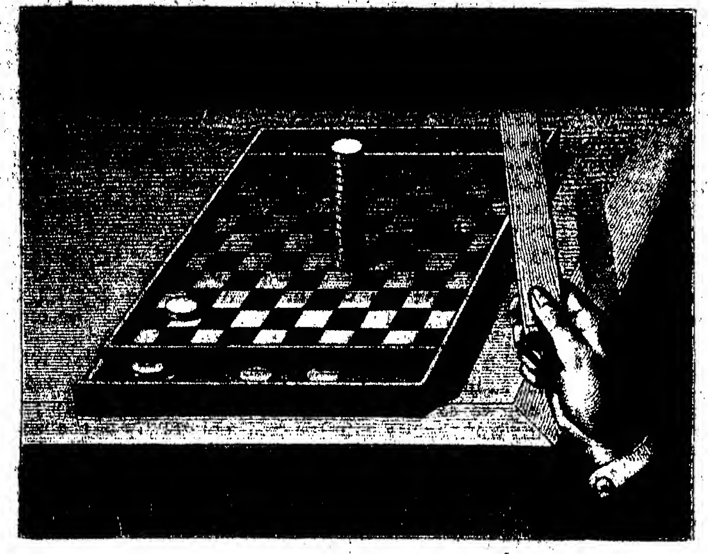


FIG. 27.

point, and cause it to melt even though as cold as, or colder than, the usual "freezing-point." This prediction was afterwards verified by Sir William Thomson, who melted ice by subjecting it to great pressure. More recently Mr. James Bottomley has devised a very beautiful experiment on regelation which requires no special apparatus for its performance. A block of ice (Fig. 25) is placed upon a suitable support, and over it is hung by a copper wire a heavy weight. It is found that in the course of a few hours the weight will have dragged the wire through the ice, as if it were no harder than a piece of cheese, yet that the ice has healed up as fast as the wire cut into it, and that it is still one solid block. This extraordinary fact can be accounted for in the following way. In the neighbourhood of the wire where it passes through the ice the pressures are not uniform, for just below the wire the portions of the ice are under pressure, owing to the pull of the heavy weight, while immediately above the wire the ice is subjected to a stress tending to draw the particles asunder, or, in other words, it is subjected to a *pull* or "negative pressure." The pressure on the ice under the wire lowers its melting-point, and causes very small quantities of it to melt; these liquid portions immediately are squeezed out, and find their way round the wire to the space above it, where, the pressure being reduced, they again freeze hard.

Our next picture (Fig. 26) is a simple illustration of the principle of the diving-bell. A wine-glass is turned mouth downwards and plunged into a jar of water. The water rises up only a very little way into the mouth of the wine-glass, owing to the air which it contains. The deeper the wine-glass is plunged the more is the air compressed and the higher does the water rise in the miniature bell. To compress the contained air into one-half of its original volume it would be necessary to plunge the wine-glass about thirty-four feet deep into water; for to halve the volume of the air inside we must double the external pressure. The pressure of the air is already about fifteen pounds on every square inch, and to double that pressure requires the additional weight of thirty-four feet of superincumbent water, for that is the depth at which the water itself presses with a force of fifteen

FIG. 28.

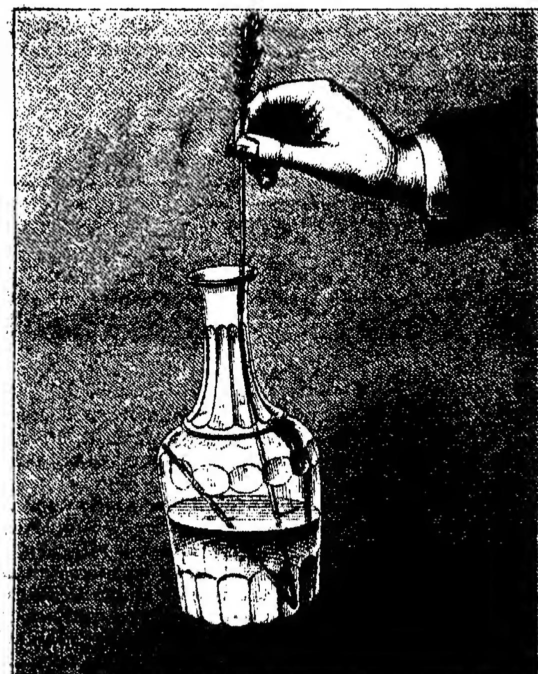

FIG. 29.

pounds on each square inch of surface. M. Tissandier, in describing this simple experiment in the pages of *La Nature*, has suggested that a few imprisoned flies or other insects may without any cruelty or hurt do duty as divers within the miniature diving-bell, and afford proof that life can go on in the inclosed air even though below the surface of water.

In speaking in a former article of the subject of *inertia* we mentioned the following familiar trick: a number of the round wooden "men" used in playing the game of draughts are piled up in a column one upon another. If the lowest one of the pile is dextrously hit with the edge of a paper-knife or other suitable article it may be knocked away from under the others without overthrowing the others. Fig. 27 shows how the experiment is arranged, the narrow slip of wood which serves as the lid of the box being here used as the weapon. Beginners in science must not mistake the meaning of the term *inertia* as applied to matter. Matter is not in itself lazy or inert. But it possesses the property of *mass*, and to set mass in motion requires the expenditure of *energy*. If we skilfully

Fig. 30.

spend the energy of the rapid blow upon the one draughtsman, it is knocked away before there is time for any considerable part of the energy to be imparted to the others that are piled upon it.

Another simple experiment, depending partly upon the inertia of matter and partly upon elasticity, is often shown as an after-dinner trick. Upon a linen tablecloth is placed a threepenny-piece between two pennies or other larger and thicker coins. Over this an empty wine-glass is placed, and the puzzle is how to get out the smaller coin without touching the glass. The very simple operation of scratching with the finger-nail upon the cloth, as shown in Fig. 28, suffices to accomplish the trick, for the little coin is seen to advance gently towards the finger until it has moved completely away from under the glass. The fibres of the linen cloth are elastic; when you scratch with your finger-nail they are drawn gently forward until the force of their elasticity becomes too great and they fly back, to be once more drawn forward, again to slip back, and so on. While the fibres are drawn forward slowly, they drag the coin with them to a minute distance. But when the slip occurs and they fly backward, they do so very rapidly, and slip back under the coin before there is time for the energy of their movement to be imparted to the coin to set it in motion. So the coin is gradually carried forward over the surface of the cloth.

We will next give a simple experiment which illustrates the principle that a substance which is very weak in one direction may be very strong in another, the "strength" of the material (that is to say, the resistance it offers before it will break) depending on the way in which a force is applied to it. It is possible to lift a decanter full of water by means of a single straw. To do this the straw must be bent as Fig. 29 shows, so that the weight comes longitudinally upon the straw. The straw is a very weak thing if it has to resist a force applied laterally. Lay a single straw horizontally, so that the two ends are supported, and then hang weights on to the middle of it: a very few ounces will break it across. But let the weights be fixed to one end of the straw, and the straw itself be hung downwards so that the pull is exerted along it, and it will support one or two pounds at least. When bent, as in the figure inside the bottle, most of the weight is applied as a thrust against the end of the straw; the bottle tilts slightly until the centre of gravity of the whole is below the point from which it hangs between finger and thumb; but in this position the sideway thrust against the middle of the straw is very small, and the material is strong enough to stand the strain to which it is subjected lengthways.

Lastly we offer an illustration (Fig. 30) of an experiment known to every schoolboy. A can or jar containing water may be whirled round the head without spilling a single drop, provided the motion be sufficiently rapid. When a moving body is subjected to the constraining action of a force which acts, like the pull of a string held in the hand, towards a fixed centre, the result is a motion around the centre of force. Were it not for the constraining force the moving body would fly away at a tangent; and to the reaction exerted successively in all directions away from the centre the name "centrifugal force" was formerly given. The water in the can, being heavy, is also subjected to this so-called centrifugal force as it moves around the fixed centre, and hence it does not fall out of the can while passing through the inverted position in the air if its speed be sufficiently accelerated.

THE GERMINATION OF WELWITSCHIA MIRABILIS

HAVING been supplied, through the kindness of the Director of Kew Gardens, with young seedlings of *Welwitschia mirabilis*, I have been enabled to draw some fresh conclusions as to the homology of the large leaf structures, which have hitherto been described as persistent cotyledons. It is true this description has been confessedly provisional, since the process of germination has not hitherto been traced.

The seeds germinate in a manner corresponding in the main with that described by Strasburger for *Ephedra campylopoda* ("Conif. und Gnet.," p. 320). The radicle first breaks through the testa, the point of perforation depending apparently upon the position of the seed during germination. The cotyledons also break through the testa, but at a different point from the radicle. The cotyledons are two in number; in one case I observed three, one being smaller than the others. They free themselves entirely from the seed, and expand to a length of 1 inch to 1½ inch, with a breadth of ⅛ inch, or rather more; it is possible, however, that they may by growth attain a larger size. The cotyledons when expanded are green, though while still in the seed they are yellow.

Their form is linear, margin entire, glabrous. Each has two main fibro-vascular bundles parallel to one another, and two or more lateral ones, also parallel to these; they all give off lateral bundles which anastomose freely. The hypocotyledonary portion of the stem extends to a length of about one to two inches; it is compressed in a plane parallel to that of the cotyledons, and is slightly swollen immediately below the point of junction with them.

Though the cotyledons are completely withdrawn from the seed at an early stage, a physiological connection is kept up between the seedling and the endosperm by a peculiar structure, produced apparently by a lateral swelling of the hypocotyledonary portion of the stem. The time and manner of its development I have not yet been able to ascertain, but in one seedling of twelve days it was found lying parallel to the cotyledons, these being still inclosed in the endosperm, whereas in the mature seeds I have not been able as yet to see any trace of it.

This structure remains in close connection with the endosperm, and is probably useful in transferring the nutritive substances from it to the embryo after the cotyledons have been withdrawn. As far as I can see at present, this lateral structure is produced merely by a process of lateral extension of tissues. The fibro-vascular bundles curve slightly into the protrusion, but I have observed no special modification of the tissues further than a lateral extension. If this be the case, it may be considered morphologically as an emergence.

It has been already observed by Strasburger ("Angiospermen und Gymnospermen," p. 155, Plate xxii., Figs. 90, 91, 93) that in the ripe embryo of Welwitschia an apical papilla is to be seen between the cotyledons; but his observations were conducted only on embryos in mature but ungerminated seeds; and here, as in other members of the group, the plumule does not develop beyond this condition of a mere papilla till germination begins. In the young seedlings (about six weeks old) which I have had the opportunity of observing, the *plumule consists of two leaves*, decussating with the cotyledons, and between these there is an apical papilla. In the most advanced specimens now growing at Kew these leaves of the plumule are about one-sixteenth of an inch in length, but no further development of leaves is at present to be seen.

These observations suggested a comparison with the youngest specimens preserved in the Kew collections: the result is the discovery of evident traces of the bases of leaf-structures below the well-known pair of large leaves, in the form of ragged ends of fibro-vascular bundles, which run directly into the tissues of the stem. These earlier leaves appear to have been at right angles to those of the existing leaves of the plant, and we may with good reason conjecture that they were the cotyledons. Full proof of this will be afforded if the plants at present growing at Kew remain healthy. If this conjecture be true the pair of large perennial leaves are *the first and only pair of leaves developed from the plumule*, and not cotyledons, as they have been hitherto assumed to be.

Other interesting points in the germination of this plant, together with a description of its minute histology, must be deferred till a later notice. This I hope to be able to publish with illustrations in an early number of the *Quarterly Journal of Microscopical Science*.

F. ORPEN BOWER

The Jodrell Laboratory, Royal Gardens, Kew,
October 9

NOTES

In the second of a series of articles in the *Pall Mall Gazette* "On Vain Discourse," in the quaint and leisurely style of our remote forefathers, the writer speaks of "the talker who thinketh he hath a vocation to popularise science, not as some of our masters come forth to stir up interest in these matters, but from folly and emptiness." He then proceeds to define him:—"He is a great breeder of vain discourses, for he deemeth that the strong meat of knowledge will sit ill on dainty stomachs, and so sets himself to save them the digesting. He watereth first to the consistency of a small fact to the page, and sweeteneth with many a line of poetry; and if there be a tough morsel of reasoning or a sharp fragment of logical defining, that he carefully throweth aside, 'et pondera rerum minutissimis verbis frangit.' For seasoning there are divers sorts of lights or colours or smells to wonder at, and pictures and tales, and praise of the wonderful nineteenth century, and of science and of such as study it. And so there is made a thin and limpid pabulum, or *extractum scientiæ dilutum*, which will not harm the delicatest, nor indeed do them any good, though it be sweet to the taste and pleasant to the eyes, and have the savour of wisdom. For knowledge that is worthy of being attained needeth faithful striving and endeavour, and skill cometh not but by assiduity in act and exercise—χαλεπὰ τὰ καλά." The lecture season is now beginning, and it would be well that those who attend science lectures should learn to distinguish between the true and the false, and this they can easily do by applying the test given by the *Pall Mall*. The spread of efficient education in science will either extinguish the popular lecture or greatly alter its character. We are glad to see the growth of outside opinion on the subject, as may be inferred from the article alluded to.

We regret to record the death of Dr. E. J. Sparks, F.R.C.P., of Mentone, which occurred at Crewkerne on the 11th instant. Dr. Sparks has been in failing health for several years, but he is one of those striking instances of what work can be done by an active mind in spite of physical weakness. He was well known as a constant contributor to the *Medical Times*, in which appeared the series of letters on the climate of the Riviera, which were afterwards developed into his excellent book on the Health-Resorts of the Riviera. The preparation of this work occupied the best portion of Dr. Sparks' later years, and it is only three months since he revisited several of the less frequented places on the Eastern Riviera for the sake of a second edition. The book is a truly scientific work. Statistics relating to climate and the various diseases for which the Riviera has been recommended have been collected and tabulated with the greatest diligence and care; and the experience of observers, both lay and medical, as to the beneficial influence of the climate is given with the greatest candour. Besides this work, Dr. Sparks published a few years ago a translation of Dr. King's "Therapeutics," the value of which was greatly enhanced by the introduction of a quantity of new matter carefully collected together from medical periodicals. It was a work of no small labour, necessitating as it did the transformation of all quantitative relations from the German into those employed in the English and American Pharmacopœias. It received on the other side of the Atlantic prompt appreciation in a manner both hurtful and complimentary. Before it could be reprinted from the stereotype plates sent over for the purpose, a pirated fac-simile edition was produced by a publisher who has hitherto forgotten to send a cheque. He brought to his medical practice an unusually thorough knowledge of the science of his profession, and a high-minded devotion to the welfare of his patients which quickly secured the confidence of all who consulted him. In friendship he was staunch, loyal, and self-sacrificing, and his loss will be long felt by a wide circle of friends.

The following are among the scientific and geographical publications announced for the present season:—By Mr. Murray: "Japan; its History, Traditions, and Religions, with the

Narrative of a Visit in 1872," by Sir E. J. Reed, K.C.B., M.P.; "Unbeaten Tracks in Japan," by Isabella Bird (these works are just published); "Personal Life of David Livingstone," by Dr. W. G. Blackie; "A Pilgrimage to Nejd," by Lady Anne Blunt; "The Power of Movement in Plants," by Charles Darwin, assisted by Francis Darwin; "The Cat; an Introduction to the Study of Back-boned Animals," by St. George Mivart; "Siberia in Europe, a Naturalist's Visit to the Valley of the Petchora," by Henry Seebohm; "The Gardens of the Sun: a Naturalist's Journal on the Mountains and in the Forests and Swamps of Borneo and the Sulu Archipelago," by F. W. Burbidge. Messrs. Allen and Co. announce: "The Expiring Continent; a Narrative of Travel in Senegambia," by A. W. Mitchelson; "A Dictionary of Ethnological and Philological Geography," by Dr. R. G. Latham; "Incidents of a Journey through Nubia to Darfur," by Sydney Ensor, C.E. Among Messrs. Crosby, Lockwood, and Co.'s announcements are: "The Fields of Great Britain; a Text-Book of Agriculture," by Hugh Clements; "A Rudimentary Treatise on Coal and Coal-Mining," by Warington W. Smyth, F.R.S. Messrs. Sampson Low and Co. announce: "New Guinea," by L. M. D'Albertis; "Seven Years in South Africa," by Dr. Holub. Messrs. Longmans promise the second series of Helmholtz's "Popular Lectures on Scientific Subjects," translated by Dr. E. Atkinson. Messrs. Chatto and Windus: "A Simple Treatise on Heat," by W. M. Williams. Macmillan and Co.: "Island Life," by A. R. Wallace; "A Visit to Wazan," by L. S. Watson; "Voyage of the *Vega*," by A. E. Nordenskjöld; "Text-Book of Geology," by Prof. Geikie; "Ideal Chemistry," by Sir Benjamin Brodie, Bart.; "A Treatise on Organic Chemistry," by Professors Roscoe and Schorlemmer; vol. ii. of Mr. F. M. Balfour's "Treatise on Comparative Embryology;" "Anthropology," by Dr. E. B. Tylor; "Mathematical Papers," by the late Prof. Clifford; "History of the Steam Engine," by R. L. Galloway.

The inauguration of the Paris Popular Observatory took place at the Trocadéro Palace on October 11, on the second terrace of the Eastern Tower. Four telescopes—three reflectors and a refractor, have been placed at the disposal of the public. No fee is taken from the visitors, who have only to make application to the Popular Observatory Office, Trocadéro, and register their names. A series of lectures on practical observations will soon begin. A room is also reserved for microscopical observations, which will be opened during the daytime.

The Sheffield Public Museum boasts of an equatorially mounted telescope which the public are permitted to use under certain restrictions and under the direction of Mr. E. Howarth, the curator.

M. Hervé-Mangon, the new director of the Conservatoire des Arts et Métiers, gave yesterday a great dinner in honour of Mr. Graham Bell, the inventor of the photophone, which was exhibited and tried in that establishment.

The Calisaya bark plants cultivated in Jamaica appear to have been replaced by an inferior hybrid between true *Cinchona Calisaya* and *C. succirubra*. In order to remedy this state of things Mr. J. E. Howard, F.R.S., the well-known quinologist, liberally placed cuttings from his authentic plant of *Cinchona Ledgeriana* at the disposal of the Royal Gardens, Kew. Three healthy plants raised from this source have lately reached Jamaica, besides others which have been sent to Ceylon.

Camoensia maxima, the most striking leguminous plant known, has flowered for the first time in cultivation in the Botanic Garden, Trinidad, to which it was sent two years ago from Kew. Welwitsch found it abundantly in the forests of Angola. The flowers are nearly a foot long, with a reddish calyx and cream-coloured petals with a golden border. The standard is 3 4 in. broad, which gives some idea of the scale of the other parts. There are living plants also at Kew, but at present it has shown no indication of flowering under glass.

A correspondent states that when he was a schoolboy at Hamburg, male crickets (species not indicated) were sold there in cages made of four playing-cards, and at the rate of a penny a-piece.

Another correspondent states that the electric lamps illuminating a large concert-room in the Champs Elysées at Paris, a year or two ago, were extremely attractive to insects of various orders. Who knows that the Thames Embankment may not become the nightly resort of members of the Entomological Society?

The Committee of the Topographical Society of London, which has been formed for the purpose of collecting and publishing maps, views, and other materials for the history of London, have made arrangements for the holding of the inaugural meeting of the Society on Thursday, the 28th inst., at 4 o'clock. The Lord Mayor has granted the use of the Long Parlour at the Mansion House, and will preside on the occasion. Cards for the meeting may be obtained from Mr. Henry B. Wheatley, F.S.A., 18, John Street, Adelphi, W.C.

We are glad to see a new edition of the late Sir J. W. Lubbock's Star Maps, under the title of "The Stars in Six Maps on the Gnomonic Projection," with explanatory notes by Mr. James Glaisher, F.R.S. Letts, Son, and Co. are the publishers.

It is proposed that an International balloon race should take place at Paris on October 31. Active steps are being taken, and the necessary authorisation will be procured without difficulty from the public authorities, but an obstacle of a quite unexpected nature remains to be solved. For motives, which it is very difficult to determine, the Parisian Company who monopolise the gas, and sell it at the enormous price of threepence per cubic metre, refuse to dispose of the commodity to aëronauts. As no provision in the charter has been made for the right of inflating balloons, it remains to be seen whether or not the gas monopolists will persist in their refusal.

M. Sadi Carnot, the French Minister of Public Works, has appointed a Commission to explore the antiquities of the Regency of Tunis, and determine what works could be executed with advantage in a country of which the welfare is of such importance for the good of the largest French dependency.

The *Pester Lloyd* gives a detailed account of the earthquake which seems to have been felt generally all over Transylvania on the night between the 3rd and 4th inst. From about 7 o'clock in the evening rumbling noises were heard throughout the night, especially in the hilly districts. About 6.15 a.m. a shock was felt which lasted a couple of seconds, and the shock was repeated, in some places twice, in others as often as ten times. Doors were opened and shut, windows rattled, bells were rung. In several places a movement of the ground was felt, in a direction from north-west to south-east; in some places this movement lasted as long as ten seconds. In the neighbourhood of Tövis a small railway-station building was overthrown. At Felvinez the shocks were very severe, lasting fully two minutes. Several public buildings had rents in the walls, and nearly the whole of the ceiling of the Reformed Church fell. At Bistritz the people were so alarmed that they rushed from their beds into the streets and open places. In general the disturbance was greater in the western portion of the province.

An interesting "Note on the Distribution of some of the more important Trees of British Columbia" has been contributed by Mr. George M. Dawson to a recent number of the *Canadian*

Naturalist. In a brief review of the general characters of the vegetation of the country the peculiarities in distribution are pointed out. The arrangement of the trees referred to is not based on any scientific principle, the Coniferæ being "placed first, as having the greatest importance both from an economic point of view and from the vast extent of country which they cover almost to the exclusion of other trees." Considering the variety of well-known timber trees to be found in British Columbia one is scarcely prepared to find it stated, with regard to the Douglas Fir (*Pseudotsuga Douglasii* or *Abies Douglasii*), that it is the "most important timber tree of British Columbia, and the only one of which the wood has yet become an article of export on a large scale." The best grown specimens of this noble tree are stated to be found near the coast in proximity to the waters of the many bays and inlets which indent it. In these situations the tree frequently exceeds eight feet in diameter at some considerable height from the ground, the height of the tree itself ranging from 200 to over 300 feet. "The wood varies considerably in appearance and strength according to its locality of growth and other circumstances. It is admirably adapted for all ordinary purposes of construction, and of late has obtained favourable notice in shipbuilding, remaining sound in water for a long time. For spars and masts it is unsurpassed, both as to strength, straightness, and length. Masts for export are usually hewn to octagonal shape from 20 to 32 inches in diameter by 120 feet long. Yards are generally hewn out from 12 to 24 inches in diameter and 50 to 102 feet long. Masts and spars are generally sent to Great Britain; other forms of timber to South America, Australia, India, China, and the Sandwich Islands. Of the *Thuja gigantea*, which in favourable situations on the coast reaches a height of 100 to 150 feet, the pale yellowish or reddish wood is stated to be very durable, though not extensively used except for shingles. The large and elegant canoes of the Indians are made of the hollowed trunks, and the fibre of the inner bark is used for ropes and cordage, as well as for paper-making and other purposes. One of the most remarkable uses for a wood is referred to under *Pinus contorta*, where it is said that the cambium layer contains much sugar, and for that reason it is eaten by the natives in the spring of the year, and in some instances large quantities of it are collected and dried for winter use.

THE *Boston Herald* gives the following account of an American experiment made on September 2:—"A novel exhibition of powerful electric lights was made last evening in the vicinity of the Sea Foam-house, Nantucket Beach, and the display was witnessed by quite a crowd of interested spectators. The Northern Electric Light Company have erected three wooden towers, each 100 feet high, and mounted upon each of these a circular row of twelve electric lights of the Weston patent, each light being estimated at 2,500-candle power. As these towers are but 500 feet apart and in a triangle, it will be seen that the light of 90,000 candles was concentrated within a limited territory. The design of the exhibition was to afford a model of the plan contemplated for lighting cities from overhead in vast areas, the estimate being that four towers to a square mile of area, each mounting lights aggregating 90,000-candle power, will suffice to flood the territory about with a light almost equal to midday. Last evening a motive power of thirty-six horses was used in generating the electricity from three Western machines, and the lights, with one single slight flicker, burned steadily and brilliantly all the evening. It is difficult to say whether the experiment proved anything or not. The claim put forward by the company is for an original plan of lighting cities and towns by grouping and elevating electric lights of any kind."

WE have received Part 1 of the *Transactions* of the Epping Forest and Essex Field Club, containing Mr. Henry Walker's interesting lecture on "A Day's Elephant Hunting in Essex."

AT the Leeds Philosophical and Literary Society the following are among the lectures to be given this winter:—October 20, Prof. Silvanus P. Thompson, D.Sc., "Waves of Sound and the Photophone"; November 16, H. Clifton Sorby, LL.D., F.R.S., "The Structure and Origin of Meteorites and Meteoric Iron"; December 7, Dr. Sydney H. Vines, "The Nutrition of Plants"; December 21, Prof. E. Ray Lankester, F.R.S., "Degeneration"; February 15, 1881, Prof. T. E. Thorpe, Ph.D., F.R.S., "The Azores"; March 1, J. W. Swan, "The Electric Light, with Demonstrations."

OUR ASTRONOMICAL COLUMN

THE BINARY STAR δ EQUULEI.—Mr. Burnham publishes a new epoch for this star, which there is now good reason to conclude will prove to be the most rapid revolver amongst the binary systems; on this account it well deserves the attention which Mr. Burnham claims for it at the hands of those observers who are in possession of instruments competent to cope with so close a double-star. The duplicity was detected by M. Otto Struve on August 19, 1852, with the Pulkowa refractor, when definition was unusually good, and the components almost equal in magnitude were "à peine séparées par une ligne noire." In 1853 and 1854 it appeared single in the same instrument. The object was elongated in the summer of 1857, and at the date 1858·59 M. Struve saw the stars separated at moments, and they were again divided in the autumn of 1874. As is pointed out in the Pulkowa Observations, vol. ix., the case is evidently a similar one to that of 42 Comæ Beren., the visual ray coinciding very nearly with the plane of the orbit, so that the companion appears to oscillate backwards and forwards almost in a right line, and that of very small extent. M. Struve has established the period of revolution of 42 Comæ to be only about twenty-five years, but δ Equulei appears to indicate a period of only thirteen or fourteen years. Mr. Burnham finds from five nights' measures with the 18½-inch Chicago refractor,

1880·60, Position 29°·1, Distance 0″·35.

In September, 1870, Dunér remarked of this star: "Oblongue, j'en suis bien sur. Les diamètres sont comme 3 : 5," and the angle was estimated 8°. The only measures except Mr. Burnham's are those of M. Otto Struve. The magnitudes of the components are so nearly equal (the American observer considered there was a difference of only about two or three tenths of a magnitude), that care will be necessary to place the smaller star in its proper quadrant. Mr. Burnham adds: "It seems certain that it is measurable with any good instrument of ten inches aperture and upwards at least one year in every six years," and he believes that it is now near its maximum distance.

FAYE'S COMET.—The following positions are extracted from Dr. Axel-Möller's ephemeris for Berlin midnight:—

	R.A. h. m. s.	N.P.D. ° ′	Log. distance from Earth.	Sun.
Oct. 22	22 48 22	88 50·8	0·0506	0·2892
24	— 48 58	89 9·8	0·0532	
26	— 49 43	89 27·8	0·0561	0·2855
28	— 50 37	89 45·0	0·0591	
30	— 51 39	90 1·2	0·0623	0·2819
Nov. 1	— 52 50	90 16·5	0·0656	
3	— 54 9	90 30·7	0·0691	0·2785
5	— 55 37	90 43·8	0·0727	
7	22 57 2	90 55·9	0·0764	0·2751

The comet remains sensibly at the same intensity of light (not far from the maximum of the present appearance) during this period. On October 26 it will be within 20′ from 1 Piscium (B.A.C. 7985), and on November 3 very close to 3 Piscium (B.A.C. 8012), stars of the sixth magnitude.

HARTWIG'S COMET.—The subjoined places of this comet are from the calculations of Dr. Oppenheim, and are also for Berlin midnight:—

	R.A. h. m. s.	N.P.D. ° ′	Log. distance from Earth.	Sun.
Oct. 22	17 52 1	76 23·8	0·0582	0·0610
24	17 58 30	77 13·0	0·0826	
26	18 4 22	77 57·3	0·1057	0·0883
28	18 9 43	78 37·2	0·1276	
30	18 14 39	79 13·2	0·1483	0·1136
Nov. 1	18 19 13	79 45·7	0·1680	
3	18 23 26	80 15·1	0·1868	0·1370

COMETS 1880, *d* AND *e*.—M. Bigourdan has continued his ephemeris of the comet discovered by Schäberle on April 6, but states from observations made at Paris that the intensity of light has diminished much more rapidly than is due to change of distance from the earth and sun; on September 30 he estimated the comet to be of the same brightness as on May 18; it is still in a favourable position for observation, as will be seen from the following extract from M. Bigourdan's ephemeris for Paris midnight:—

	R.A. h. m. s.	N.P.D. ° ′		R.A. h. m. s.	N.P.D. ° ′
Oct. 22 ...	5 56 3 ...	89 49	Oct. 30 ...	5 34 22 ...	94 55
24 ...	– 50 57 ...	91 4	Nov. 1 ...	5 28 27 ...	96 12
26 ...	– 45 38 ...	92 21	3 ...	5 22 21 ...	97 28
28 ...	– 40 6 ...	93 38	5 ...	5 16 6 ...	98 44

The Astronomer-Royal has notified the discovery of another comet by Mr. Lewis Swift of Rochester, N.Y., on the night of October 11, in R.A. 21h. 30m. and Decl. + 18°.

METEOROLOGICAL NOTES

PROF. LOOMIS, in his thirteenth contribution to meteorology, investigates the question of the great and sudden changes of temperature which are so marked a feature in the climates of a large portion of the United States. Six years' observations of the Signal Service stations have been examined, with the result that there are 118 stations at which there has occurred at least one case of a daily range not less than 40°·0. Limiting the inquiry, however, to stations at which the average number of cases amounted to six annually, it is seen that there are thirty-six such stations. The stations where the great fluctuations of temperature occur most frequently are situated south of lat. 35°, in which region the fluctuations of pressure attending the progress of storms are but little felt; and it is to be noted that these great fluctuations of temperature occur most frequently in the summer months. Thus at Wickenburg (lat. 34°·0, long. 112°·7), which is situated in a desert sandy region, with an annual rainfall of only 4·99 inches, on ten of the nineteen days ending with August 14, 1877, the temperature showed a daily range of at least 62°·0, reaching in one case to 76°·0. These enormous temperature changes are due to the extreme dryness of the air, by which the sand becomes intensely heated by the sun during the day, whereas by night the loss of heat by radiation is as great as perhaps anywhere on the globe. The general result of the inquiry is that the most remarkable cases are merely examples of the ordinary diurnal change of temperature, unaffected by the passage of storms, whilst the remaining cases, which occur in the higher latitudes of the States, are to be ascribed to the influence of storms along with the ordinary diurnal change of temperature. It also appears from a careful investigation that dry air, even when greatly heated, has but little ascensional force, and that the violent uprising of heated air, so frequently witnessed in moist climates, particularly during thunderstorms, is mainly due to the large amount of aqueous vapour with which it is charged. As regards great fluctuations of temperature in winter, Prof. Loomis points out that while, for example, a temperature of – 20°·0 occurs at Denver on the east side of the Rocky Mountains, an average temperature of 30°·0 prevails in the Salt Lake Basin, and remarks that by the movements of the atmosphere attending the progress of a great storm these contiguous masses of air with temperatures so different from each other are brought successively over the same station, and thus bring about a change of temperature amounting on occasions to 50°·0 in a single hour.

PROF. LOOMIS also carefully investigates the storms, with their characteristic low barometers, which cross the Rocky Mountains, and shows that no great barometric disturbances originate in the Salt Lake Basin; that nearly all the great barometric disturbances experienced in the Salt Lake Basin come from the Pacific, and generally from the north-west; and that nearly all these disturbances can be followed to the Atlantic, meeting it near lat. 47°·0, and occupying from two to six days in the passage, or an average of three and a half days, corresponding to an onward movement of about 700 English miles a day. As has been shown to obtain in other regions of the globe, the isobars which define storms are often not so symmetrical over a mountainous region as over a level country. In not a few cases however the isobars show considerable symmetry over the Rocky Mountains, and this feature becomes the more noticeable in very violent storms. From the observations made at Pike's Peak, 14,200 feet high, as well as at Mount Washington, 6,285 feet, it appears that the winds at great elevations circulate about a low barometer, just as they do near the level of the sea; but the position of this centre at great heights sometimes differs considerably from the low centre prevailing at the surface of the earth, and when such deviation does occur it is generally toward the north-west. Of the thirty-six cases examined, the low centre at great elevation was, in twenty-seven cases, vertical over the low centre at lower levels, in five cases to north-west, in one case to north, in another case to west, and in two cases to east. It must however not be lost sight of that this important point in the phenomena of storms cannot be exactly determined but by a multiplication of high-level stations.

DISPLAYS of auroras appear to have been remarkably frequent in America during August last. In Mr. Carpmael's Weather Report of the month for Canada it is stated that the aurora of the 12th was very brilliant, and was seen at nearly every station from Manitoba to the Atlantic. From the United States Monthly Weather Report we learn that auroras were frequent during the month, occurring on no fewer than twenty-one nights, the auroras of the 12th and 13th being of remarkable brilliancy, as well as widespread. On these nights the aurora was seen at about 100 stations from Maine westward, as far as clear skies allowed its being seen. The more prominent features of these auroras as detailed in the Report are of such interest as to suggest that a more detailed account of them, as seen in the northern hemisphere during the night of August 12 and 13, could not fail to contribute data of the greatest importance in this little-understood branch of physics.

IN the *Journal* of the Scottish Meteorological Society, recently published, there is a paper of some interest, by Mr. Buchan, on the diurnal periods of thunderstorms in Scotland. There are two well-marked types of thunderstorms, the one occurring in the summer months, and having its daily maximum frequency from 1 p.m. to 6 p.m., and the other occurring in the winter months, with its maximum from 9 p.m. to 3 a.m. Stations in the eastern division of the country where the annual rainfall is small, or only of moderate amount, have all, or nearly all, their thunderstorms during the summer months; whereas in the west, or where the climate is wet and the rainfall heavy, a very considerable proportion of the thunderstorms occur during the winter months, and these are nearly always of short duration, and are the accompaniments of the winter cyclones of North-Western Europe. In this connection it is interesting to note that the thunderstorms of Stykhisholm in Iceland are phenomena of the winter months and of the nights, only three being recorded as having happened at a time of the day when the sun was above the horizon. The maximum daily period of the summer thunderstorm coincides with the hours when the ascending columns of heated air from the earth's surface are in full activity, and the result is no doubt largely due to the circumstance that these ascending masses of heated air develop a charge of electricity as their moisture condenses into cloud. The period of maximum frequency of the winter thunderstorm occurs some hours before and after midnight, or during those hours of the day when the land surface presented to the vapour-laden winds of the Atlantic approaches to and reaches its diurnal minimum temperature, and when consequently the condensation of the vapour may be expected to reach its daily maximum. On the other hand, the minimum period in summer occurs during the early morning, the absolute minimum being at the hour just before the ascending columns of heated air are set in motion, and the number remains few till about 11 a.m., or till the tops of the heated columns have risen to some height in the atmospheres.

IN the *Journal* of the Meteorological Society for April and July last are given the results of observations made during the first six months of 1880 at about forty "climatological stations" recently established by the society. At these stations observations are taken only once a day, viz., at 9 a.m., and are restricted to temperature, cloud, and rain. An extension of these stations which would include the whole of the English sanataria, and which doubtless will gradually be effected, would furnish data for a correct presentation of the comparative climatologies of the health resorts of England.

BIOLOGICAL NOTES

NEST-BUILDING AMPHIPODS.—Mr. S. J. Smith, in a memoir on some amphipods described by Thomas Say (*Trans.*, Connecticut Acad., July, 1880), states that the tubes which certain

species make to live in are to a great extent formed of pellets of their excreta. In 1874 he watched carefully the process of constructing the tubes in several species of Amphipoda. *Microdeutopus grandimanus* (*M. minax*, Smith) was a particularly favourable subject for observation. When captured and placed in a small zoophyte trough with small branching algæ, the individuals almost always proceeded at once to construct a tube, and could very readily be observed under the microscope. A few slender branches of the alga were pulled toward each other by means of the antennæ and gnathopods, and fastened by threads of cement spun from branch to branch by the first and second pairs of peræopods. The branches were not usually at once brought near enough together to serve as the framework of the tube, but were gradually brought together by pulling them in and fastening them a little at a time, until they were brought into the proper position, where they were firmly held by means of a thick network of fine threads of cement spun from branch to branch. After the tube had assumed very nearly its completed form, it was still usually nothing but a transparent network of cement threads woven among the branches of the alga, though occasionally a branch of the alga was bitten off and added to the framework: but very soon the animal began to work bits of excrement and bits of alga into the net. In this case the pellets of excrement, as passed, were taken in the gnathopods and maxillipeds, and apparently also by the maxillæ and mandibles, and broken into minute fragments and worked through the web, upon the outside of which they seemed to adhere, partially by the viscosity of the cement threads, and partially by the tangle of threads over them. Excrement and bits of alga were thus worked into the wall of the tube until the whole animal was protected from view, while, during the whole process, the spinning of cement over the inside of the tube was kept up. When spinning the cement threads within the tube the animal was held in place on the ventral side by the second pair of gnathopods and the caudal appendages, the latter being curved beneath the anterior portion of the pleon, and on the dorsal side by the third, fourth, and fifth pairs of peræopods extended and turned up over the back, with the dactyli turned outward into the web. The spinning was done wholly with the first and second peræopods, the tips of which were touched from point to point over the inside of the skeleton tube in a way that recalled strongly the movements of the hands in playing upon a piano. The cement adhered at once at the points touched and spun out between them in uniform delicate threads. The threads seemed to harden very quickly after they were spun, and did not seem even from the first to adhere to the animal itself.

Death by Hanging.—Recent experiments regarding the nature of death by hanging or strangulation induce Prof. Tammasia to reject the view that the chief cause of such death is compression of the pneumogastric, causing paralysis of the heart (*Reale Ist. Lomb.*, fasc. xiii.). In the great majority of cases, he says, the proximate cause of death is the occlusion of the respiratory passages. The greater or lesser rapidity of the death depends on the degree of such occlusion. Compression of the pneumogastric and of the vessels of the neck may strengthen the efficacy of that direct cause, but, in the absence of the latter, it is insufficient to cause any instantaneous lethal phenomenon, as some have supposed.

Hæmoglobin in Echinoderms.—The presence of hæmoglobin in the aquiferous system of an Echinoderm (*Ophiactis virens*, one of the Ophiurida) has lately been demonstrated by M. Foettinger (Belgian Acad. *Bull.*, No. 5). The only branches of the metazoa in which it had not before been found were echinoderms and zoophytes. Simroth observed certain globules in the ambulacral canals of the former, but not observing live individuals, he missed the hæmoglobin, which may be observed if one of the arms of the living animal be broken; a drop of red colour appearing presently at the extremity. With the spectroscope the identity of the colouring matter with that of the blood of vertebrates can be easily proved. The hæmoglobin is connected with globules, of varying form and size. Most have a nucleus and are true cells. Along with these are free nuclei and small unnucleated corpuscles charged with hæmoglobin.

An Optical Property of the Cornea.—Prof. Fleischl of Vienna has recently examined fresh corneas in polarised light, and found that the corneal fibres became, under tension, doubly refractive, and then occasionally give phenomena similar to those occurring in starch granules (the theory of which has been examined by von Lang). With this condition also is connected the opacity of the cornea on rise of intraocular pressure.

Phosphoric Acid in the Urine of Cows.—It is generally supposed that the urine of herbivora does not contain phosphoric acid. M. Chevron, however, lately had occasion (*Bull. de l'Acad. Roy. de Belg.*, No. 8) to observe phosphates (a combination of potassico-magnesian phosphate with bimagnesic phosphate) in the urine of cows which had been receiving linseed oil-cake ($1\frac{1}{2}$ kil. per head daily), bran ($1\frac{1}{2}$ kil.), beet (25 kil.), and straw ($7\frac{1}{2}$ kil.), a diet which is rich in phosphoric acid (oil-cake and bran) and in potash (beet). The phosphoric acid diminished and disappeared when green clover or lucern was substituted for the beet. It appears from experiments made by Herr Bertram in Leipzig, in 1878, that lime has the property of eliminating phosphoric acid from the urine of herbivora, and M. Chevron points out that the green fodder specified undoubtedly imparted more lime than the beet did. He proposes further experiment, however, to determine exactly the cause of elimination of the acid.

Rudimentary Coma in Godetia.—While investigating the development of the embryo sac in the different genera of Onagraceæ, writes Mr. John M. Coulter, editor of the *Botanical Gazette*, Indiana (vol. v. Nos. 8 and 9, p. 75), my attention was attracted to certain hair-like projections which appeared upon the forming ovule of Godetia (probably *G. grandiflora*). A careful examination showed them to be identical in structure with the forming hairs in the coma of Epilobium. They occurred almost exclusively at the chalazal end, one or two scattered ones being detected farther down upon the raphe. A study of the development of the coma of Epilobium shows that the first indication of it is a tuberculated appearance of the chalazal end. Presently these tubercles push out into elongating nucleated cells, which eventually develop into the long hairs of the coma. Now Godetia permanently retains this tuberculated margin at the upper end, but does not usually develop its coma any further. In the cases examined, however, the forming ovules (either in reminiscence or prophecy) stretched out their tubercles into incipient hairs. Tracing these ovules in their subsequent development, it was found that these hairs gradually disappeared until, when the ovules had become anatropous, there was no indication of them. As Godetia has been merged into Œnothera, many species of the latter were examined, to see if any such thing occurred in them; but no trace of such growth was detected. This would seem to indicate that if Godetia be not entitled to generic rank, it is at least that part of Œnothera which approaches Epilobium. A discrepancy must, however, be noticed here. In Epilobium the hairs of the coma do not begin to form until the ovule has become completely anatropous; but in the Godetia observed the incipient coma had all disappeared by the time the ovule had become anatropous, beginning to form before the nucleus is half covered by the coats. These hairs appeared in greatest size and abundance when the axis of the ovule was at right angles to its anatropous position.

PHYSICAL NOTES

A beautiful illustration of the laws of polarisation of light has lately been made by M. G. Govi. To understand it requires a somewhat careful explanation. Let a parallel beam of light be passed through a polariser, then through a thin slice of quartz cut perpendicularly to the optic axis, then through an analysing Nicol prism. It is seen, as is well known, to be coloured. This coloured light when passed into a spectroscope gives a spectrum marked by one or more dark bands, corresponding to the particular rays whose relative retardations in passing through the crystal slice have produced interference. These bands are not always in one place; they are displaced right or left (according to whether the crystal is a right-handed or a left-handed specimen) if either the analyser or the polariser be rotated. A slice of quartz about 4·3 millims. thick produces a single band. One of 8·6 millims. two bands at once in the visible spectrum, the number of bands being proportional to the thickness of the crystal. Now suppose a mechanical contrivance by which both the analyser and the spectrum can be rotated at the same velocity. A direct-vision prism attached to the front of the Nicol prism realises the optical portion of this combination. There will be seen on rotation a circular spectrum, having either red or violet at the centre and either violet or red at its outer circumference. Now since the dark band spoken of is displaced by a quantity proportional to the amount of rotation, interference will take place in this circular spectrum along points which form geometrically a spiral of Archimedes. The persistence of impressions on the retina will enable this dark spiral to be seen in its entirety,

provided the rotation be sufficiently rapid. If a thicker piece of quartz be used, giving two, three, or four dark bands, the rotation-spectrum will present a most beautiful appearance, being crossed by a two-branched, or three-branched, or four-branched spiral, the separate lines of which proceed from the centre to the circumference. The sense of these dark spirals will change with the sense of the impressed rotation. The effects are very striking.

SEVERAL ingenious contemporaries of ours on this side of the Atlantic have furnished the eager appetites of their readers with diagrams of Graham Bell's photophone, of which the most casual observer cannot fail to notice the utter want of resemblance to one another. More than one at least of these is *ben trovato*.

LIQUID OZONE has been obtained by MM. P. Hautefeuille and J. Chappuis, and is found to be of a beautiful blue colour. If a mixture of oxygen and ozone at a temperature of about $-23°$ or $-25°$ be subjected to a considerable pressure, the ozone liquefies and will remain liquid even though the pressure be reduced to 10 atmospheres. Experiments involving alterations of pressure must however be carefully made; for the ozone is liable to change into oxygen with a sudden evolution of heat, producing an increase of pressure with explosive violence. It is necessary to interpose a layer of sulphuric acid upon the top of the column of mercury by which the pressure is applied in the instrument, as ozone acts directly on the mercury.

HERR HANKEL has recently (*Wied. Ann.*, No. 8) endeavoured to prove the direct transformation of vibrations of radiant heat into electricity. He had formerly shown that rock crystal has thermoelectric polar axes in the direction of its secondary axes (the six successive poles being alternately positive and negative), and he supposes the ether within the crystal to be so arranged that under influence and with participation of the material molecules it is movable in circular paths round the secondary axes, and more easily movable in one direction than in the other. Thus all along a secondary axis the more easily occurring rotation has the same direction, but looked at from without, the direction is opposite at one end to what it is at the other, so giving the opposite modifications of electricity. When radiations from without strike along such an axis, those vibrations in them whose direction coincides with that of the easier rotation of the ether-molecule in the crystal should induce rotation of this along with the material molecule, and at the two ends of the secondary axis there should be electric tensions, with opposite electricity. Herr Hankel verified this by placing an insulated metallic ball connected with a gold-leaf electroscope in the middle of one edge of a rock crystal fixed with its principal axis vertical, while sunlight was thrown from the other side along the secondary axis terminating at the ball; then the arrangement was reversed. The electroscope indicated opposite electricities in the two cases. A gas-flame or a heated ball gave similar effects, which, moreover, were proved to be due to the dark heat rays (not to the luminous rays).

THE specific rotatory power of paraglobulin in blood serum is $47°.8$ for yellow light; that of albumen, $57°.3$. As these are the only albuminoid substances present in any considerable quantity, two determinations with the aid of the polaristrobometer suffice (as M. Fredericq has shown to the Belgian Academy) for ascertaining their relative proportions. The rotation produced by the whole liquid is first determined; then the paraglobulin is precipitated with $MgSO_4$, then redissolved in a volume of water equal to that of the original serum, and the rotation-number got from this is deducted from that got previously. Each of the numbers divided by that representing the specific rotatory power of the corresponding substance indicates the quantity of the substance in 100 cc.

IN a recent brief memoir to the *R. Accademia dei Lincei* (*Atti*, June, 1880), Dr. Bartoli describes an ingenious application of the Bunsen calorimeter to determination of the mechanical equivalent of heat. A given mass of mercury at zero temperature is subjected to a considerable pressure, exactly determined, and passed through a steel tube of so small internal diameter and such length that its velocity of outflow is virtually *nil*, and so the work equivalent to the kinetic energy of the mercury issuing from the tube becomes negligible in presence of the work consumed by friction between the mercury and the walls of the tube. This tube penetrates into a metallic cylinder situated within the reservoir of the Bunsen calorimeter. The quantity of ice melted in the calorimeter serves as measure of the heat developed by the work of efflux of mercury. It is stated that the numerical results are noteworthy for their agreement with the mean of former determinations, and still more for the narrow limits between which the extreme values arrived at are comprised.

EXPERIMENTS with regard to interpretation of the unequal reversal of magnesium lines in the green part of the solar spectrum are detailed by M. Fiévez in a recent paper to the Belgian Academy (*Bull.* No. 8). He first examined the influence of relative intensity of bright magnesium lines on their visibility by observing them separately and projecting them on the solar spectrum. Then he repeated the experiments of simplification of the spectrum by varying the intensity of the spark. Lastly, he studied the influence of greater or less dispersion and definition on the number and visibility of the lines, comparing prismatic with diffraction spectra. The experimental arrangements were mainly the same as in his recent researches on the spectra of hydrogen and nitrogen. The conclusion he arrives at is that the unequal reversal in question is due merely to a difference in the intensity of the bright lines, not to a dissociation of the metal.

M. BOUTY considers he has proved (*Journal de Phys.*, September) that in simple electrolysis the Peltier phenomenon is produced according to the same laws as at the surface of contact of two metals. It is a purely physical phenomenon without known relations with the heat of combination, or with the latent heat of solution, but connected by a precise law with the thermo-electric forces of corresponding couples. Chemical actions intervene in the production of one or other of the two inverse phenomena merely as disturbing causes, either altering the nature of the surfaces or producing a secondary liberation of heat. They may mask, more or less, the phenomenon on which they are superposed, but they do not produce it.

GEOGRAPHICAL NOTES

MR. LEIGH SMITH, during his Arctic cruise in his yacht *Eira*, has evidently done some very good work this summer. After cruising about the east coast of Greenland and in the neighbourhood of Spitzbergen, finding the ice-pack too dense and too far south to get far north without danger—although he reached 79° 40′ N. in 46° 50′ E., the farthest point yet reached in that direction—Franz-Josef Land was reached on August 14. Here much exploring work was done. Land was found stretching away west and north-west from that discovered by the Austrians. A fine harbour, called after the *Eira*, was found in 80° 5′ 25″ N., 48° 50′ E., and several excursions were made from this basis, among the numerous fjörds that pierce the mainland north and north-west. From the point named by the last Dutch expedition Barentz Hook, land was traced westwards some 110 miles, and from the extreme north-west point reached land was sighted forty miles further north-west. In the sea between were several large and small islands, all covered with glaciers and snow-fields, with bluff black headlands on the southern exposure, covered with vegetation. Several Arctic flowers were collected and brought home; a number of soundings and dredgings were made, yielding interesting results, and two bears which were caught have been sent to the Zoological Gardens. Evidently there is here a considerable archipelago, if not continuous stretch of land, giving some support to Petermann's theory that the Pole is probably surrounded by numerous islands. It is stated that Mr. Leigh Smith goes back next year; we trust he will reach Eira Harbour early, and be able to still further extend our knowledge of these new Arctic lands.

THE October number of *Petermann's Mittheilungen* contains several good papers. There is an interesting account of the progress of the Japanese trading station in Corea, which now contains about 2,000 Japanese inhabitants. Important information is given as to the results of Dr. O. Finsch's voyage in the Pacific. During a stay in the Sandwich Islands he made considerable additions to our knowledge of their natural history; thence he went to Jabut (Bonham) in the south of the Marshall Group, where his collections and observations in all directions were numerous and of great value. Thence he proceeded to the Gilbert or Kingsmill Group, and afterwards to the Carolines. Some idea of the results so far may be obtained from the fact that he has sent to Europe something like thirty boxes of collections; the materials collected in ten months embrace 70 mammals, 180 birds, 800 reptiles, 1,200 fishes, 15,000 molluscs, 800 crustaceans, 400 spiders, 1,400 insects, and about 150 other animals, besides 700 plants, and two boxes of minerals. In anthropology there are 50 skulls and 55 casts of faces, representing the peoples

of 20 different islands, besides 1,500 ethnographical objects. Dr. Hann contributes "Some Results of Recent Meteorological and Hypsometric Observations in Equatorial East Africa;" Col. Mason-Bey, a detailed account of Dar-fur; and Prof. Ratzel, a paper on the Formation of Fjörds in Inland Seas.

UNDER the title of "Some Heroes of Travel," the Society for Promoting Christian Knowledge has issued a volume by that versatile and successful compiler Mr. Davenport Adams. It contains the stories of Marco Polo, G. F. Ruxton (Mexico and the Rocky Mountains), Barth, T. W. Atkinson (Siberia and Central Asia), Miss Tinné, Mr. McGahan, Col. Warburton, (Australia), Major Burnaby, and Sir Samuel Baker. Mr. Adams seems to have done his work conscientiously, and the book is likely to interest youthful readers and those fond of tales of adventure.

VOL. v. of Dr. Robert Brown's "Countries of the World" (Cassell) includes Siberia, the Chinese Empire, Burmah, and the other countries of the Indo-Chinese peninsula, India and neighbouring countries, Central Asiatic States, Russian Central Asia, and Persia. The new volume is quite up to the mark of the previous ones, and the numerous illustrations are well selected.

M. E. S. ZEBALLOS, writing from Buenos Ayres to *L'Exploration*, states that he has returned from the exploration of the Pampas of the Argentine Republic, and instead of finding them the featureless dead level which they are usually described, he discovered majestic mountains, lakes, rivers, and other features, which will materially change the map of South America. M. Zeballos kept minute records of his expedition, topographical, descriptive, scientific, meteorological, &c., which we hope will be placed within the reach of European geographers.

IN the last number of the *Bulletin* of the Eastern Siberian (Iskutsk) Section of the Russian Geographical Society is the continuation of the Report of M. Tcherski of the results of his three years geological exploration of the neighbourhood of Lake Baikal.

THE fourth Belgian expedition, under Capt. Raemackers, had got well into Central Africa from Bagamoyo by the end of August.

THE FIRST DECADE OF THE UNITED STATES FISH COMMISSION—ITS PLAN OF WORK AND ACCOMPLISHED RESULTS, SCIENTIFIC AND ECONOMICAL[1]

THERE are now no less than nine departments of the Government devoted, in part or wholly, to researches in pure and applied science—the Geological Survey, the Coast and Geodetic Survey, the Naval Observatory, the National Museum, the Department of Agriculture, the Entomological Commission, the Tenth Census, with its special agencies for the study of the natural resources of the country, the Smithsonian Bureau of Ethnology, and the Commission of Fish and Fisheries. The Smithsonian Institution, established upon an independent foundation, should also be mentioned, as well as the Medical Museum of the Army and the various laboratories under the control of the Army and Navy Departments.

The Geological Survey is not now carrying on any of the schemes of zoological and botanical investigation engaged in by its predecessors.

The work of the Entomological Commission and that of the Census, though of extreme importance, are limited in scope and duration, while that of the Agricultural Department is necessarily, for the most part, economical.

The work of the National Museum is chiefly confined to the study of collections made by Government Surveys, or individual collectors, as sent in to be reported upon.

The work of the Fish Commission, in one of its aspects, may perhaps be regarded as the most prominent of the present efforts of the Government in aid of aggressive biological research.

On the 9th of February, 1871, Congress passed a joint resolution which authorised the appointment of a Commissioner of Fish and Fisheries. Prof. Baird, at that time Assistant-Secretary of the Smithsonian Institution, was appointed, and entered at once upon his duties.

The summer of 1880 marks the tenth season of active work since its inception in 1871. The Fish Commission now fills a place tenfold more extensive and useful than at first. The present essay aims to show, in a general way, what it has done, is doing, and expects to do—its purposes, its methods, its results.

[1] Read before the American Association for the Advancement of Science, Boston, August 28, 1880, by G. Brown Goode.

The work is naturally divided into three sections—

1. The systematic investigation of the waters of the United States and of the biological and physical problems which they present.—In making his original plans the Commissioner insisted that to study only the food-fishes would be of little importance, and that useful conclusions must needs rest upon a broad foundation of investigations purely scientific in character. The life-history of species of economic value should be understood from beginning to end, but no less requisite is it to know the histories of the animals and plants upon which they feed, or upon which their food is nourished; the histories of their enemies and friends, and the friends and foes of their enemies and friends, as well as the currents, temperatures, and other physical phenomena of the waters in their relation to migration, reproduction, and growth. A necessary accompaniment to this division is the amassing of material for research to be stored in the National and other Museums for future use.

2. The investigation of the methods of the fisheries of the past and present, and the statistics of production and commerce in fishery products.—Man being one of the chief destroyers of fish, *his* influence upon their abundance must be studied. Fishery methods and apparatus must be examined and compared with those of other lands, that the use of those which threaten the destruction of useful fishes may be discouraged, and that those which are inefficient may be replaced by others more serviceable. Statistics of industry and trade must be secured for the use of Congress in making treaties or imposing tariffs, to show to producers the best markets, and to consumers where and with what their needs may be supplied.

3. The introduction and multiplication of useful food-fishes throughout the country, especially in waters under the jurisdiction of the general Government, or those common to several States, none of which might feel willing to make expenditures for the benefit of the others.

Although activity in this direction may be regarded in the light of applied rather than pure scientific work, it is particularly important to the biologist, since it affords opportunities for investigating many new problems in physiology and embryology.

Since the important fisheries centre in New England the coast of this district has been the seat of the most active operations in marine research. For ten years the Commissioner, with a party of specialists, has devoted the summer season to work at the shore at various stations along the coast from Connecticut to Nova Scotia. A suitable place having been selected, a temporary laboratory is fitted up with the necessary appliances for collecting and study. In this are placed from ten to twenty tables, each occupied by an investigator, either an officer of the Commission or a volunteer. From 1873 to 1879 important aid was rendered by the Secretary of the Navy, who detailed for this service a steamer to be used in dredging and trawling, and this year the steamer built expressly for the Commission is employed in the same manner.[1]

The regular routine of operations at a summer station includes all the various forms of activity known to naturalists: collecting along the shore, seining upon the beaches, setting traps for animals not otherwise to be obtained, and scraping with dredge and trawl the bottom of the sea at depths as great as can be reached by a steamer in a trip of three days. In the laboratory are carried on the usual structural and systematic studies, the preparation of museum specimens and of reports. Since the organisation of the Commission the deep-sea work and the investigation of invertebrate animals has been under the charge of Prof. Verrill, who had for many years before the Commission was established been studying independently the invertebrate fauna of New England.

In addition to what has been done at the summer station, more or less exhaustive investigations have been carried on by smaller parties on many parts of the coast and in interior waters.

[1] The number of dredging and trawling stations on record is as follows:—

1871.	Wood's Holl	345
1872.	Eastport. 200 by hand, 36 by steamer	236
1873.	Portland	149
1874.	Noank...	223
1875.	Wood's Holl	169
1877.	Salem	
"	Halifax	
1878.	Gloucester	378
1879.	Provincetown	
		1,500

The number of seine hauls is about 600.

The fauna of the Grand Banks and other off-shore fishing-grounds has been partly explored. In 1872, 1873, and 1874 dredging was carried on from the Coast Survey steamer *Bache* by Prof. Packard and Mr. Cooke, Prof. Smith, Mr. Harger, and Mr. Rathbun. In 1879 Mr. H. L. Osborne spent three months in a cod-schooner collecting material on the Grand Banks, and Mr. N. P. Scudder as long a time on the Holibut Grounds of Davis's Straits.

A most remarkable series of contributions has been received from the fishermen of Cape Ann. When the Fish Commission had its head-quarters at Gloucester, in 1878, a general interest in the zoological work sprang up among the crews of the fishing-vessels, and since that time they have been vying with each other in efforts to find new animals. Their activity has been stimulated by the publication of lists of their donations in the local papers, and the number of separate lots of specimens received to the present time exceeds 800. Many of these lots are large, consisting of collecting-tanks full of alcoholic specimens. At least thirty fishing-vessels now carry collecting-tanks on every trip, and many of the fishermen, with characteristic superstition, have the idea that it insures good luck to have a tank on board, and will not go to sea without one. The number of specimens acquired in this manner is at least 50,000 or 60,000, most of them belonging to species otherwise unattainable. Each holibut vessel sets, twice daily, lines from ten to fourteen miles in length, with hooks upon them six feet apart, in water 1,200 to 1,800 feet in depth, and the quantity of living forms brought up in this manner, and which had never hitherto been saved, is very astonishing. Over thirty species of fishes have thus been added to the fauna of North America; and Prof. Verrill informs me that the number of new and extra-limital forms thus placed upon the list of invertebrates cannot be less than fifty.

A permanent collector, Mr. Vinal N. Edwards, has been employed at Wood's Holl and vicinity since 1871, and many remarkable forms have also been discovered by him. No dredging has yet been attempted by the Commission south of Long Island. Dr. Yarrow, Mr. Earll, and others, have collected from Cape May to Key West. The Gulf States Coast was explored last winter by a party conducted by Mr. Silas Stearns, who spent nine months in studying the food-fishes and useful invertebrates in behalf of the Commission and the Census. The entire Pacific coast has been scoured by Prof. Jordan for the Commission and the Census, and the ichthyology of that region has been enriched by the discovery of sixty species new to the fauna, forty of them being new to science. A similar investigation on the great lakes has been carried over a period of several years by the late Mr. Milner and Mr. Kumlien. The ichthyology of the rivers of the country has received much attention from the many experts employed by the Commission in fish-cultural work.

In addition to these local studies may be mentioned the general explorations such as are now being carried on for the oyster by Mr. Ernest Ingersoll and Mr. John F. Ryder, for the shad by Col. McDonald, for the smelt and the Atlantic salmon by Mr. C. G. Atkins, and the Quinnat salmon by Mr. Livingston Stone.

A partial indication of what has been accomplished may be found in the number of species added to the various faunal lists. Take, for instance, the cephalopod mollusks of New England, in Prof. Verril's recently published monographs; twenty species are mentioned, thirteen of which are new to science. Ten years ago only three were known.

I am indebted to Prof. Verrill for the following estimate of the number of species added within the past ten years to the fauna of New England, mainly by the agency of the Commission:—

	Formerly known.	Additions.	Now known.
Crustacea	105	193	298
Pycnogonida	5	10	15
Annelida	67	238	305
Vermes	39	100	139
Mollusca	317	109	426
Echinodermata	47	41	88
Anthozoa or Polyps	20	35	55
Hydrozoa or Acalepha	102	78	180
Tunicata	26	25	51
Polyzoa	56	91	147
Brachiopoda	5	0	5
Sponges	10	80	90
	800	1,000	1,800

It is but just to say that many of these species were obtained by Prof. Verril in the course of his independent explorations in Maine and Connecticut previous to 1871.

A similar estimate for the fishes indicates the discovery of at least 100 species on the Eastern Atlantic coast within ten years; half of these are new to science. Forty species have been added to the fauna north of Cape Cod; sixteen of these are new and have been found within three years. Seventeen have been described as new from the Gulf of Mexico. Sixty and more have been added upon the west coast. The results of the summer campaigns are worked in winter in the Peabody Museum of Yale College, under the direction of Prof. Verril, and by the specialists of the National Museum.

One of the important features of the work is the preparation of life-histories of the useful marine animals of the country, and great quantities of material have been accumulated relating to almost every species. A portion of this has been published. More or less complete biographical monographs have been printed on the bluefish, the scup, the menhaden, the salmon, and the whitefish, and others are nearly ready. Another monograph which may be referred to in this connection is that of Mr. Starbick on the whale-fishery, giving its history from the earliest settlement of North America.

The temperature of the water in its relation to the movements of fish has from the first received special attention. Observations are made regularly during the summer work, and at the various hatching-stations. At the instance of the commissioner, an extensive series of observations have, for several years, been made under the direction of the chief signal officer of the army, at lighthouses, light-ships, life-saving and signal stations, carefully chosen along the whole coast. This year thirty or more fishing schooners and steamers are carrying thermometers to record temperatures upon the fishing-grounds, a journal of the movements of the fish being kept at the same time. One practical result of the study of these observations has been the demonstration of the cause of the failure of the Menhaden fisheries on the coast of Maine in 1879—a failure on account of which nearly 2,000 persons were thrown out of employment. Another important series of investigations carried on by Commander Beardsley of the Navy shows the error of the ordinary manner of using the Casel-Miller deep-sea thermometer; still another series made by Dr. Kidder of the Navy, and to be carried out in future, had for its object the determination of the temperature of the blood of marine animals. Observations have also been made by Mr. Milner upon the influence of a change from sea water into fresh water, and from fresh water into sea water upon the young of different fishes. Mr. H. J. Rice carried on a series of studies upon the effect of cold in retarding the development of incubating fish-eggs. A series of analyses have been made by Prof. Atwater to determine the chemical composition and nutritive value of fish as compared with other articles of food. This investigation is still in progress. In connection with the work of fish-culture, much attention has been paid to embryology. The breeding times and habits of nearly all of our fishes have been studied and their relations to water temperatures. The embryological history of a number of species such as the cod, shad, alewife, salmon, smelt, Spanish mackerel, striped bass, white perch, and the oyster, have been obtained, under the auspices of the Commission, by Messrs. Brooks, Ryder, Schaeffer, Rice, and others.

The introduction of new species in water in which they were previously unknown is of special interest to the student of geographical distribution. Through the agency of the Commission the German carp has already been placed in nearly every State and Territory, although the work of distribution has only just begun, and the tench (*Tinca vulgaris*) and the golden orfe (*Idus m lanotus*) have been acclimated; the shad has been successfully planted in the Mississippi valley and on the coast of California, and the California salmon in the rivers of the Atlantic slope. The lake whitefish of Europe has been introduced into a lake of Wisconsin. As an act of international courtesy, California salmon have been successfully introduced into New Zealand and Germany. The propagation work has increased in importance from year to year, as may be seen by the constant increase in the amount of the annual appropriation. A review of the results of the labours of the Commission in increasing the food supply of the country may be found in the annual reports. The rude appliances of fish culture in use ten years ago have given way to scientifically devised apparatus, by which millions of eggs are hatched where only thousands were before, and the demonstration of the possibility of stocking rivers and lakes to any

desired extent has been greatly strengthened. This work was for six years most efficiently directed by the late Mr. James W. Milner, and is now in charge of Major T. B. Ferguson, also Commissioner for the State of Maryland, by whom has been devised the machinery for propagation on a gigantic scale, by the aid of steam, which is now so successfully in use.

The investigation of the statistics and history of the fisheries has perhaps assumed greater proportions than was at first contemplated. One of the immediate causes of the establishment of the Commission was the dissension between the line and net-fishermen of southern New England with reference to laws for the protection of the deteriorating fisheries of that region. The first work of Prof. Baird as Commissioner was to investigate the causes of this deterioration, and the report of that year's work includes much statistical material. In the same year a zoological and statistical survey of the great lakes was accomplished, and various circulars were sent out in contemplation of the preparation of monographic reports upon the special branches of the fisheries, some of which have already been published.

Some thirty trained experts are now engaged in the preparation of a statistical report on the present state and the past history of the fisheries of the United States. This will be finished next year, but the subject will hereafter be continued in monographs upon separate branches of the fisheries, such as the holibut fishery, the mackerel fishery, the shad fishery, the cod fishery, the herring fishery, the smelt fishery, and various others of less importance.

Hundreds, and even thousands of specimens of a single species are often obtained. After those for the National Museum have been selected, a great number of duplicates remain. These are identified, labelled, and made up into sets for exchange with other museums and for distribution to schools and small museums. This is in accordance with the time-honoured usage of the Smithsonian Institution, and is regarded as an important branch of the work. Several specialists are employed solely in making up these sets and in gathering material required for their completion. Within three years fifty sets of fishes in alcohol, including at least ten thousand specimens, have been sent out, and fifty sets of invertebrates, embracing 175 species and 25,000 specimens. One hundred smaller sets of representative forms intended for educational purposes, to be given to schools and academies, are now being prepared. The arrangement of the invertebrate duplicates is in the charge of Mr. Richard Rathbun; of the fishes, in that of Dr. T. H. Bean. Facilities have also been given to many institutions for making collections on their own behalf. Six annual reports have been published, with an aggregate of 5,650 pages. These cover the period 1871 to 1878. Many papers relating to the work have been published elsewhere, particularly descriptions of new species and results of special faunal exploration.

The season of 1880 was opened by the participation of the Commission in the International Exhibition at Berlin. The first honour-prize, the gift of the Emperor of Germany, was awarded to Prof. Baird, not alone as an acknowledgment that the display of the United States was the most perfect and most imposing, but as a personal tribute to one who, in the words of the president of the Deutscher Fisherei Verein, is regarded in Europe as the first fish-culturalist in the world.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—This year the term commences somewhat later than usual. The professorial lectures on natural science begin next week. At the University Museum Dr. Odling lectures on Typical Alcohols, Prof. Clifton on Experimental Electricity, Prof. Price on Hydro mechanics, Prof. Story-Maskelyne, M.P., on the Elements of Crystallography, Prof. Prestwich on Stratigraphical Geology, and Prof. Rolleston on Digestion.

Lectures are also given in the Chemical Department at the Museum by Mr. W. W. Fisher, on Inorganic Chemistry, by Mr. J. Watts on Organic Chemistry, and by Dr. F. D. Brown on Chemical Affinity. In the Biological Department Messrs. C. Robertson, W. H. Jackson, and A. P. Thomas form classes for instruction in Microscopy and Zoology. Mr. Barclay Thompson gives a course on the Comparative Anatomy of the Mammalia. In the Clarendon Laboratory Mr. Stocker lectures on Elementary Mechanics, and, with Mr. V. Jones, gives instruction in practical physics.

At the University Observatory Prof. Pritchard will lecture on Spherical Astronomy, including instruments, and will give a course of six lectures on the Precession of the Equinoxes, including the Lunar Physical Libration. The Observatory is opened on Monday and Tuesday evenings during the term to members of the University who desire to obtain instrumental practice. In his annual report to the Board of Visitors the Professor gives an account of the work carried on during the past year at the Observatory. The long series of observations in reference to the Inequalities in the Moon's Rotation are now finished, and the results will be shortly published. The calculations were brought to a successful issue during the Long Vacation, and afford a general confirmation of the investigations of Bouvard, Nicollet, and Wichmann, and establish the existence of small but sensible inequalities in the moon's rotation. Careful measurements have also been made by Mr. Plummer of the relative positions of forty stars in the Pleiades, and Mr. Jenkins has measured the relative co-ordinates of 250 stars in the cluster 39 Messier. Careful observations have also been made of the component stars of ξ Ursæ Majoris and 70 Ophiuchi. With regard to the instruments the Professor writes:—

"The large refractor has been thoroughly examined and cleaned by Mr. Grubb, the artist who constructed it. This at present is in an efficient working condition in every respect. From our own resources we have thoroughly overhauled the De La Rue Reflector, and it also is in excellent condition. It is fortunate for the University that both these instruments pass from time to time under the experienced and critical eye of Dr. De La Rue himself. For a time Dr. De La Rue's metallic speculum was replaced by an excellent silvered glass mirror, executed by Mr. With; the newer mirror possessed the greater capacity of the two, in point of brilliancy of reflected light, but was not deemed quite equal to Dr. De La Rue's in point of definition; we have therefore returned to the use of the original speculum.

"In order to carry out a new and important series of astronomical observations I soon found that the use of a chronograph was indispensable; accordingly I have, in conjunction with Mr. Grubb, devised a very inexpensive but practically efficient form of that instrument. The total cost of this instrument, together with a corresponding and necessary addition to the mechanism of the sidereal clock, has not exceeded 10*l*. I am told on the best authority that this form of the chronograph will henceforth prove a desirable adjunct in other observatories.

"With the view of bringing practical astronomy within the reach of a moderate expenditure I have (again in conjunction with Mr. Grubb) devised a modification of existing small equatorial telescopes, which I anticipate will prove a boon to beginners in astronomical science.

"Lastly, I have devised and carried into execution a simple form of precessional globe for the use of students in astronomy. It affords very ready means of representing the risings and settings of the stars, and the general aspect of the heavens at the remotest periods of time, past and future, and as seen at any locality."

In the Botanic Garden Prof. Lawson will give instruction on the Minute Anatomy of the Vegetable Tissues.

The following lectures are given in those colleges which possess laboratories. At Christ Church Mr. Vernon Harcourt lectures on the Non-metallic Elements, and Mr. R. E. Baynes on Dynamical Electricity and Conduction of Heat. At Balliol College Mr. J. W. Russell lectures on Problems in Mechanics, and Mr. H. B. Dixon on Elementary Heat and Light. At Exeter College Mr. Lewis Morgan lectures on Practical Histology, and at Magdalen College Mr. C. J. Yule gives a course of demonstrations on the Chemical Composition of the Body.

AN examination for Natural Science Scholarships is being held by Trinity and Exeter Colleges. The former College has this year for the first time offered a scholarship for proficiency in science. At Merton College the science scholarship (Postmastership) was not awarded.

AT Balliol College there will be offered next month a science scholarship, on the foundation of Miss Brakenbury, open to all candidates without limitation of age, who shall not have exceeded eight terms from matriculation. The scholarship is of the annual value of 80*l*., and is tenable for four years during residence. Papers will be set in the following subjects:—(1) Mechanical Philosophy and Physics, (2) Chemistry, (3) Physiology. Candidates will not be expected to offer themselves in more than two of these. There will be a practical examination in one or more

of the above subjects if the examiners think it expedient. Intending candidates should communicate with the Master of Balliol before November 12. There will also be offered two exhibitions worth 40*l.* a year, the examination for which will comprise the elements of Physics, Chemistry, or Physiology, as well as Classics and Mathematics.

CAMBRIDGE.—Dr. Michael Foster will lecture on elementary physiology; Mr. Langley will lecture to the advanced class on general physiology twice a week; Mr. Lea takes physiological chemistry; and Dr. Gaskell the physiology of the circulation.

Mr. VENN will lecture during the next two terms on scientific method.

MR. FREEMAN of St. John's College is to lecture as deputy for Prof. Challis, owing to his infirm health.

DR. REGINALD THOMPSON of Trinity College is to be one of the Examiners for 3rd M.B., and Dr. Cheadle to be Assessor to the Regius Professor of Physic.

THE list of lecturers at Newnham College this term includes the names of Miss Crofts (English History and Literature), Miss Merrifield (Greek), Miss Harland (Algebra), and Miss Scott (Analytical Conics). The lectures are now delivered at the College, and not in Alexandra Hall.

AT St. Thomas's Hospital Medical School Mr. Robert Lawson has obtained the Entrance Scholarship in Natural Science, of the value of 100*l.*, and Mr. Herbert Lankester that of 60*l.*

AT the meeting of the Council of the College of Physical Science, Newcastle-on-Tyne, on October 11, it was decided without opposition that a lady candidate, Miss Isabel M. Aldis, should be allowed to hold an exhibition in the College. This decision completes the opening of the advantages of the College to lady students. They were previously admitted to all the lectures, but this is the first time that a lady has been a candidate for an exhibition.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, October 11.—M. Wurtz in the chair. The following papers were read:—On the *rôle* of time in the formation of salts, by M. Berthelot. Experiments with several hundred saline mixtures prove that the period of change in saline reactions, comprised between the moment when the system has become physically homogeneous and that when it attains its chemical equilibrium, is excessively short, and wholly included in the short duration of the calorimetric experiment. The same period in ethene reactions, on the other hand, is incomparably longer. The instantaneity in the former case is proved by an application of the author's theorem of slow actions.—On pellagra in Italy, by M. Faye. In the past year there have been 40,000 well-marked cases of the disease in Lombardy, and 30,000 in Venetia, the richest and most productive provinces in Italy. It is unknown in Naples, Sicily, and Sardinia (so poverty and bad hygiene do not seem to be the causes). Wherever pellagra appears in the endemic state *polenta* or *cruchade* are eaten, *i.e.*, varieties of unfermented bread (made from maize and millet), and M. Faye thinks the substitution of fermented bread would prove salutary.—On the photophonic experiments of Prof. Bell and Mr. Sumner Tainter, by M. Breguet.—On algebraic equations, by Mr. West.—Earthquakes at Smyrna on July 29, by Dr. Charpentin. The ravages and phenomena of this earthquake were limited to the Sipyle chain and the adjoining plains in a perimeter of only a few leagues; but the *contre-coup* was felt at great distances (Broussa, Rhodes, &c.). Chronometers at Athens were stopped. More than 3,000 years ago there seems to have been a volcano under Sipyle, and this point has been the centre of earthquakes in that region. The approximate coincidence (in time) of this last Smyrna earthquake with earthquakes at Manilla, the Azores, and Naples, is remarkable.—On the effects produced by cultivation of absinthe as insectifuge, and on its preventive application against phylloxera, by M. Poirot. Among the absinthe plants covering large tracts in North America the author has never seen flies, ants, worms, or any insects, nor yet scorpions, tarantulas, nor rattlesnakes. Land manured with absinthe might be fatal to the metamorphoses of phylloxera.—Ephemerides of comet *b* 1880 (continued), by M. Bigourdan.—Observations of comet *d*, 1880 (discovered by Dr. Hartwig at Strassburg) at the Paris Observatory, by M. Bigourdan.—On the resolvent function of the equation $x^m + px + q = 0$, by M. Pujet.—On a property of Poisson's function, and on the integration of equations with partial derivatives of the first order, by M. Gilbert.—On a very extensive class of linear differential equations with rational coefficients, whose solution depends on the quadrature of an irrational algebraic product, by M. Dillner.—Principle of an algebraic calculus which contains as particular species the calculus of imaginary quantities and quaternions, by M. Lipschitz.—On the partition of numbers, by M. David.—On the mechanical actions of light, theoretical considerations capable of serving in interpretation of Prof. Bell's experiments, by M. Cros. In 1872 M. Cros presented a memoir to the Academy, in which, guided by theoretical considerations, he affirmed *à priori* the results of experiments which he thinks have a notable similarity to Prof. Bell's. In one experiment a ray of light interrupted n times a second was to be sent into a tube resonating with a note of n vibrations. The alternate rarefaction and condensation of the gaseous medium might make the tube speak.—Study of the distribution of light in the solar spectrum, by MM. Macé and Nicati. The maximum intensity is in the yellow, very near D. The perception of blue and violet diminishes much more slowly with diminished illumination than that of less refrangible colours. From the extreme red to green of about 0·5 μ wave-length, the law of distribution of intensity is the same whatever the illumination. Between eyes equally capable of discerning colour, there are very sensible differences.—Vibratory forms of circular pellicles of saposaccharic liquid, by M. Decharme. With a given diameter of pellicle the numbers of nodals are inversely proportional to the corresponding lengths of the vibrating rod (which produces the waves).—On the place which boron occupies in the series of simple bodies, by M. Etard. He places boron in the family of vanadium, very near that of phosphorus.—On propylacetal and isobutylacetal, by M. de Girard.

BALFOUR'S "COMPARATIVE EMBRYOLOGY"

A Treatise on Comparative Embryology. By Francis M. Balfour, M.A., F.R.S., Fellow and Lecturer of Trinity College, Cambridge. In Two Volumes. Vol. I. (London: Macmillan and Co., 1880.)

IT is scarcely possible to exaggerate the expressions of gratitude which are due from zoologists to Mr. Balfour for the execution of the great task which some three or four years ago he set himself. Zoologists have to be thankful to him not only for the admirable style in which he has carried out his work, but for the promptitude with which he has achieved it. Mr. Balfour's object was to produce a work in which all that has been written during the last ten or fifteen years on the structural features exhibited by animals during their growth from the egg to the adult condition should be digested, and its import carefully estimated; the result being set forth in a systematic way, so that the broad conclusions arrived at by the almost innumerable studies of "development from the egg" in all sorts and conditions of animals should be pointedly placed before the reader. At the same time he aimed to provide for the purpose of reference and for the guidance of future students something like a complete bibliography, accompanied by an analysis in many cases, of the works which have been published on special forms.

It is very well known to those who are in a position to make a comparative estimate, that during the last fifteen years in no branch of science has there been such activity, such abundance of discovery, of careful observation and ingenious speculation, as in biology; and this activity has tended more and more to concentrate itself upon the study of the mode in which the complex adult organism (whether plant or animal), with all its astounding powers and its beauty of form—slowly, surely, and yet by most improbable and devious ways, advances to its complete estate from the condition of a microscopic structureless globule of albuminous slime. This marvel of development is one which has only recently come to man's knowledge, and it seems likely that the fascination which the study of it can exert will be such as to attract the energies of an ever-increasing crowd of observers.

Mr. Balfour's book gives for those who are to come a *résumé* or summing up of the labours of those who have up to this date worked for and created our knowledge of what this process of growth from the egg is and signifies.

The first volume deals with the history of development in all groups of animals excepting the Vertebrata. The labour which it has involved will be understood when it is stated that the author gives references to five hundred and seventy-two separate memoirs or books, most of which he has thoroughly read, and from many of which he gives extracts or carefully condensed abstracts.

The thoroughness with which the subject is presented to the student may be appreciated by a consideration of the fact that two hundred and seventy-five woodcuts are given in this volume, which are, with few exceptions, prepared especially for this work, either from the author's original drawings or from the drawings of the writers whom he is summarising.

The work is divided into an "Introduction" and a "Systematic Embryology." In the Introduction we have chapters on "The Ovum and the Spermatozoon," on "The Maturation and the Impregnation of the Ovum," and on "The Segmentation of the Ovum." The systematic portion is divided into chapters, each of which corresponds with one of the large divisions of animals, *e.g.* Porifera, Platyelminthes, Rotifera, Mollusca, Chætopoda, &c.

Mr. Balfour, it is hardly necessary to say, has not performed his task as an ordinary maker of books. He is, as all zoologists know, one of the foremost students of embryology in Europe, and has added a very large proportion himself to that great heap of isolated embryological memoirs and monographs which it is the purpose of his book to condense and render accessible to a wider circle of students. Consequently we find not only new and original observations scattered here and there in the chapters of this treatise, but on the very numerous matters which call for the expression of an opinion or the exercise of judgment between conflicting statements of preceding observers, we have the conclusions, always modestly formulated, of a thoroughly competent critic.

In fact those who are already advanced in the study of embryology will find that Mr. Balfour has freely and most legitimately made use of speculative views of his own, as a series of strings on which to thread the almost innumerable observed facts which have to be put on record and kept ready, as it were, for the future building up of embryological doctrine. The reader, on the other hand, who has not yet reached the degree of knowledge at which such speculations become intelligible, will find that there is so much in Mr. Balfour's pages of hard, solid, descriptive record of the actual developmental changes of one animal after another, that he will certainly not feel cause to complain.

It would be out of place to discuss in these pages any of the new theoretical considerations which Mr. Balfour puts forward. With some of them it is possible to find fault; at the same time they are all ingeniously supported and indicate close reasoning and a large survey of facts on the author's part. They serve, as Mr. Balfour himself recognises, to stimulate inquiry, and when advanced not by a paper-philosopher, but by a most exceptionally industrious observer, they cannot fail to command respect.

If we venture to offer any remark which suggests how possibly Mr. Balfour's book might have been even more excellent than it is, it must be clearly understood that as it stands we hold it to be a perfect mine of valuable information and well-considered suggestion. We should, however, have been glad had it been possible for the author to give more attention to the history of the various stages of progress in our knowledge of embryology in general, and of each particular group. Full justice is done to recent authors, and his own contemporaries receive ample recognition from Mr. Balfour; but the successive steps by which a particular point of view has been arrived at are not always definitely indicated and due merit assigned to each of those who in past times has laboured to bring about the present phase of science. This, no doubt, has not entered into Mr. Balfour's plan on account of the additional responsibility and labour which it would have involved, and the increase in size of what is already

a voluminous treatise. But such treatment of the subject has a very high educational value and a certain ethical importance.

Further, it may be noted that the author has necessarily a difficulty to contend with in the scope itself of his book. Embryology is not a natural nor a convenient division of biological science. The study of the organism in its complete form cannot be advantageously separated from the study of the coming about of that form, and indeed it is very difficult for a writer who proposes to himself to describe the developmental changes of organisms to draw the line consistently in the various cases which he describes, and to say that at such a point his business with the organism ceases and that of the "antipædologist" begins. It is because the knowledge of embryological facts is to so large an extent new, that separate treatises on embryology are necessary. It is as a supplement to treatises on the structure or anatomy of animals which do not sufficiently deal with embryology that such a distinct treatise is needful, and such need is merely the result of the late development of embryological research.

In the course of time we shall no doubt see a complete fusion of "embryology" and "antipædology"—the facts of structure to be observed in the youth and in the maturity of organisms being treated as a matter of course concurrently. Nothing could conduce more directly to this desirable state of things than the really remarkable and successful effort which Mr. Balfour has made to gather together and present in a compact and logical form the embryological results which have been and still are pouring forth from Russian, German, English, French, and American laboratories in an overwhelming stream, calculated to daunt by its velocity any but the most determined student. E. RAY LANKESTER

THE SIEVE-TUBES OF DICOTYLEDONOUS PLANTS

Beiträge zur Kenntniss des Siebröhrenapparates dicotyler Pflanzen. Von Dr. Karl Wilhelm. (Leipzig: W. Engelmann, 1880.)

IT is perhaps natural, owing to its peculiarities, and especially to the character of the cell walls, that the soft bast was comparatively lately investigated and described;[1] but it is surely a surprising fact that the ground should have been left open till the present year, for a thorough investigation of the development of those tissues which are characteristic of the phloem.

In the "Comparative Anatomy" of De Bary we find a full account of what was known in 1877 of the structure and development of the soft bast; at the same time the writer pointed out several questions concerning which further investigation was required. He drew especial attention to our want of knowledge of the relation of the cambiform cells[2] to the sieve-tubes, and of the development of the sieve plate, the callus mass, and the contents of the sieve-tube. It has been the object of Dr. Wilhelm's researches to supply information on these several points; while at the same time he affords us many other interesting details.

Owing to the wideness of the subject it was impossible for the author to extend his researches beyond a limited number of types. Those selected were *Vitis vinifera*, L., *Curcubita pepo*, L., and *Lagenaria vulgaris*, Ser. It will be seen that Dr. Wilhelm has selected plants having sieve-tubes of the two different types common among the Dicotyledons, viz., Cucurbita and Lagenaria where the structure is more simple, Vitis where it is complicated by the presence of several sieve-plates side by side on the same cell wall. In a note at the end of the paper the author specially asserts that his results only apply to the plants named; while further research must show whether the structure described is really typical.

The main results arrived at are as follows:—Those formative cells of the bast which are set apart for the development of a member of a sieve-tube, usually suffer a longitudinal division into two unequal cells: the larger forms one member of the sieve-tube; the other, which is smaller and shorter, develops into the companion-cell (*Geleitzelle*). The latter may, in Cucurbita and Lagenaria, again divide. The walls separating the companion-cells from the sieve-tube are fitted, and the cell contents richly protoplasmic. It will be seen that these cells, being sister cells of the members of the sieve-tubes, must be distinguished from the larger cells, which are usually termed "cambiform;" these latter being formed by division from formative cells of the bast, but not being in direct genetic connection with the cells, which develop into members of the sieve-tubes.

Dr. Wilhelm finds that the "callous" condition of the sieve-plate is not, as previously supposed, the result of a secondary change of the plate; on the contrary, the differentiation of the sieve-plate begins by the change of the cellulose to "callus" at a number of points. It is in the callus masses, formed at these points, that the pores of the sieve later appear. The callus may extend itself from these points so as to cover the whole face of the plate, and completely inclose the cellulose sieve. A callus-skeleton is thus formed which may be isolated.

The callus varies in volume, increasing with age, or on approach of the period of rest; in which case the pores may be completely stopped; or decreasing as the period of summer activity approaches, when the pores are again opened. This result may be obtained by artificial means. It is best seen in Vitis; it is probable that this variation of volume of the callus is by no means universal.

As regards the substance of the callus it will be seen from the following reactions that it cannot be identified with any of the substances previously described. With acids and alkalies it swells quickly; if the reagents be strong it is dissolved. Ammoniacal sub-oxide of copper attacks it only slightly, or not at all; by use of this reagent the callus-skeletons before mentioned may be obtained free. Solution of iodine in alcohol does not colour it; solution of iodine in potassium iodide colours it yellow to brownish yellow. This with Schultz's solution gives a deep red brown; when used alone the latter reagent gives no colour, but causes considerable swelling.

Thus far we have only discussed the cell walls. While the development of the sieve has been going on, but before the perforations are formed, a change appears in

[1] The sieve tubes were discovered by Hartig (1837). His observations were many years after verified by other observers, especially von Mohl, Nägeli, and Hanstein.

[2] De Bary, "Vergl. Anat.," p. 337.

the contents of the young sieve-tubes. Isolated drops or irregular masses appear in the layer of protoplasm lining the cell cavity before the disappearance of the nucleus. These consist of a slimy stuff (*Schleim*) apparently rich in nitrogen.[1] The separate masses later fuse together to form a band, which is usually much narrower than the girth of the cell. Between this and the wall of the sieve tube a protoplasmic envelope intervenes (*Hüllschlauch*). The central cavity within these is filled with "sieve-tube sap." For further details concerning the contents of the sieve-tubes the reader must be referred to the original work.

The author has not been able to observe directly the first appearance of connection through the pores of the sieve; but suggests that it is effected by the outgrowth of protuberances of the envelope (*Hüllschlauch*) from opposite sides of the sieve, which penetrate it and coalesce to form the connecting strings.

The presence of starch grains noticed by Briosi is confirmed by Wilhelm in Vitis. He finds them in members of sieve-tubes which are still closed. He opposes the idea that they pass through the sieve on ground of their size. In Cucurbita and Lagenaria they are absent. Besides the communication of sieve-tubes with one another laterally, so as to form a complete system, Dr. Wilhelm has observed in the case of Vitis a further connection, through the medullary rays, of tubes lying on opposite sides of the ray. This is effected by special sieve tubes, produced by transformation of cells of the medullary ray, so as to form a series of very short members; these correspond in development and structure with the ordinary sieve-tube. They traverse the medullary rays in an obliquely tangential direction. Such communications are not found in Cucurbita or Lagenaria.

The question of function has not been solved by these observations. Dr. Wilhelm still holds the view, propounded by Nägeli, that the function of the sieve-tube is the transference of indiffusible substances from place to place in the plant.

In conclusion it may be remarked that the paper is well written, but that it is of such a character as to be interesting only to the specialist. The plates, of which there are nine, are executed with great skill and exactitude.

F. ORPEN BOWER

OUR BOOK SHELF

The Elementary Geometry of Conics. By C. Taylor, M.A. Third Edition. (Cambridge: Deighton, 1880.)

MR. TAYLOR has been before the public as a writer on geometrical conics since 1863, in which year he brought out his "Geometrical Conics"; in 1872 we have the first edition, and in 1873 the second edition of his "The Geometry of Conics," a smaller work than his first book (1863). Now we have a third edition with the above title. In May, 1875, Mr. Taylor, in a paper entitled "On the Method of Reversion applied to the Transformation of Angles" (read before the Mathematical Society, and subsequently printed in a more extended form in the *Quarterly Journal*, No. 53, 1875, with the title "The Homographic Transformation of Angles"), called attention to a "neglected work on conics by G. Walker, F.R.S. (1794)": in this work we first meet with the properties of a circle, which Walker calls the *generating circle*, but which Mr. Taylor, in the work before us, styles the *eccentric circle*; in the free use of this circle consists the main feature in the alterations made in this new edition; further, though still keeping well in view the proving chord-properties independently of tangent-properties, there is a rearrangement of the text; so that the two properties are not treated of in distinct chapters. In other ways also we think this little work is improved, but we need say no more upon a third edition.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Ceraski's New Variable Star

UNLESS the principal fact mentioned below has already come to your notice, you may like to bring it before the astronomical public in the columns of NATURE.

The true period of the variable star recently discovered at Moscow (*Durchmusterung*, zone + 81°, No. 25) appears to be two days and a half, instead of five as given in NATURE, vol. xxii. p. 455. Minima were observed at the Harvard College Observatory on September 23 and 28. The changes of the star will accordingly be visible in England on October 13, 18, 23, 28, &c., during the three or four hours before or after midnight. The rapidity of the change is probably greater in the case of this star than in that of any other known variable, the variation exceeding a magnitude in the course of one hour. The total variation is more than two magnitudes. A star of about the eighth magnitude (No. 30 of the same zone) is within a few minutes of the variable, and may readily be compared with it. The phenomenon of the variation is consequently a striking one, even as seen in a small telescope. The approximate place of the variable for 1881 is in R.A. 0h. 51m. 48s., Decl. +81° 14'·1.

EDMUND C. PICKERING

Harvard College Observatory, Cambridge, U.S., October 2

LORD LINDSAY'S Dun Echt Circular, No. 10, which I received on Saturday morning, October 23, prepared me to watch for a probable minimum of M. Ceraski's remarkable variable star B.D. + 81°.25' on the same night. From my observations the minimum appears to have occurred at about 11h. 10m. G.M.T., the star then being of about 9·1 magnitude. At 9h. 5m. I noted it about equal to a neighbouring star, B.D. + 81° 30', which I gauged 8·1 mag., and at 13h. 50m. it had regained the same magnitude. When about minimum I thought the variable to be slightly ruddy, but as it brightened up again it lost this tint and appeared to be white, or bluish white, as when I first observed it. It has a small bluish 11½ mag. companion, the P. and D. of which I roughly estimated to be 60° and 10" respectively. The star was observed by Carrington in 1855, on December 19, 21, and 30, his estimated mags. being 8·0, 8·0, 9·0. Possibly the star may have been near minimum at his third epoch.

Knowles Lodge, Cuckfield, October 25 GEORGE KNOTT

"Solid Ice at High Temperatures"

THE interesting results announced by Prof. Thomas Carnelley, of Firth College, Sheffield, in relation to the physical conditions under which *ice* persistently maintains its *solid state* when exposed to the influence of heat (NATURE, vol. xxii. p. 435), deserves some notice. When he speaks of obtaining "solid ice at temperatures so high that it was impossible to touch it without *burning* one's self," it is evident that this *burning quality appertains to the hot vessel containing the ice, and not to the solid ice itself.* For it is obvious that under the given conditions *the temperature of the surface of the ice is kept at least as low as 0° C. by the rapid vaporisation of it while in a solid state.*

The phenomenon of a body remaining persistently at a low temperature when surrounded by a hot vessel—through the influence of the rapid change of state—is analogous to the well-known results of Boutigny and Faraday in relation to the freezing of water and mercury in a hot vessel by means of large

globules of sulphurous acid and liquid carbonic acid while in a "spheroidal condition." In these cases, notwithstanding the proximity of the hot vessel, the temperatures of the globules of SO_2 and CO_2 are respectively as low as − 10° and − 73° C.

It has long been remarked by physicists that some substances pass *directly* from the *solid* to the *gaseous* state, without undergoing liquefaction: that is, when heated, *they sublime without melting*. Such bodies, under ordinary atmospheric pressures, have their *boiling* points *lower* than their temperatures of *fusion*; hence they *volatilise* without *melting*. Moreover it has long been known that such substances may be made to *fuse* by subjecting them to an *abnormal pressure* sufficient to *raise* their boiling points *above* their points of fusion. Thus the classical experiments of Sir James Hall show that carbonate of lime may be *fused* when heated under a pressure sufficient to prevent the CO_2 from escaping (*Trans.* Royal Soc. Edin., vol. vi. pp. 71–186, 1805). In like manner metallic arsenic sublimes without melting at 180° C., under the ordinary pressure of the atmosphere; but the experiments of Landolt in 1859 show that under artificial pressure it melts in globules at a low red heat. It is evident that in these cases the *rapid vaporisation* of the solids under ordinary circumstances *prevents* the temperature from reaching the point of fusion; but when subjected to additional pressure the conditions of liquefaction are secured. On the other hand, in the case of *ice*, it is obvious that the *withdrawal of pressure* by *lowering* its boiling-point places it in the same category with metallic arsenic under ordinary conditions of pressure.

In relation to the *literature* of this subject it is proper to add the following quotations from M. V. Regnault's "Elements of Chemistry" (American Translation, Philadadelphia, 1865, vol. i. p. 279). In speaking of the fusion of metallic arsenic under pressure he says:—"The distance between the point of fusion and that of ebullition of any body may, however, be increased at pleasure. For *the point of ebullition of a body is the temperature at which the tension of its vapour is equal to the pressure exerted upon it*; and hence by increasing the pressure the boiling-point is raised without sensibly affecting the point of fusion." Again, he says:—"Reciprocally it is evident that a *volatile solid body* may be always subjected to so slight a pressure that it will *boil* at a temperature *inferior* to that at which it *melts*. Thus ice at the temperature of − 1° C. possesses an elastic force represented by 4·27 mm.; in other words, it boils at a temperature of − 1° C. under the pressure of 4·27 mm. Ice may therefore be entirely volatilised *by ebullition* under this feeble pressure, without reaching its point of fusion, which is 0° C."

Berkeley, California, September 30 JOHN LECONTE

Wire Torsion

THE phenomena described by Major Herschel in his letter to NATURE, vol. xxii. p. 557, and about which he asks for information, are, we think, quite easily explained by what is known of the fluidity of metals. Yielding, or flowing, seems to occur in all metals after a certain limiting stress has been reached; indeed it probably occurs, although perhaps to an immeasurably small extent, even with small stresses (see *Proc.* Roy. Soc. No. 204, p. 411, 1880); but there is generally a limiting stress beyond which the increase of strain due to yielding becomes comparable in magnitude with the ordinary strains, which instantaneously disappear on the removal of the load. The bell-smith pulls his copper wire, and makes it much longer before he thinks it fit for use; in a similar way the telegraph constructor stretches, or *kills* the iron wire before he erects the line. Up to a certain limit of pulling force, the wire obeys the well-known laws of elasticity; slightly above that limit there is considerable fluid-yielding, there being but very little yielding below that limit; and at any instant during the lengthening if the man ceases to pull, the wire shortens a little. In fact at any stage the wire obeys the elastic law for *small* stresses. Eventually the man ceases to pull, knowing that the metal has lost most of its fluid properties, which can only be restored to it by annealing. The same thing occurs in brass, although to a smaller extent than in copper, which can be experimentally proved in the following way:—Stretch a piece of well-annealed brass wire in the manner described by Major Herschel until it is nearly breaking; and immediately set the wire vibrating. Now the note given out by the stretched brass wire, which, as is well known, depends on the tensile stress, will be found rapidly to go down in pitch. If the wire be tightened up again sufficiently with the screw, the original note will again be heard, and the pitch will again go down, but not so rapidly as before. Repeat this process until no flattening of the note is heard; then in this state we think that the experimenter will find the wire to break with much less torsion than before, and to obey Hooke's law more exactly. If it be desired to repeat the yielding or flowing process, the wire must be previously again annealed.

Mere sudden straining, even nearly up to the breaking stress, is not sufficient to destroy the fluidity of brass; time is required. The yielding behaviour of a brass beam when loaded has been studied by Prof. Thurston (*Trans.* American Soc. of Civil Eng. vol. vi. p. 28), and we may add that we have found that the permanent state is always more rapidly reached when the wire is subjected to rapid vibrations.

It may be because torsion of a wire is more visible than longitudinal strains (the twist being inversely proportional to the fourth power of the diameter for a given twisting moment, whereas the longitudinal strain for a given load is inversely proportional to the square of the diameter) that fluidity is so much more apparent in torsional experiments; but we think it probable that fluidity will be found always much more apparent when the volume of the material acted on is unchanged, that is, when the stress is mainly one of shear as it is in torsion.

However this may be we can explain why wire which has been "killed" for pulling forces is not "killed" for twisting, and why it is more difficult to kill for twisting than for tensile stresses. It is well known to wire-drawers that in whatever state copper or brass wire may be, whether annealed or not, it may be drawn smaller, although no doubt it requires less care to draw it if it is annealed. We cannot merely pull wire much smaller, it has to undergo a lateral pressure such as the die gives it. Now in twisting a wire it everywhere receives this lateral pressure, that is—imagine a right-handed spiral filament being lengthened by the twist—then the other component of the twist gives to the filament a compression at right angles to its length which enables it to extend. It seems that this lateral pressure is needed to overcome some sort of friction in the particles of the metal tending to prevent their moving into the axis of the wire, and which therefore is greater as the section of the wire is larger, and it is probably for this reason that a very thin wire extends much more, for a given initial length, before it is killed than a thick wire. We have known a length of about fifteen inches of fine copper wire which had just been drawn, and which had been well killed, to bear six or seven hundred complete turns in a lathe, one end being fixed, the other end turned, and the wire kept pretty taut before it was accidentally broken, and even afterwards parts of the wire could be considerably lengthened by pulling. The nature of the explanation of this apparent annealing for tensile stresses arising from previous torsion will be gathered from what follows.

We infer that the three or four turns given to the wire at the beginning in Major Herschel's experiment were not sufficient to produce permanent torsional set; why then should increasing the tension during the torsion cause torsional set as well as lengthening of the wire? This is, we think, a more important question than the one presented to us by the observations of fluidity in the latter half of Major Herschel's letter, and which arose from the metal having belonged to what Prof. Thurston calls the "tin class" as distinguished from metals of the "iron class."

The explanation we think is as follows, and it leads to the conclusion that torsional fluidity is not independent of tensile stress:—

Suppose right- and left-handed spirals had been imagined in the wire in question, making everywhere angles of 45° with the axis of the wire; then torsional strain, however set up, would consist in the production of a difference in length of these two sets of spirals. Now a twisting moment produces this effect; it lengthens, say the right-hand spiral and shortens the left, and we know that up to a certain limit, which is tolerably high, the same effect is produced whatever be the tensile stress in the wire, which latter simply tends to lengthen both spirals equally. In fact if Hooke's law is true, the torsion is independent of the tension. But above a certain limit of pull in the wire, the strain in the direction of the right-handed spiral being everywhere due to the sum of two tensile stresses, becomes so great that fluidity sets in and permanent set is produced; whereas in the direction of the left-handed spiral the stress is due to the difference between the tensile stress and the compressive part of the torsional shearing stress, and this difference being small, no permanent tensile set is produced, or at all events one much less than in the case of the other spiral. Consequently if all stresses now cease to act

a permanent difference would remain in the lengths of the two spirals, that is, there would now be a permanent twist.

Information regarding the fluidity of tempered steel, copper, brass, lead, tin, &c., will be found in the papers of M. Tresca, and in the second of the Cantor lectures delivered by Mr. Anderson before the Society of Arts April 19, 1869, as well as in Mr. Anderson's book on the "Strength of Materials," and in Mr. Bottomley's reports communicated at the Meetings of the British Association in 1879-80. We do not think, however, that much of the valuable information on the fluidity of metals which is scattered through the *Proceedings* of the different societies has yet been collated. Wire-drawers, watch and clockmakers, as well as the makers of philosophical instruments and of other small machinery, have a considerable amount of knowledge of this subject which they cannot systematise and make known to others, but which, nevertheless, they make ready use of in their work.

Finally, we would suggest that if Major Herschel wants his wire to obey Hooke's law for small twists only, he will not find it necessary to destroy the properties which are due to its being annealed. If, however, he desires to use greater twists, it will be necessary to leave the wire under a fairly large pull for a considerable time without twisting it until it ceases to continuously yield to tensile stresses of greater intensity than that of the shear stress to which it has afterwards to be subjected. And if in Mr. Allan Broun's gravimeter it be necessary to employ such large twisting couples as Major Herschel was using in his experiments, we would suggest the employment of a longer and thicker wire.

W. E. AYRTON

London, October 18

On the Skin-furrows of the Hand

IN looking over some specimens of "prehistoric" pottery found in Japan I was led, about a year ago, to give some attention to the character of certain finger-marks which had been made on them while the clay was still soft. Unfortunately all of those which happened to come into my possession were too vague and ill-defined to be of much use, but a comparison of such finger-tip impressions made in recent pottery led me to observe the characters of the skin-furrows in human fingers generally. From these I passed to the study of the finger-tips of monkeys, and found at once that they presented very close analogies to those of human beings. I have here few opportunities of prosecuting the latter study to much advantage, but hope to present such results as I may attain in another letter. Meanwhile I would venture to suggest to others more favourably situated the careful study of the lemurs, &c., in this connection, as an additional means of throwing light on their interesting genetic relations.

A large number of nature-prints have been taken by me from the fingers of people in Japan, and I am at present collecting others from different nationalities, which I hope may aid students of ethnology in classification. Some few interesting points may here be mentioned by way of introduction.

Some individuals show quite a *symmetrical* development of these furrows. In these cases all the fingers of one hand have a similar arrangement of lines, while the pattern is simply reversed on the other hand. A Gibraltar monkey (*Macacus innus*) examined by me had this arrangement. A slight majority of the few Europeans I have been able to examine here have it also.

An ordinary botanical lens is of great service in bringing out these minor peculiarities. Where the loops occur the innermost lines may simply break off and end abruptly; they may end in self-returning loops, or, again, they may go on without breaks after turning round upon themselves. Some lines also join or branch like junctions in a railway map. All these varieties, however, may be compatible with the general impression of symmetry that the two hands give us when printed from.

In a Japanese man the lines on both thumbs form similar spiral whorls; those of the left fore-finger form a peculiar oval whorl, while those of the right corresponding finger form an open loop having a direction quite opposite to that of the right fore-finger in the previous example. A similar whorl is found on both middle fingers instead of a symmetrically reversed whorl. The right ring-finger again has an oval whorl, but the corresponding left finger shows an open loop.

The lines at the ulno-palmar margin of this particular Japanese are of the parallel sort in both hands, and are quite symmetrical, thus differing from the Englishman's considerably. These instances are not intended to stand for typical patterns of the two peoples, but simply as illustrations of the kind of facts to be observed. My method of observation was at first simply to examine fingers closely, to sketch the general trend of the curves as accurately as possible, recording nationality, sex, colour of eyes and hair, and securing a specimen of the latter. I passed from this to "nature-printing," as ferns are often copied.

A common slate or smooth board of any kind, or a sheet of tin, spread over very thinly and evenly with printer's ink, is all that is required. The parts of which impressions are desired are pressed down steadily and softly, and then are transferred to slightly damp paper. I have succeeded in making very delicate impressions on glass. They are somewhat faint indeed, but would be useful for demonstrations, as details are very well shown, even down to the minute pores. By using different colours of ink useful comparisons could be made of two patterns by superposition. These might be shown by magic lantern. I have had prepared a number of outline hands with blank forms for entering such particulars of each case as may be wanted, and attach a specimen of hair for microscopic examination. Each finger-tip may best be done singly, and people are uncommonly willing to submit to the process. A little *hot* water and soap remove the ink. Benzine is still more effective. The dominancy of heredity through these infinite varieties is sometimes very striking. I have found unique patterns in a parent repeated with marvellous accuracy in his child. Negative results, however, might prove nothing in regard to parentage, a caution which it is important to make.

I am sanguine that the careful study of these patterns may be useful in several ways.

1. We may perhaps be able to extend to other animals the analogies found by me to exist in the monkeys.

2. These analogies may admit of further analysis, and may assist, when better understood, in ethnological classifications.

3. If so, those which are found in ancient pottery may become of immense historical importance.

4. The fingers of mummies, by special preparation, may yield results for comparison. I am very doubtful, however, of this.

5. When bloody finger-marks or impressions on clay, glass, &c., exist, they may lead to the scientific identification of criminals. Already I have had experience in two such cases, and found useful evidence from these marks. In one case greasy finger-marks revealed who had been drinking some rectified spirit. The pattern was unique, and fortunately I had previously obtained a copy of it. They agreed with microscopic fidelity. In another case sooty finger-marks of a person climbing a white wall were of great use as negative evidence. Other cases might occur in medico-legal investigations, as when the hands only of some mutilated victim were found. If previously known they would be much more precise in value than the standard *mole* of the penny novelists. If unknown previously, heredity might enable an expert to determine the relatives with considerable probability in many cases, and with absolute precision in some. Such a case as that of the Claimant even might not be beyond the range of this principle. There might be a recognisable Tichborne type, and there might be an Orton type, to one or other of which experts might relate the case. Absolute identity would prove descent in some circumstances.

I have heard, since coming to these general conclusions by original and patient experiment, that the Chinese criminals from early times have been made to give the impressions of their fingers, just as we make ours yield their photographs. I have not yet, however, succeeded in getting any precise or authenticated facts on that point. That the Egyptians caused their criminals to seal their confessions with their thumb-nails, just as the Japanese do now, a recent discovery proves. This is however quite a different matter, and it is curious to observe that in our country servant-girls used to stamp their sealed letters in the same way. There can be no doubt as to the advantage of having, besides their photographs, a nature-copy of the for-ever-unchangeable finger-furrows of important criminals. It need not surprise us to find that the Chinese have been before us in this as in other matters. I shall be glad to find that it is really so, as it would only serve to confirm the utility of the method, and the facts which may thus have been accumulated would be a rich anthropological mine for patient observers.

Metamorphic Rocks, Ireland

THERE appears to be confusion as to the times when metamorphic action occurred among the Irish rocks; my experience would point to the following:—

In the Carnsore district, South-East Wexford, there are metamorphic rocks for a long time supposed to be of Lower or Cambro-Silurian age; I however proved that they were upturned, contorted, metamorphosed, and denuded, prior to the overlying fossiliferous Cambro-Silurian rocks being deposited, and for the reasons given in the Geological Survey Memoir it is probable these metamorphic rocks are of Cambrian age.

In the hills north of Pomeroy, Co. Tyrone, there are metamorphic rocks, which were upturned, contorted, metamorphosed, and denuded, prior to the overlying fossiliferous "Pomeroy rocks" having been deposited. The fossils in the latter would point to their being Cambro-Silurians; consequently the metamorphic rocks are older, and for reasons given in a paper read before the Royal Irish Academy I believe they are the equivalents of the "great micalite series," West Galway, or the equivalents of the Arenig group of Wales. Thal is either Upper Cambrian, or *Passage beds* between the Cambro-Silurian and Cambrian.

In Erris, North-West Mayo, there is a tract of excessively metamorphosed rocks, supposed by Griffith to be older than the associated altered Cambro-Silurians, and this opinion is shared in by Mr. McHenry, who more recently examined them.

From the above it is evident that there was a *period of intense metamorphosis prior to the Cambro-Silurian age.*

The Cambrian (Arenig group?) and Cambro-Silurian of Galway and South-West Mayo must, in part, have been altered prior to the deposition of the Upper Silurians on them; while the general metamorphism of the South-East Ireland Cambro-Silurians, *which was quite irrespective of the intrusion of the Leinster granite*, was probably at about the same time. If the Comeragh Mountain rocks are Glengariff grits, *i.e.* Silurians, the age of the metamorphic action is evident, as in Waterford these rocks underlie those of the Comeragh Mountains. In addition to the general metamorphism in the rocks of South-East Ireland, there was also a local and secondary action in connection with the protrusion of certain granitic rocks.

The testimony of the West Galway and South-West Mayo rocks alone, however, would prove *a period of intense metamorphic action at the close of Cambro-Silurian time.*

In South-West Mayo, as proved by Mr. Symes and myself (*Maps and Memoirs of the Geol. Survey*), there is a considerable area of metamorphosed Upper Silurian rocks, which prove *another period of intense metamorphic action subsequent to the dawn of Upper Silurian times.* The secondary metamorphism previously mentioned in South-East Ireland may also be of this age, as the granitic rocks allied with the metamorphic, in both areas, are very similar.

Thus there are records of at least three periods of intense metamorphic action, and probably there were two others subsequently—one in the Triassic and another in the Miocene time—to account respectively for the metamorphic rocks in the neighbourhood of the Mourne granite, Co. Down, and those associated with the granitic rock near Portrush, Co. Antrim.

Formerly, as mentioned by me in the "Geology of Ireland," the period of greatest metamorphism was considered to have been at the close of the Cambro-Silurian time; now, however, more recent research has taught us that metamorphic rocks, formerly supposed to be Cambro-Silurians, are Cambrians; so it seems possible the metamorphic action prior to Cambro-Silurian time may have been greater than that subsequent to it.

The Number of Known Species of Hemiptera-Heteroptera

As Mr. Pascoe, in his very "handy book of reference" for zoological classification, says of the Hemiptera-Heteroptera that "in round numbers there may be about 10,000 species in this sub-order," I am induced to give my census of the group.

On completing, about a year ago, MS. lists of the families which Stål unfortunately did not live to include in his "Enumeratio Hemipterorum," I was tempted to try and ascertain the total number of species that had been described. This I found to be about 7,800 (the actual number arrived at is 7,780). Of these, 7,445 belong to the Geocorisæ or Gymnocerata (mostly terrestrial bugs, but including four families which inhabit the surface of water), and 334 to the Hydrocorisæ or Cryptocerata (almost all aquatic species). Of the Geocorisæ 1,503 are European, 3,248 are natives of the rest of the Old World, and 2,694 are American; of the Hydrocorisæ the corresponding numbers are 95, 120, and 119. The largest family of the Geocorisæ in Europe is the Capsidæ with 500 species, as against 134 and 312 in the rest of the Old World and America respectively. Amongst the Hydrocorisæ the family Corixidæ is most numerous in species, the numbers being: for Europe 72, the rest of the Old World 17, and America 34. But as these two families contain many inconspicuous species, and species having a strong resemblance *inter se*, and as Europe has been (naturally) more thoroughly investigated than the other regions, it is likely that many extra-European species of these families remain yet to be discovered.

Of what may be the actual number of species of Hemiptera-Heteroptera existing it is difficult to form an estimate. It is only of late years that much attention (comparatively) has been directed to the order, and from the number of new species sent home by the few collectors who condescend to collect bugs, it is evident that very great additions to the list will in course of time be made. Even within the last twenty years the list has been more than doubled, as in A. Dohrn's catalogue, published in 1859, only 3,627 are mentioned.

Of the sub-order Homoptera it would be rather difficult to make a census. In Dohrn's catalogue somewhere about 3,000 species are catalogued—a number not very far short of that of the Heteroptera. In the British and European lists the number of Homoptera is about two-thirds that of the Heteroptera.

On the Classification of Rivers

IT has often occurred to me that a convenient classification of rivers might be obtained by arranging them according to their "water-discharge." Such a classification would not only indicate the relative position of one river to another in a descending scale, but would enable a rough estimate to be borne in the memory of the amount of water any particular river may discharge.

I therefore venture to suggest the following arrangement: and have given below the names of seventeen rivers, the discharges of which I have obtained from various sources, for which I would refer the reader to NATURE, vol. xxii. p. 486.

Discharge of Cubic Feet per second

First Rate. Above 2,000,000.	Second. Above 1,000,000.	Third. Above 500,000.	Fourth. Above 250,000.	Fifth. Above 100,000.
Amazon.	Congo.	Yang'tse. Plate. Mississippi.	Danube. Shat-el-Arab.	Ganges. Indus. Arrato. Nile. Yellow River.

Sixth. Above 50,000.	Seventh. Above 25,000.	Eighth. Above 10,000.	Ninth. Above 5,000.	Tenth. Below 5,000.
Rhone. Rhine. Po.			Pei-ho.	Thames.

Woodlane, Falmouth, October 19 H. B. GUPPY

Yuccas under Cultivation

IN NATURE, vol. xxi. p. 315, in the report of the *Proceedings* of the Linnean Society, it is stated that "the yuccas fruit rarely under cultivation, the large white pendulous flowers being in the wild plant fertilised by a moth of the genus *Pronuba*." The yucca has been introduced and is very abundant in this colony, especially round Noumea. It fruits freely; in fact I rarely see a plant in which many, if not most, of the flowers do not produce seed-pods. In my own garden they seem to be fertilised by the common bee, of which I have a hive, others being in the neighbourhood. If I remember rightly, *Pronuba* is a genus of large moths having yellow underwings. We have a species identical with, or closely resembling, an old Ceylon friend, but it is rare; still it does exist here, and *may* assist in the fertilisa-

tion, though I should say, from the number of flowers fertilised, that other agencies preponderate. E. L. LAYARD

British Consulate, Noumea, New Caledonia, July 31

Intellect in Brutes

I CONFESS I do not see much "intellect" in a snake biting its own tail (cf. NATURE, vol. xxii. p. 40); on the contrary, I consider the creature evinced remarkable stupidity. Perhaps however you will think what I now relate will show that snakes do possess reasoning powers.

Many years ago, while in Ceylon, I lived in a house in "Slave Island," raised on a high platform. The steps up to the door had become loosened, and behind them a colony of frogs had established themselves. One morning I watched a snake (a cobra) creep up, insert his head into a crack, and seize a frog, which he there and then swallowed. But the crack that admitted the thin flat head and neck of the ophidian would not permit of the same being withdrawn when the neck was swollen with the addition of the frog inside it. The snake tugged and struggled, but in vain, and after a series of futile attempts disgorged its prey and withdrew its head. But the sight was too tantalising. Again the head was inserted in the crack and the coveted morsel swallowed, and again the vain struggles to withdraw were renewed. *I saw this repeated several times*, till, gaining wisdom by experience, the snake seized the frog by one leg, withdrew it from its coigne of vantage, and swallowed it outside. E. L. LAYARD

I SEND you the following dog story, the truth of which is vouched for by the young lady who owned the animal. Her pet dog, a black-and-tan-terrier, was well known to the neighbours for his intelligence. He had established a remarkable friendship for a certain kitten, although given to fierce attacks on all others. This kitten was infested with fleas, which, when the dog discovered, he took her by the nape of the neck, in truly parental fashion, and *soused her up and down in a bucket of water*. He would then take her out into the sunshine and carefully pick out the drowned fleas.

A friend of mine, a naturalist, and a very conscientious man, whose word can be implicitly trusted, gives the following, to which he was an eye-witness. His grandfather, then a very old but hale and hearty man, had a splendid Newfoundland. There was a narrow and precipitous road leading from the fields to the house. It was regarded as a very dangerous place. One day when the old gentleman was doing some work about the farm his horse became alarmed and started off with the wagon along this causeway. The chances were that he would dash himself and the empty wagon to pieces. At once the dog seemed to take in the situation, although until that time he had been impassive. He started after the horse at full speed, overtook him, caught the bridle, and by his strength arrested the frightened creature until help could reach him. My friend gives many other stories of this fine dog, and thinks he had a decided sense of humour. I will repeat that both of these tales come to me well authenticated, and I could, by seeking permission, give names and places. W. WHITMAN BAILEY

Broun University, Providence, R. I. (U.S.A.), October 10

Atmospheric Phenomenon

LAST evening (October 21) at 5.45 p.m. I observed four huge radiating arms of faint white light, like the spokes of a gigantic wheel, rising from a centre apparently on the west-south-west horizon, and extending almost to the zenith. I say apparently on the west-south-west horizon, because an intervening house prevented me from seeing the nucleus of the diverging rays. The aspect of the phenomenon was more suggestive of an aurora than anything else I know of, but the beams of light seemed to be quite stationary, and although I fancied their brilliancy increased at one time for a few moments, I cannot be sure. Other fainter rays appeared to me to divide the west-south-west sky with those I have mentioned; but on that point I am also not sure. The sun set at 4.53 p.m., and twilight ended about 6.43 p.m., at which time the appearance I have attempted to describe was no longer visible. The sky was heavily clouded.

I should very much like to know the cause of this (to me) singular exhibition of light. B.

Kentish Town, N.W., October 22

Temperature of the Breath

WITH reference to the high reading, 107°-108°, noticed by Dr. Dudgeon when a thermometer tightly wrapped up in the folds of a silk handkerchief was kept in the mouth for five minutes, might I ask Dr. Dudgeon if he has verified this reading by immersing the thermometer, with a handkerchief tightly rolled round its bulb, in a vessel of water, at say 108°, the temperature of the water being simultaneously taken by a standard thermometer with its bulb uncovered? It seems to me that there is some danger of actually squeezing up the reading of a delicate thermometer when twenty or thirty folds of a silk handkerchief tightly encircle its bulb. F. J. M. P.

October 23

Crossing Rapid Streams

HAVING read some letters lately in your paper on the subject of crossing rapid streams by means of carrying heavy stones, it strikes me that the following may be of interest to your readers. It is an extract from a survey report by Lieut. (now Major) Woodthorpe, R.E., written in 1876, describing the method, which he saw practised by men of the Nàgà tribes, for crossing a deep stream too rapid for their feeble powers of swimming, and about twenty yards wide:—

"Taking large stones in their hands, they waded in up to their necks, and throwing up their legs and lowering their hands, the stones carried them to the bottom, along which they crept on all-fours till they reached the shallows on the other side."

The rough bottom afforded them sufficient hold to withstand the modified current and resist flotation. C.

Mussoorie, September 28

Construction of Telescopes and Microscopes

PERHAPS some of your readers may be able to inform me whether there exists in English or French a work on geometrical optics, in which the author applies himself thoroughly to explain the optical (not the mechanical) construction of telescopes and microscopes. Works like those by Parkinson and Polter stop short exactly where the application of theory to the construction of the best instruments begins. P. C.

September 30

BENJAMIN PEIRCE, F.R.S.

WE regret to have to record the death at Cambridge, Mass., on October 6, of Prof. Peirce of Harvard University, following upon an illness of three months from Bright's disease. Prof. Peirce was the son of a former librarian of the university, Benjamin Peirce, who died in 1831. For the past thirty-five years he has occupied a professorship at Harvard; and as a lecturer, author, thinker, and investigator, has not only ranked amongst the first of a numerous corps of professors, but also among the first of American men of science. Devoting himself originally to mathematics, Prof. Peirce has successively pursued exhaustive studies in all the branches more closely allied to mathematics, and has obtained eminence equally in physics, astronomy, mechanics, and navigation. His numerous investigations in these various departments, while read before various scientific societies, have been published, unfortunately, for the most part in the briefest possible form, and the results of many of his researches are to be found only in the manuals he published on various subjects. As an author Prof. Peirce was highly esteemed upon both sides of the Atlantic, his work on analytical mechanics, which appeared in 1857, being regarded then even in Germany as the best of its kind. His chief works are a "Treatise on Algebra," a "Treatise on Plane and Solid Geometry," "Pure Mathematics," a "Treatise on Sound," "Ocean Lanes for Steamships," "Tables of the Moon," "System of Analytic Mechanics," "Potential Physics," "Linear Associative Algebra," "Analytic Morphology," and "Criterion for the Rejection of Doubtful Observations." As a lecturer Prof. Peirce was highly esteemed in both scientific and popular circles. It is related that in 1843, by a series of popular

lectures on astronomy, he so excited the public interest that the necessary funds were supplied for erecting an observatory at Harvard. A remarkable series of lectures on "Ideality in Science," delivered by him in 1879 before the Lowell Institute in Boston, attracted the general attention of American thinkers, on account of the thoughtful consideration of the vexed question of science and religion.

Much of Prof. Peirce's activity was absorbed by his duties as the head of the American Coast Survey, a position in which he succeeded Prof. Bache. He brought to this work the same degree of zeal and ability which were so brilliantly evidenced by his predecessor, and constantly maintained the well-earned reputation of the Coast Survey among the hydrographic efforts of our day. Prof. Peirce was one of the founders of the American National Academy of Sciences. In 1853 he presided over the American Association for the Advancement of Science. The degree of LL.D. was conferred upon him twice, by the University of North Carolina (1847), and by Harvard University (1867). He was elected an Associate of the Royal Astronomical Society (1849), and a Fellow of the Royal Society of London (1852), and of the Royal Societies of Edinburgh and Göttingen.

Prof. Peirce leaves behind him his wife, a daughter, and three sons. Of the latter one is Professor of Mathematics at Harvard, and another is Professor at Johns Hopkins University.

RECENT CHEMICAL RESEARCH

THE masses of facts accumulated in the text-books on chemistry are already portentous: each month, almost each week, adds to the store.

The difficulty of getting a stable standing-ground from which to survey, in order, if possible, to find the meaning of these facts, increases likewise.

Fortunately from time to time there are found investigators who, turning from the easy toil of adding new compounds to those which are as yet but imperfectly known, concern themselves with the fundamental questions of chemical science.

Why are the properties of bodies so largely modified under certain conditions? This is the all-important question for the chemist. Before this question can be answered for a series of substances the properties of those substances must be accurately known, and the variations in their properties under varying conditions—themselves definitely ascertained—must be determined. Among the properties of substances those which we usually call physical are, as a rule, more susceptible of accurate measurement than those which we call chemical.

But these physical properties must be connected in some way with the chemical structure of the little parts, or molecules, of which we conceive the substances to be built up.

To determine what this connection is in the case of a definite physical property, and for a series of chemical substances, is at present one of the most promising problems which presents itself to the chemical inquirer.

But these physico-chemical problems require for their solution, a practical knowledge both of chemical and physical methods; methods of laboratory work and methods of reasoning on the results obtained. Students of nature trained in both methods are not extremely abundant.

The suggestion made in the preface to Armstrong and Grove's new volume on Organic Chemistry, that each chemical school should regularly prepare special series of pure compounds, and should let it be known that physical observers can procure these compounds in order to determine their physical properties, is well worthy of being acted on by all in whose hands may rest the arrangement of the work of any chemical school.

The older method of regarding chemical physics as consisting of a little chemistry loosely tacked on to a great deal of ordinary physics, is disappearing; and chemists and physicists now recognise that the problems which each attacks are, in very many instances, but different aspects of the same question.

The more thoroughly the chemical worker is trained in the correct use of dynamical principles and dynamical reasoning, the more likely is he to succeed in his search for chemical truth.

Very recently two papers have appeared, the contents of which illustrate the importance of the results obtainable by physico-chemical methods.

Brühl has published in Liebig's *Annalen*—and in a condensed form in the Berlin *Berichte*—the results of his investigations on the connection between physical properties and chemical constitution of carbon compounds; and Thomsen, in the *Journal für practische Chemie* (and also in the *Berichte*) has given the first two instalments of his thermal work bearing on the isomerism of carbon compounds.

I propose to give a short account of the work of these two chemists: let us begin with Thomsen's.

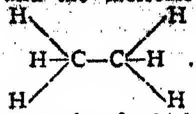
The "heat of formation" of a compound substance is the difference between the sum of the heats of combustion of the constituent elements of the compound, and the heat of combustion of the compound itself. But this heat is not the true "heat of formation" of the molecule of the compound; it is only the algebraic sum of various heat disturbances. The thermal change which accompanies the formation of a compound molecule from various elementary molecules consists of various parts: (1) heat absorbed in dissociating the molecules of the different elements; (2) in some cases, heat absorbed in liquefying or gasefying the constituent elements; (3) heat evolved in the formation, from the dissociated elementary atoms, of the new compound molecules; and (4) in some cases heat evolved in the liquefaction or solidification of the gaseous compound molecules. If the physical state of the various substances concerned be constant throughout the experiment, (2) and (4) may be neglected; and the heat of formation will be equal to the difference between the heat absorbed in splitting the elementary molecules, and that evolved in the falling together of the atoms so produced, in the new configuration. The value of the first part of this operation will always be constant for the same element or elements; but the value of the second part will depend upon the configuration assumed by the elementary atoms in the new compound molecules.

Now the generally accepted chemical theory of isomerism is that it (isomerism) is dependent on varying configuration of the same atoms. Some chemists have urged that isomerism is more probably due to the possession, by the different compounds, of different amounts of energy. But these two theories are really parts of the same theory. Thomsen's method, indeed, may be said to be based on this fundamental identity.

Given the dissociated elementary atoms, they may arrange themselves in various ways, each arrangement will be attended with a definite but different evolution of heat, hence, inasmuch as the heat absorbed in the preliminary elemental dissociation is fixed, the heats of formation of the various isomeric molecules will be different.

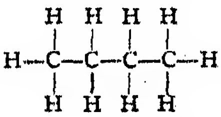
But when it is said that isomerism depends on atomic configuration, two things are included in this statement. Let us consider isomerism in a hydrocarbon; the carbon atom combines with four, and not more than four, hydrogen atoms to form a compound molecule. The carbon atom is said to be tetravalent; this is usually graphically expressed by the symbol $=C=$. The maximum number of hydrogen atoms which two carbon atoms can combine with to form a definite molecule will be six,

and the molecule will be graphically represented as

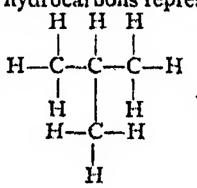


. But we also know of a compound the molecule of which contains two carbon, but only four hydrogen atoms, this is represented as $\frac{H}{H}>C=C<\frac{H}{H}$, and a third hydrocarbon, C_2H_2, is represented as $H—C \equiv C—H$. In the first molecule the carbon atoms are commonly said to be "singly-linked," in the second "doubly-linked," and in the third "trebly-linked." We do not as yet attach any definite physical conception to these phrases; a compound said to contain "singly-linked" carbon atoms is, as a fact, incapable of combining with hydrogen or other monovalent element, whilst a compound said to contain "doubly-linked" carbon atoms can combine with two monovalent atoms for each pair of doubly-linked carbon atoms it is represented as containing; and a compound said to contain "trebly-linked" carbon atoms is capable of combining with four monovalent atoms for each pair of trebly-linked carbon atoms in the graphic formula thereof.

These are instances of isomerism said to be due to differences in the linking of the atoms of the isomeric molecules. But according to the generally accepted theory isomerism may arise among hydrocarbons in which all the carbon atoms are singly-linked; such isomerism is due to different relative arrangements of parts of the molecule. We may suppose all the carbon atoms arranged in a chain, or we may suppose ramifications of these atoms; thus the hydrocarbons represented as



and



would be isomeric.

Thomsen deals only with isomerism due to differences in the linking of atoms. If from a certain number of dissociated carbon and hydrogen atoms a compound be produced containing only "singly-linked" carbon atoms, that compound is not capable of taking up any more hydrogen; but if a compound be produced containing "doubly-linked" carbon atoms, that compound is capable of taking up more hydrogen. But in the act of combining with more hydrogen, heat will be evolved; hence the heat of formation of the first compound is greater than that of the second. The heat of formation of an isomeric compound containing "trebly-linked" carbon atoms would be less than that of either of the preceding.

Thomsen, from the results of his own and other experiments, has calculated the heat of formation, from amorphous carbon, of a pair of singly-linked, a pair of doubly-linked, a pair of trebly-linked, and a pair of quadruply-linked carbon atoms. From these values he has calculated the heats of formation of isomers containing singly, doubly, or trebly-linked carbon atoms. The calculations involve certain assumptions, but the applications of his results to actual hydrocarbons show very close agreement between the calculated and the actually determined "heats of formation."

Thomsen furnishes us with a thermal value for the formation of each of the three possible linkings of the group C_2 in the molecule of compounds. The value of this result to the chemist is great; a determination of the heat of combustion of a hydrocarbon may now yield him much information as to the structure of the molecule of that hydrocarbon.

Thomsen's results also strengthen the commonly-accepted theory of isomerism, and they point towards a dynamical explanation of this theory and to the possibility of attaching a definite physical idea to the phrases "singly" or "doubly-linked" atoms.

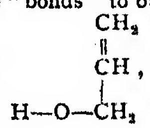
As Thomsen has succeeded in tracing a quantitative connection between the heats of formation of certain molecules containing carbon and the linking of the carbon atoms in these molecules, so Brühl has shown that the linking of carbon atoms exerts a definite, measureable influence on the *molecular refractions* of compounds of this element.

Landolt showed many years ago, that in many compounds, the atoms of each elementary substance, possessed a definite specific refractive capacity independently of the way in which the atoms might be grouped.

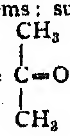
Molecular refraction is defined as $\left(\frac{\mu - 1}{d}\right)$. M, where μ = refractive index, d = density of substance, and M = molecular weight.

The difference between the molecular refraction of a compound containing carbon, hydrogen, and oxygen, and that of a compound containing the same number of carbon and hydrogen atoms, but free from oxygen, gave the atomic refraction of oxygen. Numbers were thus found expressing the atomic refraction of carbon, hydrogen, oxygen, and a few other elements. Gladstone and Dale showed, however, that the observed molecular refractions of many carbon compounds, especially the compounds existing in essential oils, were greater than the refractions calculated from Landolt's numbers: it seemed that the grouping of atoms did exert, in certain cases, an influence on the refractive power of molecules.

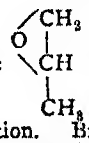
Brühl finds that certain groups of isomeric carbon compounds possess but one molecular refraction; in these groups the refractive power of the molecules is independent of the grouping of the atoms; in other isomeric groups, however, the molecular refraction varies. The members of the latter groups of isomers are always represented in structural formulæ as containing "doubly-linked" carbon atoms. Now if the molecular refraction be conditioned by the linking, but not by the grouping, of the atoms in the molecule, it follows that the atomic refraction of each monovalent element must be a constant number, inasmuch as there is but one way of linking a monovalent atom to other atoms. Such isomers as ethylene chloride, $ClH_2C—CH_2Cl$, and ethylidene chloride, $Cl_2HC—CH_3$, should possess the same molecular refraction. But the atomic refraction of any polyvalent atom, *e.g.* oxygen, must vary according as the atom is linked by one, two, or more "bonds" to other atoms: such isomers as allylic alcohol



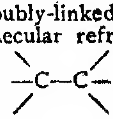
, acetone



, and propylene oxide



should possess each a distinct molecular refraction. Brühl's actual results confirm these deductions. There is then a definite value for the atomic refraction of the carbon, or oxygen, atom according as that atom is "singly-linked" or "doubly-linked" to other atoms: in other words, the molecular refraction of a compound containing the group



is different from that of the isomer containing the group $>C=C<$; and the molecular refraction of a compound containing the group $>C=O$ is different from that of the isomer

containing the group $>C—O—$. Brühl obtains a definite numerical value for the refractive power of each of these groups.

Now although the molecular refraction of isomers with similarly linked, but differently grouped, carbon or oxygen atoms is constant, the refractive indices and the densities of these isomers are not the same. There is, therefore, a definite connection between the densities and refractive indices of carbon compounds, and the grouping, as distinguished from the linking, of the atoms in these compounds. The densities and refractive indices of the isomers, ethylene chloride and ethylidene chloride (see *ante*) are not the same. Brühl has not determined any exact numerical value for the refractive power of this or that grouping of carbon or other atoms; generally, however, he has shown that the more ramifications there are in the structural formula of a carbon compound, the smaller is the density and the smaller the refractive index of that compound. Thus the density of butylic iodide, $CH_3—CH_2—CH_2—CH_2I$, is 1·6166, and the refractive index (μ) is 1·49601; but the density of the isomeric isobutylic iodide,

$$\begin{array}{c} CH_3—CH—CH_3 \\ | \\ CH_2I \end{array}$$

, is 1·6056, and the refractive index is 1·49192.

Generally, then, it would appear that when rays of light pass through a series of isomeric carbon compounds, the isomerism of which is traceable only to differences in the grouping of the constituent atoms, then that ray which passes through the densest compound is more bent from its original course than any of the other rays; but that when isomerism is due to differences in the linking of the atoms, then the amount to which the rays are bent is dependent not only on the density, but also on the molecular "structure" of the compounds.

Brühl considers also the connection existing between the boiling points, and other physical constants, of isomeric carbon compounds containing only singly-linked polyvalent atoms, *i.e.* compounds the isomerism of which is due only to variations in the grouping of the atoms, and the structural formulæ of these compounds. His results establish a considerable probability in favour of the rule, that in such isomeric groups, those compounds which have the smallest molecular volumes, have also the highest boiling points, greatest specific gravities and refractive indices (*not* greatest *molecular refraction*), and longest time of flow through capillary tubes; and very probably these compounds have also the smallest amount of ramification in their molecular structure.

Brühl thus put into the hand of the chemist another means whereby he may readily learn much concerning the inner structure of the substances which he examines. Brühl's results, as also those of Thomsen, exhibit a close connection between physical properties of compounds and the valency, or specific saturation power, of the elementary atoms which build up these compounds.

As the theories of modern chemistry are so largely based on the idea of valency, the results of Brühl and Thomsen are most welcome, as at once tending to confirm the general soundness of the methods of the Newer Chemistry, and exhibiting at least two measurable physical phenomena as closely connected with the exercise of valency.

The results of both observers emphasise the difference which chemists have long recognised between two kinds of isomerism: that due to "grouping," and that due to "linking" of atoms. Is it not at least possible, in view of these results, that a greater part of the chemical energy of molecules containing doubly (or trebly) linked polyvalent atoms is kinetic, than is the case in isomeric molecules, the atoms of which are all singly-linked? if indeed the chemical energy of the latter molecules be not wholly potential. Double-linking might then mean greater kinetic energy; and the entropy of a molecule containing only singly-linked atoms would be greater than that of its isomer, some of the atoms in which were doubly-linked.

The consideration of valency of atoms is closely connected with the more general subject of chemical affinity; and the work of Thomsen and Brühl suggests many questions connected with affinity which press for answers.

A short account was given in this journal (vol. xx. p. 530) of the work of Guldberg and Waage, and of Ostwald, on chemical affinity. The latter naturalist has recently extended his methods of observation: in his earlier papers he used physical methods, determining the changes in the specific volumes, and also in the refractive indices, of solutions of acids and bases when these acted chemically on each other, and hence calculating the amount of chemical action. Ostwald now employs a more purely chemical method; he allows acids of known strength to react on a solid salt in excess, and determines the amount of action at definite intervals. His results, so far as they have extended,[1] strikingly confirm the numbers which he before obtained for the relative affinities of the commoner acids.

The application of the theory of Guldberg and Waage to reactions between a solid and a liquid, the former being in excess, requires that a definite and stable condition of equilibrium should be reached at the expiry of not too great a time. Doubt was thrown on Ostwald's results because it was said that such equilibrium had not been attained. In his latest paper Ostwald has carefully examined this point, and has shown that the required equilibrium is attained, and maintained, and that therefore such reactions are well suited for the study of general problems of affinity. Ostwald's future results, as he extends the application of the chemical method, will doubtless be very interesting.

All the work which has been here shortly noticed tells unmistakably that chemistry is rapidly passing out of the natural history stage of progress into that stage where her facts will be accurately grouped under general laws, which laws will admit of quantitative statement, and of quantitative deductions being made from them.

The recent work in chemistry also illustrates the need of a wide training in the methods of various sciences for the investigator of this branch of natural phenomena. One man begins with a purely chemical investigation, another with one which appears wholly physical; before long they find that their paths meet, and that the problem which each had attacked without thought of the other, can be solved, and even then solved but partially, only by the united effort of both.

M. M. PATTISON MUIR

JAPAN[2]

I.

MR. MURRAY is to be congratulated on being able to bring out simultaneously two such excellent books on a country which for some years has probably attracted more interest than any other country in the world. Although they both treat of the same subject, they differ much in their method of treatment. Indeed the one may be said to be complementary of the other; and any one who reads them both with care will be able to form a very complete idea of the present condition of an unusually interesting country and people. Sir Edward Reed went out practically as the guest of the Japanese Government, and had ample opportunities of seeing the

[1] His papers are in the *Journal für practische Chemie* of the last and present year.

[2] "Japan: its History, Traditions, and Religions, with the Narrative of a Visit in 1879." By Sir Edward J. Reed, K.C.B., F.R.S., M.P. Two vols. With Map and Illustrations. (London: John Murray, 1880.) "Unbeaten Tracks in Japan." By Isabella L. Bird. Two vols. With Map and Illustrations. (Same Publisher.)

official side of the life of the country, of gaining a knowledge of what is being done to graft the results of Western civilisation on a civilisation centuries older, and which has been developed on totally different lines. From first to last he was in the hands of the leading Government officials of the country, who spared no pains to make his visit as pleasant as it could possibly be. During the whole of his three months' visit to the country, from the beginning of January, 1879, he had seldom an hour to himself, and what time he could subtract from his sleep was given to the writing up of his notes on his day's work, for work it must have been, harder than even an obstruction night in Parliament. From the young Mikâdo down to the most subordinate provincial official, every one was anxious to convince the great English engineer that the enthusiasm with which they received him was genuine, and that they would only be too glad to let him inspect every detail of the great work they were endeavouring to carry out for their country. From beginning to end his visit to the country was a triumphal progress, and, as might have been expected, Sir Edward Reed left the country with a high opinion of its Government, and deeply impressed with the genuineness and thoroughness of its progress. Miss Bird, on the other hand, went to Japan, as she went to the Sandwich Islands and the Rocky Mountains, solely in pursuit of health, which she sought and found by travelling alone in those parts of the country rarely if ever frequented by foreigners, living in common inns and humble houses, and finishing up with a sojourn among that curious people known as the Ainos, the probable aborigines of Japan. She of course had every protection which the influence of Sir Harry Parkes, our representative, could procure her, and her passport was powerful enough to secure a courteous reception wherever she went; indeed she found travelling safer in Japan than it is in some European countries. To some extent it may be said that Sir Edward Reed was shown the outside and the brightest side of Japanese life, while Miss Bird plodded her way through the unfrequented heart of the country, and saw much of the light and shade in the everyday life of the common people. The two travellers had this in common, that no obstacle was put in the way of their seeing all that they desired to see, leaving one with the conviction that the Japanese Government has really nothing to conceal, and that their enthusiasm for progress is, for the present at least, genuine. Thus the two works, as we have said, afford a fairly complete picture of all sides of Japanese life.

Sir Edward Reed's headquarters were of course at Tokio, where he was courteously received by the young Emperor, who impressed him as a man thoroughly anxious to do the best he can for his people, but old and careworn beyond his years from the many trials he has had to undergo since his accession. Here he met with most of the ministers and other public officials, and he has a good word to say about every one of them. All the public sights were of course seen, and especially the great temples, both Shinto and Buddhist. Indeed a great part of the narrative is occupied with accounts of the numerous temples visited by Sir Edward, their architecture, ornaments, relics, and history, and the legends connected with them; and they seem to be all so much alike that we think some of the space thus occupied might have been devoted to other details of his interesting journey. After a month's stay in Tokio, Sir Edward and his son, who accompanied him, and a few of whose interesting notes are embodied in his father's narrative, were taken in a lighthouse steamer round the south coast of the main island through the Inland Sea to the outside of Shimonoséki Strait. The number of excellent lighthouses, constructed on the very latest principles, is remarkable in a country whose adoption of Western institutions is scarcely ten years old. Various points on the coast were touched at, and the vessel finally left at Osaka. From this point the journey into the interior of the main island and back to Yokohama was performed in those curious man-cabs known as "jinriki-shas," which were only introduced seven years ago, but which look as long-established as cabs in London, up to Kioto, the old capital of the country, down to the sacred city of Nara, and back by the ancient Shinto shrines of Isé, at the south entrance to Owari Bay. During this busy journey the time not devoted to inspecting Shinto and Buddhist temples was spent in visiting public works of various kinds, manufactories, schools of all grades, dining, mostly in Japanese fashion, and being amused by dances and other spectacles of a strictly indigenous kind. How much the great bulk of the people have yet to learn is evident from the fact that in many parts of their route through the most frequented part of the country the people would crowd to the doors and run from their work in the fields to get a look at the "Chinese" riding in their jinriki-shas.

It would be impossible to give the reader any idea of one-tenth of the things which Sir Edward Reed saw and which he tells about. As an engineer he was naturally much interested in the public works and manufactures of the country, and the magnitude of some of the Government factories, and the perfection which they have already reached, impressed and delighted him. Even the engineering feats of Old Japan astonished him sometimes, as in the case of the great blocks of stone in the castle of Osaka, the beauty and grandeur of which he says it would be impossible to exaggerate. "The whole or most of the walls are notable for these very large blocks of granite, which vie with the largest of those built into the great pyramid of Cheops, near Cairo, in Egypt; but as the main entrance to the castle proper is approached, one sees block after block of the most astonishing proportions, until at and opposite to the entrance itself are single stones of such immense size that one is almost driven to doubt whether his senses are not deceiving him. It is so difficult to understand how such huge masses can have been quarried, transported, raised to such a height, and there worked into walls. I could not conveniently measure the largest stones, but I feel sure that some of them must be over twenty feet in height, nearly twice that in length, and several feet thick, and must weigh three hundred to four hundred tons."

Into their paper-manufacture the Japanese have introduced the best modern machinery, and paper has for centuries played an important part in the everyday life of the Japanese. Partitions, table-cloths, napkins, curtains, carriage-covers, and innumerable other things are made of this material, and Sir Edward thinks it would be a good thing to introduce some of the articles thus made into our own country. He paid much attention to the native art of the country, of which it is evident we have the most erroneous ideas. The ordinary reproductions of Japanese pictures which we see here, are wretched caricatures, and in this as in many other points we have much to learn before we have any adequate idea of the real nature of Japanese civilisation. They have ever so many schools of art going back for centuries, and many of their pictures are well worth studying, and capable of affording genuine pleasure. Their method of producing their famous lacquer-work, and their various contrivances for casting, interested him greatly, and he gives much curious information on these and similar matters.

Some idea of the multifarious industries of the country and of the zeal of the Government in encouraging them may be gathered from Sir Edward's account of the industries of Kioto. "Under the city government of Kioto there is an industrial department, the Kuwangiyoba, which was established in 1870 specially for the promotion of the industrial arts, and which has the following branches:—1. An experimental gardening department (Saibaishi

Kenjo), commenced in 1872, for the cultivation of foreign and Japanese fruits and vegetables; 2. A shoe-manufactory (Seikuwajo), begun at the same time, for extending the manufacture of boots and shoes of European style; 3. A weaving-factory (Shokkoba), begun in 1873, where silks and other fabrics are woven, principally in foreign looms: this branch sent three workmen to Europe to learn the art of foreign weaving; 4. A physical and chemical branch (Semikiyoku), which has a sub-branch at Miyadju, in Tango, eighty miles distant, and which, with the assistance of two foreign workmen, is promoting and teaching the manufacture of chemicals, soap, effervescing and lemon drinks, *cloisonné* ware, porcelain, &c.; adjoining it is the Senkojo, for teaching dyeing on foreign methods; 5. The female industrial school, Jokoba, already mentioned; 6. The Bokujo, or more properly Bokuchikujo, which is an experimental farm, established in 1871 with the object of improving the breeding of cattle and of teaching agriculture, the foreign cattle and sheep being chiefly purchased in America, and the milk produced being sold in the city; a branch farm exists at Komo in Tamba, about sixteen miles from Kioto; 7. A department (Yosanba) for promoting the multiplication of silkworms; 8. A pauper industrial department (Jusansho), established in 1869, with a branch at Dosembo, in the south-eastern part of Kioto County, where agriculture and the manufacture of earthenware are the principal employments of the pauper colony; 9. A street-sweeping department (Kuwakaisho), where compost is prepared on the French method; 10. A paper-manufactory, established in 1875. There exist also separate branches for making and teaching how to prepare leather, beer, and mineral waters. A museum is in course of formation."

Of course the educational establishments of the country interested Sir Edward greatly. We have heard much of the admirable university of Tokio and its famous engineer-

Fig. 1.—Mount Fuji.

ing school. But all over the country, at least so much of it as Sir Edward Reed visited, Government is evidently doing what it can to give facilities for education of the best kind. Schools of all grades and for all classes and both sexes are being everywhere established, and some of those Sir Edward visited seemed to be admirably organised, though some of the subjects taught, especially to girls, are amusing. We all know what a hold science has taken upon the Japanese ever since they opened their country to European and American influence. They have been shrewd enough to see that through the encouragement of science lies the surest road to national progress, and the Government has spared no pains nor expense to place education in science in the first rank; and this feature is seen throughout all their schools. The present purpose of the Government is evidently to make education universal all over the country, and to bring it up to a standard equal to that of the foremost countries in Europe. Every soldier Sir Edward Reed noticed in the barracks at Osaka had a little library of books all to himself, and this is a relic of the old days of Japan, when the *samurai* class were at once the soldiers and scholars of the country. Sir Edward is sanguine enough to hope that the time may come in this country when soldiers will occupy a comparatively high position in the social scale, "and when the army will attract to it the surplus members of the civil community of all grades that are respectable and well instructed." Sir Edward was, moreover, struck with the size of the men in various parts of the country, as contrasted with the little fellows that are sent over here to be educated, and with the common idea entertained in Europe of the stature of Japanese. Indeed Sir Edward's testimony on this point is so novel and so different from that which has been generally accepted, that we should like to see some attention given to the subject by those in a position to throw light upon it. Sir Edward met at Kioto Mr. Akamatz, a highly-educated Buddhist priest, who had been to Europe to study and report on the

religions of the West, and who spoke English well. "It may be interesting," Sir Edward says, "to some of my readers to learn that this excellent priest, possessing a knowledge of England and the English, and also the chief priest who was our host on this occasion, find embraced in their section of the Buddhist faith all that they consider good and true in the Christian religion, and are not without hope of seeing England adopt this view, and with it the tenets and practice of their faith, which they consider most excellent. It will be gratifying, doubtless, to the many good people at home who look upon Buddhists as eligible for conversion to their particular views of the Christian religion (whatever they may happen to be in each case), to find their own generous and beneficent intentions so entirely reciprocated."

Over Sir Edward, as over others who have been to Japan, the quiescent (not necessarily extinct) volcano, Fuji-yama, seems to have exercised an influence akin to fascination. He was never tired of looking at the snow-covered cone, rising nearly 13,000 feet above the sea in solitary grandeur, and like no other mountain in the world. For hundreds of miles around it is the prominent feature in the landscape, and the first object that meets the traveller's sight coming from south or east. "But the best evidence of the sacred character of Fuji is to be found, I think, in the fact that every person who speaks or writes about it seems naturally to rise more or less into a reverent state of feeling as he does so. It has a real, a strong, and a solemnising influence on all who behold it. Even when it is viewed from beyond other mountains, its sovereign character is very striking; and when it is seen springing with one tremendous and sublime flight from sea to sky, it is of more sovereign character still."

But the record of what Sir Edward Reed saw while he was in Japan forms a comparatively small part of the two

Fig. 2.—Curious Japanese Bridge.

volumes he has written. His interest in the country and its people is so great that he has put himself to considerable trouble to master their history, their religions, their political and social systems, their art and manufactures, in short everything that could enable him to understand a civilisation so real, but so entirely different from anything in Europe. The results of all this study, with the conclusions he has come to both from this and from his visit to the country, occupy a considerable part of the work. That a man of the scientific eminence and political experience of Sir Edward Reed should take so much interest in Japan seems to us a proof that it really deserves the attention of all thoughtful men; and whatever conclusions such an observer may come to ought to have considerable weight with those who are not quite sure what to think of the strange social and political phenomenon that has been taking place for upwards of ten years in the farthest East. Unless, however, the subject is approached in the spirit with which Sir Edward Reed has taken it up, a spirit of thorough seriousness, with an adequate idea of the worthiness of the subject for earnest inquiry, it had better be left alone. A little learning here is a dangerous thing, and has led some triflers to find only amusement in Japanese history and Japanese ways, as if this were merely a toy civilisation, and not a complicated system which has been the development of ages. Sir Edward traces, in his first volume, the history of the Japanese from the earliest "God-period" down to the present time; discusses their two great religions, the native Shintoism and imported Buddhism, their political and social system, their foreign relations, the recent reforms, and the existing government. In the second volume, besides the narrative of his journey, he has interesting chapters on art and on the proverbs and phrases of the people; and both in the second volume and in the introduction he has elaborate

discussions on the ethnology of the Japanese, their language and literature. Sir Edward does not profess to know all these subjects at first hand, but has, with perhaps only one exception, chosen for his guidance the most trustworthy authorities attainable. Sir Edward gives several examples of what the Japanese language is capable of in the way of poetry; we have space for only one specimen:—

"Types of our children are the tiny grasses,
Tender and fr[illegible]ile in the ample moorland:
We know n[illegible] to what fragrance their infant sprouts may blossom,
Nor wist to what sweetness their unborn fruits may ripen,
But hoping ever wait till autumn tells their story.
Oh! cherished children, may ye never perish,
Flowerless, fruitless, in the early springtime,
Nor like this petal trampled by the wayside,
Fall in the fuller promise of your prime."

A people that are capable of thinking and writing thus deserve better than to be laughed at.

Sir Edward Reed left Japan with the highest respect for the people and their efforts to bring themselves abreast of the civilisation of Europe and the United States, and with a firm belief in the determination and earnestness of the Emperor and his ministers. He evidently is strongly of opinion that the new phase upon which Japan has entered is no mere spurt which will collapse in a few years, but a permanent change for the better in the direction of the civilisation of the country. That the result will be a complete assimilation to European ways, as some people seem to think and hope, is not to be wished for and not in the nature of things to be expected. With all their admiration for the science and the arts of Europe, the Japanese respect themselves sufficiently to see that there is much in their old civilisation that may well be retained. Indeed the problem is one of the meeting of two forces. A new force from an entirely different direction has struck in upon the course of the old civilisation, with the result of a permanent change of direction; but that change cannot be entirely in the direction of the new force. Nor will the final result be a lapse back into the old ways; even in the brief period since the country was opened to European influence the change has been so wide and deep that any such lapse is inconceivable. Those who are in the habit of decrying the country tell us that the Japanese are everything by turns and nothing long; their upwards of 2,000 years of gradual development in one direction, and their steady continuance in the course entered upon about fifteen years ago, belies the sneer, which probably owes its origin to that official quarter whose contemptuous treatment of the Japanese Government Sir Edward Reed so strongly laments. We earnestly hope that the Japanese will go on during the next fifteen years as they have done in the past, and by that time the current in the new channel will be so broad and powerful that it will require a force of equal power to seriously change its direction, and we do not know where that is to come from. The problem in national development being worked out by the Japanese is of the highest possible interest, and what is its real nature cannot be better learned than from the two valuable volumes which so busy a man as Sir Edward Reed has found time to put together.[1]

NOTES

THE foundation-stone of the new museum of McGill College, Montreal, to which we referred some time ago, was laid on September 21 by the Marquis of Lorne. Principal Dawson in thanking Mr. Redpath, the donor, for his generous gift, stated that the museum would be not merely a place for the exhibition of specimens, but a teaching instrument and a laboratory of original research; a great natural science department of the University, in which the classes in geology and biology would receive their instruction, original workers would be trained in all departments of natural science, and from which would go forth the men—and, he trusted, the women also—best fitted to bring to light the hidden treasures of the Dominion, and to avert by the aid of science the injuries with which any of its industries might be threatened. Dr. Dawson referred to other noble examples of private local or national liberality on the American continent, besides those of which Montreal can boast—to "the great National Museum at Washington, which is intended to rival, and if possible surpass, the British Museum; the Central Park Museum of New York, on which that great city has lavished vast sums of money; the Zoological Museum of Harvard, whose revenues would suffice to support some entire universities in this country; or the foundations of Mr. Peabody, which have established great museums in several American cities." And he hoped that this latest gift to Montreal would stimulate other benefactions, especially for their Faculty of Applied Science, so that the physical apparatus and class-rooms of the University might be as well provided for as their natural science collections.

MR. MERRIFIELD, F.R.S., the retiring president, proposes at the annual meeting of the London Mathematical Society on November 11, to cast his valedictory address into the form of "Considerations respecting the Translation of Series of Observations into Continuous Formulæ." The following is the proposed new Council:—Mr. S. Roberts, F.R.S., president; Dr. Hirst, F.R.S., and Mr. J. W. L. Glaisher, F.R.S., vice-presidents; Mr. C. W. Merrifield, F.R.S., treasurer; Messrs. M. Jenkins and R. Tucker, honorary secretaries; other members, Prof. Cayley, F.R.S., Mr. H. Hart, Prof. Henrici, F.R.S., Dr. Hopkinson, F.R.S., Mr. A. B. Kempe, Mr. R. F. Scott, Prof. H. J. S. Smith, F.R.S., Messrs. Lloyd Tanner, H. M. Taylor, and J. J. Walker.

WE take the following from the New York "Monthly Index to Current Periodical Literature," &c.:—"The new Warner Observatory which is being erected at Rochester, N.Y., is attracting much attention in social and literary as well as scientific circles. The new telescope will be twenty-two feet in length, and its lens sixteen inches in diameter, thus making it third in size of any instrument heretofore manufactured, while the dome of the Observatory is to have some new appliances for specially observing certain portions of the heavens. It is to be the finest private observatory in the world, and has been heavily endowed by Mr. H. H. Warner. Prof. Swift has laboured under numerous disadvantages in the past, and the new comet which he recently found was in spite of many obstacles; but as the new institution is to be specially devoted to discoveries, there are good reasons to expect very many scientific revelations in the near future from the Warner Observatory at Rochester."

THE *Times* has shown considerable pluck in having erected at its office one of Mr. Jordan's glycerine barometers, described in NATURE, vol. xxi. p. 377. In the issue of the 25th inst. and following days are published the readings of this gigantic barometer at intervals of two hours from 2 p.m. to 2 a.m. This will be continued regularly, a second edition of the paper giving the two-hourly readings from midnight to noon. These daily records with a barometer on such an enormous scale will be of the greatest value. The *Times* rightly states that it seems unquestionable that an instrument of this kind is admirably suited for practical use at meteorological stations, at seaports, in collieries, and in all other situations where it is of importance for the unpractised eye to notice frequently and easily the changes taking place in atmospheric pressure.

[1] For the illustrations in this article we are indebted to the courtesy of Mr. Murray.

THE results of the observations made from the two balloons sent up from the Crystal Palace on Thursday last have not yet been discussed. But it may be stated that the direction of the wind was remarkably steady, as during the run the two balloons were constantly kept in view of each other in spite of the want of light and transparency of air. This result is all the more to be noted that the variations in the altitude of the two balloons were frequent and considerable, 0 to 5000 feet. The variation of temperature did not amount to more than 5° C. between the maximum of the readings and their minimum. A peculiar current was observed just on arriving on the coast, which is usual under such circumstances. The composition of the clouds was very complex. First, a layer of transparent fog covered almost the whole of the land and gave a watery appearance to it; second, cumuli described as analogous to pulled bread were floating at a height of 1000 metres and descended gradually as the sun was nearing to the horizon; and lastly, a large number of parallel strati stretching south-westerly in the direction of the sun, and seemingly diverging from it. The velocity of the wind was about half a mile per minute, and pretty well determined by observers located in one of the two towers of the Crystal Palace. As to the prognostication of the route, it was nicely done by Mr. Coxwell, who told M. de Fonvielle that he should land between Portsmouth and Winchester. A question arose between M. de Fonvielle and Commander Cheyne about the bearing, the latter's compass having been reversed by an optical illusion, but the azimuth was given with great accuracy, and the uncertainty between the two would not have lasted for a minute if the possibility of the error could have been ascertained. The swinging of the balloon round its axis was sufficient to prevent the use of a new compass designed on purpose for aëronauts.

IT has been represented to us that in our notice of Prof. Owen's work the statement that "he was lecturer on palæontology at the School of Mines in Jermyn Street in 1856" may lead to a misapprehension. We have therefore to state that although Prof. Owen delivered a course of lectures in the theatre of the School of Mines in the year in question, he held no appointment in that institution.

MR. GRAHAM BELL has been honoured in the scientific, as well as other circles of Paris during the past week. He exhibited his photophone at the establishment of M. Antoine Breguet and elsewhere, and was the object of much curiosity wherever he went as "l'homme qui fait parler la lumière."

AT the opening meeting of the Geologists' Association on November 5, the president, Prof. Rupert Jones, will read a paper on the origin and progress of that society.

THE next number of the Victoria Philosophical Institute's *Journal* is announced to contain papers by Prof. Stokes, F.R.S., Prof. Hughes of Cambridge, Prof. Nicholson, M.D., F.R.S.E., of St. Andrew's, and Dr. Hormuzd Rassam, with maps and details of his discoveries.

MR. FLETCHER of Warrington has sent us a specimen of a new gas-heating burner which seems well adapted for many purposes and trades which are as yet unsupplied with satisfactory heating apparatus. It seems to us to have all the advantages claimed for it by Mr. Fletcher. It has from three to four times the power of any burner similar in appearance; the flame is *solid*, intensely hot, and perfectly free from smell; it gives a duty higher than the calculated theoretical maximum for the gas consumed, and it cannot be damaged by the dirtiest work. In case the perforated copper dome gets choked with dirt, it can when the burner is warm be lifted off and washed or brushed clean. Any liquid spilt so as to get inside the burner flows out by the side tube without the possibility of damaging the burner. The body of the burner is cast all in one piece, without a joint, thus doing away with one great fault, causing liability to leakage in most of the burners at present in use. Altogether this burner seems to be one of the greatest advances yet made in the practice of heating by gas. Mr. Fletcher has also sent us a useful practical paper on Heating (including cooking) by Gas, read the other day before the Philosophical Society of Glasgow.

PART iii. is to hand of the magnificent "Bedfordshire Pomona," the illustrations of the apples and pears in which continue to be as numerous and life-like as ever, so much so as to make one's mouth water. The papers in this part are on "The Crab, its Characteristics and Associations," by Mr. Edwin Lees, F.L.S.; "The Orchard, its Products: Cider and Perry," by the Rev. C. H. Bulmer; the latter a paper of considerable length, minute detail, and great practical value. Mr. David Bogue is the London publisher.

AMONG the lectures to be given this winter at the Museum and Library, Queen's Road, Bristol, are the following:—November 22, Prof. S. P. Thompson, B.A., D.Sc., "The Rainbow," illustrated with experiments by the electric light; January 17, 1881, Prof. Rolleston, M.A., M.D., F.R.S., F.L.S., Linacre Professor of Anatomy and Physiology, Oxford, "The Early Races of the British Isles"; January 31, Sir John Lubbock, Bart., M.P., F.R.S., F.L.S., "Fruit and Seeds"; February 14, Rev. J. M. Wilson, M.A., F.R.A.S., Head Master of Clifton College, "Double and Multiple Stars"; February 28, Dr. W. H. Stone, F.R.C.S., Lecturer on Physics at St. Thomas's Hospital, "The Measurement and Determination of Musical Pitch," illustrated with experiments; March 14, Prof. W. J. Sollas, M.A., F.R.S.E., F.G.S., Curator of the Bristol Museum, "Coal and the Bristol Coalfields."

WE have received the Catalogue of the General Lending Department of the Newcastle-on-Tyne Public Library, a very thick volume, with a much thinner one containing a list of the books of the Juvenile Lending Department. We may notice them more at length in a future number.

WE have received a very favourable Sixth Annual Report from the West London Scientific Association and Field Club, which commenced its new session on the second Tuesday of this month.

THE *Reports* of the Dunedin (N.Z.) Naturalists' Field Club for 1878-80 are, we regret to see, desponding. It finds some difficulty in keeping up the interest of its members, rather a strange thing in the land of the New Zealand Institute. The Report contains catalogues of the indigenous and introduced flowering plants occurring in the Dunedin district.

ON September 23 Rangoon was visited by three distinct shocks of earthquake; all parts of the province had previously been visited by shocks. A shock of earthquake lasting two seconds was felt at Cordova on the 21st inst., accompanied by a loud subterraneous rumbling. A slight shock, lasting six seconds, was also felt at Madrid on the same day. The shock was stronger in the centre of the city than in the outskirts, and shocks occurred in several towns of the province of Zamora, but no damage has been done. On the same date a shock, the after effects of which were felt in almost every part of the country, occurred both at Lisbon and Coimbra, without however doing any damage.

IT is stated that at the National Exhibition to be opened at Milan next year there will be a captive balloon, on the model of the one which was so successful in Paris in 1878. It will measure not less than 180 feet in circumference, 84 feet in height, and contain 15,000 cubic feet of gas. To it will be

attached a safe and solid car, capable of containing seats for at least eight persons. A steam-engine is to regulate the ascent and descent, and it will rise to a height of about 900 feet, affording a splendid view of Milan and the plains of Lombardy. The balloon will be constructed at Milan, M. Henri Beudet, the well known and experienced aëronaut, having been sent for to direct the work.

THE coal-beds on the Souris River, Manitoba, have proved very rich, and are to be developed during the winter.

THE Japan papers call attention to the almost limitless mineral wealth lying dormant in the country, and which is only waiting for development to become a profitable source of revenue. Of coal there is an abundant supply, but only the Takashima mine has been fitted with modern appliances. There are several other coal mines which are only unprofitable because improperly worked, and now it is averred that Prof. Atkinson during a sojourn in the Mitake Mountains of the Koshu Province has discovered another valuable deposit of coal.

MR. NORTH, who was sent by the Natal Government to examine the Newcastle coal-fields, has reported favourably on the quantity and quality of the coal.

ON Friday evening, October 22, previous to distributing at the Manchester Mechanics' Institute the prizes and certificates gained by the students at this year's Science and Arts, Society of Arts, City and Guilds of London Institute, and Union of Lancashire and Cheshire Institute's examinations, Prof. Ayrton delivered an address on Technical Education and on the future of Mechanics' Institutions. Of the two original objects for which Mechanics' Institutions were established fifty years ago, to provide clubs for artisans and places for giving popular scientific lectures, it was shown that the latter had to a great extent been abandoned; also that the mere novel utility of such institutions in furnishing the means for the holding of science and art classes would also be taken away from them when the teaching of elementary science became the duty of our elementary schools. There remained, however, for Mechanics' Institutions a great new field of activity in the teaching of applied science to mechanics, not the teaching of abstract scientific principles and the applications only perhaps afterwards, but the teaching of these scientific principles *through* the apparatus in use in daily life; in fact, that Mechanics' Institutions could well furnish the machinery by means of which numerous technical classes throughout the country which were so much needed could be rapidly established, the money voted by the City and Guilds of London Institute as payment on the results of the technological examinations, together with funds locally subscribed, furnishing the motive power. What the lecturer thought technical teaching should consist of was illustrated by the kind of work now going on at the temporary laboratories of the City Guilds Institute at Finsbury; stress was laid on the fact that there were no distinct students' fees there for laboratory work and for lectures, but that every fee, small as it was, entitled each student to at least two hours' practical work in the laboratories for every one hour of lecture; so that in fact all the 150 students had laboratory work which did not consist in the mere repetition of qualitative lecture experiments, but in the making of accurate quantitative measurements, all bearing as far as possible directly on each student's trade. Of this practical illustrations were given. Prof. Ayrton concluded by warning technical instructors from attempting to follow ordinary college methods of *synthetical* teaching, which, although most valuable for a young lad prepared to spend several years at college, was quite unsuitable for an artisan engaged all day in following his trade. Technical education, he considered, must be distinctly *analytical*—the complete machine as the artisan knew it must be taken at once, and the science developed, so to say, from the machine itself; and that it was men with a good practical knowledge of their trade and with an aptitude for science rather than men versed in science, but with only a mere book knowledge of industries, that were wanted both as candidates for the technological examinations and as students to be trained up as technical instructors.

IN the note on the late Dr. Sparks in NATURE, vol. xxii. p. 591, for Dr. King's "Therapeutics" read Dr. Binz's "Therapeutics."

THE additions to the Zoological Society's Gardens during the past fortnight include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. W. B. Tustin; two Polar Bears (*Ursus maritimus*), an Ivory Gull (*Larus eburneus*) from the Arctic Regions, presented by Mr. Leigh Smith, F.Z.S.; a Crested Porcupine (*Hystrix cristata*) from India, presented by Mr. W. Middleton; three Gaimard's Rat Kangaroos (*Hypsiprymnus gaimardi*) from Australia, presented by Mr. A. B. Gow; a — Brocket (*Cariacus sp. inc.*), a White-bellied Opossum (*Didelphys albiventris*), a Brazilian Hare (*Lepus brasiliensis*) from Quipapà, Pernambuco, a White-bellied Guan (*Ortalida albiventris*), a Black Tortoise (*Testudo carbonaria*) from Garanhuns, presented by Mr. W. A. Forbes, F.Z.S.; a Frigate Bird (*Fregata aquila*) from Fernando de Noronha, presented by the Rev. G. Bayldon; a Yellow-headed Conure (*Conurus jendaya*) from Pernambuco, presented by Mr. C. A. Craven; two American Black-backed Geese (*Sarcidiornis carunculata*) from the Sertoes of Pernambuco, presented by Miss Davis; a White-throated Finch (*Spermophila albogularis*) from Pernambuco, presented by Mr. S. Jones; a Herring Gull (*Larus argentatus*), British, presented by Mr. J. Palmer; a Horrid Rattlesnake (*Crotalus horridus*) from Quipapà, Pernambuco, presented by Mr. H. E. Weaver; a Bonnet Monkey (*Macacus radiatus*) from India, a Black Iguana (*Metopoceros cornutum*) from Galapagos (?), deposited; a Rock Cavy (*Ceredon rupestris*), a Green-winged Trumpeter (*Psophia viridis*), a White-bellied Parrot (*Caica leucogaster*), a Red vented Parrot (*Pionus menstruus*), two Golden-headed Parrakeets (*Brotogerys tui*), two Toco Toucans (*Ramphastos toco*), an Orinoco Goose (*Chenalopex jubata*) from Brazil, a Rufous Pigeon (*Columba rufina*), a Yarrell's Siskin (*Chrysomitris yarrelli*), two Scaly Doves (*Scardafella squamosa*) from Parahyba, three Picazuro Pigeons (*Columba picazuro*), a Black Tanager (*Tachyphonus melaleucus*), a Black-headed Tanager (*Orchesticus ater*), a Passerine Ground Dove (*Chamæpelia passerina*), three Yellow-shouldered Hangnest (*Icterus tibialis*), from Pernambuco, a Brazilian Tanager (*Ramphocœlus brasilius*), a Blue and Black Tanager (*Calliste brasiliensis*) from Bahia, a White-eyebrowed Guan (*Penelope superciliaris*) from Panellas, four Cactus Conures (*Conurus cactorum*), two Banded Tinamous (*Crypturus noctivagus*), seven Tataupa Tinamous (*Crypturus tataupa*) from Garanhuns, a Great-Billed Rhea (*Rhea macrorhyncha*) from Agoas Bellas, Pernambuco, two Orchard Hangnests (*Icterus spurius*), a Baltimore Hangnest (*Icterus baltimore*) from North America, purchased; two Squirrel-like Phalangers (*Belideus sciureus*), born in the Gardens; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. F. W. Manley; a Dunlin (*Tringa cinclus*), a Sanderling (*Calidris arenaria*), British, presented by Mr. Edmund Elliot, M.R.C.S.; a Horned Lizard (*Phrynosoma cornutum*) from Texas, presented by Mr. W. C. Boyd; a Waxwing (*Ampelis garrulus*), European, deposited; a Black Saki (*Pithecia satanas*) from Lower Amazons, a Roseate Spoonbill (*Platalea ajaja*), a Great-billed Rhea (*Rhea macrorhyncha*) from South America, purchased.

OUR ASTRONOMICAL COLUMN

CERASKI'S VARIABLE OF SHORT PERIOD.—It will be seen from a letter which Prof. Pickering, the Director of the Observatory of Harvard College has addressed to us, that, contrary to

the opinion expressed by Dr. Julius Schmidt from his earlier observations, the true period of this notable variable star, instead of being a little less than five days, appears to be a little less than half this interval, otherwise *minima* observed at Harvard College, will not accord with those of May and August observed in Europe.

It is probable that Schwerd observed the star near a *maximum* at meridian transit at Speyer on March 11, 1828, when he estimated its magnitude 6·7, and near a *minimum* at transit on May 12 in the same year, when he rated it only 10m. If we compare the observation of March 11 with that of Dr. Schmidt, who fixed a *minimum* to August 12 at 6h. mean time at Athens, and assume 7662 periods to be included in the interval, we get for the duration of one period 2·49084d., or 2d. 11h. 46·81m., which closely accords with half the period assigned by Schmidt from his own observations and those of Ceraski. This reckoning from August 12·1841 Greenwich mean time, and correcting for the light-equation, will give the following times of geocentric minima observable in this country:—

	h. m.			h. m.	
Oct. 28 ...	9 33	G.M.T.	Nov. 17 ...	7 47	G.M.T.
Nov. 2 ...	9 7	,,	22 ...	7 21	,,
7 ...	8 40	,,	27 ...	6 54	,,
12 ...	8 14	,,	Dec. 2 ...	6 28	,,

And for the times of visible maxima, supposing this phase to occur midway between the minima, we find—

	h. m.			h. m.	
Oct. 29 ...	15 27	G.M.T.	Nov. 18 ...	13 40	G.M.T.
Nov. 3 ...	15 0	,,	23 ...	13 14	,,
8 ...	14 33	,,	28 ...	12 48	,,
13 ...	14 7	,,	Dec. 3 ...	12 21	,,

If S be the sun's longitude, and R the earth's radius-vector, the correction for the light-equation (geocentric—heliocentric) for 1880 may be found from

$$\text{Cor.} = 224{\cdot}0s \text{ R. sin } (S + 19^{\circ}\ 17'{\cdot}4).$$

We have received from Lord Lindsay a circular containing the same information that is given in Prof. Pickering's letter, with the addition of a diagram showing the *Durchmusterung* stars in the vicinity of the variable, which for 1881·0 has R.A. 0h. 51m. 48s., N.P.D. 8° 46'·0.

[Mr. Knott's observation on October 23, received since the above was in type, as compared with Athens, August 12, seems to require a somewhat longer period, with minima a half hour or so later than we have computed.]

THE ROTATION OF JUPITER.—In No. 2,342 of the *Astronomische Nachrichten* (to which we refer for numerical details) Dr. Julius Schmidt has a communication wherein he finds, from observations of the red spot upon the disk of Jupiter by himself and others in 1879–80, an interval of 9h. 55m. 34·4s. for the time of the planet's rotation upon its axis, a result that he considers may be adopted until the observations generally have attained a greater degree of precision than they appear to possess at present. With due care and practice, however, he believes that such observations will be found to admit of much greater accuracy, and illustrates this by his own experience at Athens in the present year. In the same communication he also discusses observations of a dark oval spot (a more favourable object than any used by Airy and Mädler) during 104 rotations in 1862; these observations give 9h. 55m. 25·68s. for the period of rotation, a result closely agreeing with those of 1834–35.

CHEMICAL NOTES

A NEW method of preparing acetylene is described by Dr. W. Suida in *Wien. Akad. Ber.* The method consists in heating iodoform and mercury ethide in sealed tubes to 120°; the products of the reaction are acetylene, ethylene, ethylic iodide, and mercury ethyliodide.

THE same *Berichte* contains a paper by Herr v. Dumreicher on the relative stabilities of nitrous and nitric oxides, and of nitrous and nitric oxides when acted on stannous chloride. Nitrous oxide is not reduced even at 100°; nitrous acid is reduced to nitrous oxide; nitric oxide and nitric acid are reduced to hydroxylamine, and subsequently to ammonia. The reaction may be applied to the estimation of nitric acid.

IN the *Proceedings* of the Academy of Rome Signor Cossa communicates the results of experiments on didymium tungstate: he has determined the specific heat of this salt to be 0·0831—temperaturature limits are not given. Taking the atomic heat of tungsten as 6·4, and that of oxgen as 4, this result points rather to the formula for didymium tungstate, $DiWO_4(Di = 98)$, than to that now generally accepted, $Di_2(WO_4)_3(Di = 147)$.

A NEW organo-metallic compound containing the divalent radicle $(CH_2)''$ is described in the *Journal* of the Chemical Society by Sakurai; the formula of the new substance, for which the name *Monomercuric methylene iodide* is proposed is $I(CH_2)HgI$. This is the first known metallic compound containing a *divalent* hydrocarbon radicle.

G. BOUCHARDAT claims, in *Compt. rend.*, to have converted amylene, by successive removals of hydrogen, into cymene. Hitherto attempts to pass, by a simple series of reactions, similar to those by which the passage from one isologous group to another is effected, from the paraffin to the aromatic group of compounds, have not been successful.

ACCORDING to the experiments of Macagno (*Bied. Centralbatt*) the mellowness of old wine is due more to an increase in the amount of glycerine present, than to a decrease in the tannin; there must also be a certain proportion between the amounts of alcohol and tannin, in order that the wine may keep well.

IN the *Annales Chim. Phys.* Berthelot describes an apparatus in which the combination of two gaseous constituents to form a gaseous compound may be conducted, so as to allow of an accurate measurement of the thermal change which accompanies the chemical change.

A DISCUSSION as to the value to be assigned to the atomic weight of antimony is at present being carried on. From analyses of the bromide and other salts, Prof. Cooke of Harvard concludes that the generally-accepted number, 122, is too large, and that 120 is more nearly correct. Herr Schneider, whose experiments had been criticised by Cooke, replies in the *Journal für Pract. Chem.* He sharply criticises Cooke's methods, gives the details of new experiments, and asserts strongly that 122 is much more nearly correct than 120.

No results of special importance have lately been published regarding the densities of the vapours of the halogen elements. An objection made by Pettersson and Ekstrand to V. Meyer's method, viz. that solid bodies condense air on their surface, which air they again give up when strongly heated, has been shown by Meyer, in the last number of the Berlin *Berichte*, to have no weight against his experiments.

Two important papers on atmospheric ozone have been published in the *Berichte* by E. Schöne. This observer, who has given much careful study to the subject of ozone, says that the smell of ozonised oxygen does not at all resemble the peculiar odour noticed after a lightning flash. The true smell of ozone is, however, frequently noticeable in ordinary air, and coming from the clothes of persons who may enter a room from the open air in winter. The ordinary potassium iodine papers are valueless as ozone measurers, according to Schöne. A small amount of ozone in moist air produces a greater depth of colour on these papers than a larger amount of ozone in dry air. The humidity of the air and the hygroscopic character of the material from which the paper is made therefore largely influence the depth of colour produced. It has been supposed that much ozone is produced in the neighbourhood of waterfalls, but the increased depth of colour of the potassium iodide papers is only due, says Schöne, to the great humidity of the air. Schönbein's "ozonometer" serves as a very rough hygrometer. Paper coated with thallous hydrate is recommended as a measurer of the relative amount of "oxidising principle" in the air: the paper is coloured brown—owing to production of thallic oxide—by ozone or hydrogen peroxide. A table is given showing the variations in "oxidising principle" during 1879. The general conclusions are briefly these:—1. The papers are coloured more deeply during the day than during the night; this difference is more apparent during the long days of the year. 2. Increased wind-force causes increased coloration, because a greater amount of oxidising substance is brought in contact with the paper during the time of exposure. 3. Cloudiness and rain especially influence the coloration; the heavier the rain the smaller the coloration of the paper. Direct determinations of hydrogen peroxide have shown that when the thallium papers are much coloured this compound is present in the atmosphere in comparatively large quantity. Herr Schöne regards the actual existence of ozone in the atmosphere as at present an open question.

MR. A. VILLIERS publishes in the September number of *Annales Chim. Phys.* a lengthy and important paper on the

conditions of equilibrium of mixtures of alcohols and mineral acids. He considers in detail the velocity, and limits of etherification of the more important mineral acids, and arrives at many valuable results.

GEOGRAPHICAL NOTES

AT the last meeting of the Berlin Geographical Society news was received through a German trade house in Tangier that Dr. Lenz had reached Timbuctoo, and that he hoped to be at St. Louis, in Senegal, in the month of July. If this is correct Dr. Lenz has made a rapid journey in this direction, as he only left Tangier on December 22 last. Caillé, however, in 1828, travelled from Timbuctoo to Fez in four months. The last letter received from him by the Society was from Tenduf, in the beginning of May, twenty days' journey from Timbuctoo.

THE *Zeitschrift* of the Berlin Geographical Society, Nos. 88, 89, has a valuable map by Herr Richard Kiepert, showing the work done in Angola in 1876 by Dr. H. von Barth in the region of the Bengo and Lucalla, and of Herr Otto Schütt in 1877-79 on the Lower Quanza. Dr. von Möllendorff discusses the methods of transcribing Chinese geographical names, and concludes that the Pekin form of the Guan-hua, or so-called Mandarin dialect, would be best for general purposes. But Dr. von Möllendorff asks whether, while selecting this form generally, it is advisable to make exceptions in certain cases. Such names, for example, as already exist in familiar forms might be excepted, as Pekin, Canton, Hongkong, Swatow, &c. With other names, especially for special maps, a change from the uniform method of writing might be adopted. Maps of districts for the use of travellers would evidently be of greatest service when the local forms of names were given. Perhaps the Guan-hua might be used for the names of great towns, large rivers, and mountains, while smaller places might have the local forms of their names. For a map of the whole of China, or of the greater part of it, containing little more than the district towns, evidently the Guan-hua would be the preferable form. In books it would perhaps be best to give both forms. It is, no doubt, high time that some attempt at uniformity should be made, but the difficulty is by no means easy of solution, owing partly to the letters of the alphabet not being sounded uniformly in all European languages. Herr von Möllendorff instances the absurdity of the present want of system by the ways in which the Chinese name of the Yellow River is spelled. These are confusing enough, but what will he say when he sees "Houan Hé" (for Hwang-ho) at the head of the interesting communication just received from Col. Prejevalsky? We cannot entirely concur in Herr von Möllendorff's definition of "Kwan-hwa," popularly translated "Mandarin dialect," and he himself makes the orthographical jumble much worse by writing "Guan-hua," which we should imagine few sinologues would attempt to defend. The vexed question, however, may find a solution before long in an unexpected quarter, for the Statistical Department of the Chinese Maritime Customs at Shanghai, we believe, have under consideration a system of spelling for adoption in their reports and other publications, and this, if adopted, will probably come by degrees into general use. Dr. Hildebrandt gives an account of a visit he made to the Amber Mountains in the north of Madagascar; Herr K. Himy continues his elaborate paper on the region around the Kara-Kul, and much of the number is occupied with the journal in North Africa of the late Dr. Erwin von Bary.

THE new number of the Lyons Geographical Society's *Bulletin* contains several items of interest. M. Morice's paper on French Cochin-China is published with a sketch map, followed by some notes by the Abbé Desgodins on the hydrography and orography of Tibet, and a communication by the Abbé Faure on Potosi in Bolivia. Among the other contents are Père Brucker's notes on the geographical positions in Eastern Turkistan and Jungaria determined in 1876 by two Jesuit missionaries, and the report on Col. Flatters' explorations in the Central Sahara last spring.

M. VENUIKOFF has just published at Geneva an historical sketch of the geographical discoveries made in Asiatic Russia from the most remote times to our own days, illustrated by Perthes' map of North and Central Asia.

THE China Inland Mission have been informed by Mr. Samuel Clarke, one of their agents in the Chinese province of Szechuen, that, in company with Mr. Mollman, of the British and Foreign Bible Society, he lately made a journey from Chungking, on the Upper Yangtsze-kiang, to Chêngtu-fu, the capital of the province, on which he travelled by unfrequented roads, where, so far as he could learn, no foreigner had ever been seen before; several previously unvisited towns were also entered. Mr. Clarke calls especial attention to the commercial activity prevailing along his route, and the frequency with which markets were held.

THE Asiatic Society of Bengal have just published, as an extra part of their *Journal*, a "Vocabulary of the Language of Eastern Turkistan," by the late Mr. R. B. Shaw, the well-known traveller, supplemented by two Turki vocabularies of birds and plants by Mr. J. Scully, lately on special duty at Kashgar.

FROM the Vienna *Allgemeine Zeitung* we gather that Dr. Emil Holub contemplates undertaking another lengthened journey in Central South Africa, provided that he can obtain the necessary funds. It is estimated that 50,000 florins will be required for the purpose, and it is proposed to raise this sum by a public subscription, the Austrian Geographical Society heading the list.

THE September number of the *Boletin* of the Madrid Geographical Society contains a detailed account of the Marquesas Islands, with map, by D. Ricardo Beltrán of Rózpide.

IT is stated that the *Gulnare*, with Capt. Howgate's expedition, landed at Rittenbank in Greenland, Dr. Pavy and Mr. Clay, whose intention is stated to be to make natural history collections and explore the northern limits of Greenland. This, we believe, is the same M. Pavy (a Frenchman) whose projected polar expedition suddenly collapsed in San Francisco seven years ago.

THE Austrian *Monatsschrift für den Orient* for October contains an article by Prof. Vambéry on the commercial importance of the Upper Oxus, in which he endeavours to show that there, and not on the Lower Oxus, is trade likely to be developed. Dr. Paulitschke gives an interesting sketch of the progress of African exploration during the past seventy years.

ON MAXIMUM AND MINIMUM ENERGY IN VORTEX MOTION[1]

I. A FINITE volume of incompressible inviscid fluid being given, in motion, filling a fixed, simply continuous, rigid boundary, the fact of its being in motion implies molecular rotation, or (as it may be called for brevity) vorticity. Helmholtz's law of conservation of vorticity shows that, whether the boundary be kept fixed as given, or be moved or deformed in any way, and brought back to its given shape and position, there remains in every portion of the fluid which had molecular rotation a definite constant of vorticity; and his formula for calculating energy for any given distribution of vorticity allows us to see that the energy may be varied by the supposed operation on the boundary.

II. The condition for steady motion of an incompressible inviscid fluid filling a finite fixed portion of space (that is to say motion in which the velocity and direction of motion continue unchanged at every point of the space within which the fluid is placed) is that, with given vorticity, the energy is a thorough maximum, or a thorough minimum, or a minimax. The farther condition of *stability* is secured by the consideration of energy alone for any case of steady motion, for which the energy is a thorough maximum or a thorough minimum; because when the boundary is held fixed the energy is of necessity constant. But the mere consideration of energy does not decide the question of stability for any case of steady motion in which the energy is a minimax.

III. It is clear that, commencing with *any* given motion, the energy may be increased indefinitely by properly-designed operation on the boundary (understood that the primitive boundary is returned to). Hence, with given vorticity, there is no thorough maximum of energy in any case. There may also be *complete annulment* of the energy by operation on the boundary (with return to the primitive boundary), as we see by the following illustrations:—

1. The case of two equal, parallel, and oppositely rotating vortex columns terminated perpendicularly by two fixed parallel planes, which, by proper operation on the boundary, may be so

[1] By Sir William Thomson, British Association, Swansea, Section A, Saturday, August 28.

mixed (like two eggs "whipped" together) that, infinitely near to any portion of either, there shall be some of the other.

2. The case of a single Helmholtz ring, reduced by diminution of its aperture to an infinitely long tube coiled within the inclosure.

3. The case of a single vortex column, with two ends on the boundary, bent till its middle meets the boundary; and farther bent and extended, till it is broken into two equal and opposite vortex columns; and then farther dealt with till these two are whipped together to mutual annihilation.

IV. To avoid for the present the extremely difficult general question illustrated (or suggested) by the consideration of such cases, confine ourselves now to two-dimensional motions in a space bounded by two fixed parallel planes and a closed cylindric surface perpendicular to them, subjected to changes of figure (but always truly cylindric and perpendicular to the planes). It is obvious that, with the limitation to two-dimensional motion, the energy cannot be either infinitely small or infinitely great with any given vorticity and given cylindric figure. Hence, under the given conditions, there certainly are at least two stable steady motions. We shall, however, see further that possibly in every case except cases of a narrow, well-defined character, and certainly in many cases, there is an infinite number of stable steady motions.

V. In the present case, clearly, though there are an infinite number of unstable steady motions, there are only two stable steady motions—those of absolute maximum and of absolute minimum energy.

VI. In every steady motion, when the boundary is circular, the stream lines are concentric circles, and the fluid is distributed in co-axial cylindric layers of equal vorticity. In the stable motion of maximum energy, the vorticity is greatest at the axis of the cylinder, and is less and less outwards to the circumference. In the stable motion of minimum energy the vorticity is smallest at the axis, and greater and greater outwards to the circumference. To express the conditions symbolically, let T be the velocity of the fluid at distance r from the axis (understood that the direction of the motion is perpendicular to the direction of r); the vorticity at distance r is—

$$\tfrac{1}{2}\left(\frac{T}{r}+\frac{dT}{dr}\right).$$

If the value of this expression diminishes from $r = 0$ to $r = a$, the motion is stable, and of maximum energy. If it increases from $r = 0$ to $r = a$ the motion is stable and of minimum energy. If it increases and diminishes, or diminishes and increases, as r increases continuously, the motion is unstable.

VII. As a simplest subcase, let the vorticity be uniform through a given portion of the whole fluid, and zero through the remainder. In the stable motion of greatest energy, the portion of fluid having vorticity will be in the shape of a circular cylinder rotating like a solid round its own axis, coinciding with the axis of the inclosure; and the remainder of the fluid will revolve irrotationally around it, so as to fulfil the condition of no finite slip at the cylindric interface between the rotational and irrotational portions of the fluid. The expression for this motion in symbols is:—

$$T = \zeta r \text{ from } r = 0 \text{ to } r = b;$$
$$\text{and } T = \frac{\zeta b^2}{r} \text{ from } r = b \text{ to } r = a.$$

VIII. In the stable motion of minimum energy the rotational portion of the fluid is in the shape of a cylindric shell, inclosing the irrotational remainder, which in this case is at rest. The symbolical expression for this motion is—

$$T = 0, \text{ when } r < \sqrt{(a^2 - b^2)} \text{ and } T = \zeta\left(r - \frac{a^2 - b^2}{r}\right),$$
$$\text{when } r > \sqrt{(a^2 - b^2)}.$$

IX. Let now the liquid be given in the configuration VII. of greatest energy, and let the cylindrical boundary be a sheet of a real elastic solid, such as sheet-metal with the kind of dereliction from perfectness of elasticity which real elastic solids present; that is to say, let its shape when at rest be a function of the stress applied to it, but let there be a resistance to change of shape depending on the velocity of the change. Let the unstressed shape be truly circular, and let it be capable of slight deformations from the circular figure in cross section, but let it always remain truly cylindrical. Let now the cylindric boundary be slightly deformed and left to itself, and held so as to prevent it from being carried round by the fluid. The central vortex column is set into vibration in such a manner that longer and shorter waves travel round it with less and greater angular velocity.[1] These waves cause corresponding waves of corrugation to travel round the cylindric bounding sheet, by which energy is consumed, and moment of momentum taken out of the fluid. Let this process go on until a certain quantity of moment of momentum has been stopped from the fluid, and now let the canister run round freely in space, and, for simplicity, suppose its material to be devoid of inertia. The whole moment of momentum is initially—

$$\pi\zeta b^2(a^2 - \tfrac{1}{2}b^2);$$

It is now

$$\pi\zeta b^2(a^2 - \tfrac{1}{2}b^2) - M,$$

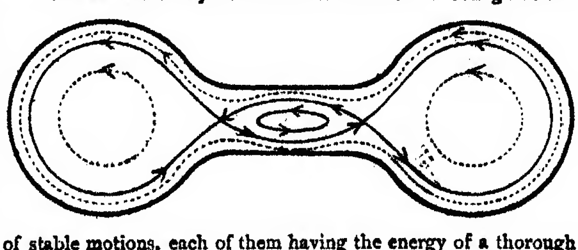
and continues constantly of this amount as long as the boundary is left free in space. The consumption of energy still goes on, and the way in which it goes on is this: the waves of shorter length are indefinitely multiplied and exalted till their crests run out into fine laminæ of liquid, and those of greater length are abated. Thus a certain portion of the irrotationally revolving water becomes mingled with the central vortex column. The process goes on until what may be called a vortex sponge is formed; a mixture homogeneous on a large scale, but consisting of portions of rotational and irrotational fluid, more and more finely mixed together as time advances. The mixture is, as indicated above, altogether analogous to the mixture of the substances of two eggs whipped together in the well-known culinary operation. Let b' be the radius of the cylindric vortex sponge, b being as before the radius of the original vortex column—

$$\tfrac{1}{2}b'^2 = \tfrac{1}{2}b^2 + \frac{M}{\zeta b^2}.$$

X. Once more, hold the cylindric case from going round in space, and continue holding it until some more moment of momentum is stopped from the fluid. Then leave it to itself again. The vortex sponge will swell by the mingling with it of an additional portion of irrotational liquid. Continue this process until the sponge occupies the whole inclosure.

After that continue the process further, and the result will be that each time the containing canister is allowed to go round freely in space, the fluid will tend to a condition in which a certain portion of the original vortex core gets filtered into a position next to the boundary, and the fluid within it tends to a more and more nearly uniform mixture of vortex with irrotational fluid. This central vortex-sponge, on repetition of the process of preventing the canister from going round, and again leaving it free to go round, becomes more and more nearly irrotational fluid, and the outer belt of pure vortex becomes thicker and thicker. The final condition towards which the whole tends is a belt constituted of the original vortex core now next the boundary; and the fluid which originally revolved irrotationally round it now placed at rest within it, being the condition (VIII. above) of absolute minimum energy. Begin once more with the condition (VII. above) of absolute maximum energy, and leave the fluid to itself, whether with the canister free to go round sometimes, or always held fixed, provided only it is ultimately held from going round in space; the ultimate condition is always the same, viz., the condition (VIII.) of absolute minimum energy.

XI. That there may be an infinite number of configurations



of stable motions, each of them having the energy of a thorough minimum as said in IV. above, we see, by considering the case, in which the cylindric boundary of the containing canister consists of two wide portions communicating by a narrow passage, as shown in the sketch. If such a canister be completely filled with irrotationally moving fluid of uniform vorticity, the streamlines must be something like those indicated in the sketch.

[1] See *Proceedings* of the Royal Society of Edinburgh for 1880, or *Philosophical Magazine* for 1880; Vibrations of a Columnar Vortex; Wm Thomson.

Hence if a small proportion of the whole fluid is irrotational, it is clear that there may be a minimum energy, and therefore a stable configuration of motion with the whole of this in one of the wide parts of the canister; or the whole in the other; or any proportion in one and the rest in the other; or a small portion in the elliptic whirl in the connecting canal, and the rest divided in any proportion between the two wide parts of the canister.

ON THE SPECTRA OF THE COMPOUNDS OF CARBON WITH HYDROGEN AND NITROGEN

MESSRS. LIVEING AND DEWAR have made a long series of observations on this subject, of which the following is a brief abstract[1] by the authors :—

The first experiments were made with a De Meritens dynamo-electric machine, arranged for high tension, giving an alternating current capable of producing an arc between carbon poles in air of from 8 to 10 millims. in length. The carbon poles used had been previously purified by prolonged heating in a current of chlorine.

The arc was taken in different gases inside a small glass globe about 60 millims. in diameter, blown in the middle of a tube. The two ends of the tube were closed with dry corks, through which were passed (1) the carbons inserted through two pieces of narrow glass tubing; (2) two other glass tubes through which currents of the gases experimented with were sent.

The arc taken in a globe of air gave a tolerably bright continuous spectrum, above which the green and blue hydrocarbon bands were seen, also the seven bands in the indigo (wave-lengths 4,600 to 4,502, Watts) as in the flame of cyanogen, and much more brightly the six bands in the violet (wave-lengths 4,220 to 4,158, Watts) and five ultra-violet.

Carbonic acid gas, hydrogen, nitrogen, chlorine, carbonic oxide, nitric oxide, and ammonia were then successively substituted for air in the globe, with the result that in carbonic acid, hydrogen, chlorine, and carbonic oxide, the above-mentioned bands in the indigo, violet, and ultra-violet died away, while in nitrogen, nitric oxide, and ammonia, they were always well seen.

These different gases were used in order to eliminate to a large extent the influence of electric conductivity on the character of the spectrum; and the green and blue hydrocarbon bands were seen, more or less, in all of them.

Next observations were made of the spectra of flames of sundry compounds of carbon.

In the flame of cyanogen, prepared from well-dried mercury cyanide, passed over phosphoric anhydride inserted in the same tube, and burnt from a platinum jet fused into the end of the tube, the hydrocarbon bands were almost entirely absent, as Plücker and Hittorf had found; only the brightest green band was seen, and that faintly. The indigo, violet, and ultra-violet bands, on the other hand, were well developed.

These three sets of bands in the indigo, violet, and ultra-violet are in the sequel referred to as the "cyanogen bands," though it is possible that they may be producible by other compounds of carbon with nitrogen.

The flame of hydrocyanic acid burning in air showed very much the same as that of cyanogen.

In the flame of a mixture of purified hydrogen and carbon disulphide no hydrocarbon bands at all could be detected.

Nor could they be detected in the flame of a mixture of carbonic oxide and hydrogen burnt in air.

When a mixture of hydrogen or of carbonic oxide with carbon tetrachloride vapour was burnt, hydrocarbon bands made their appearance, but were weak.

On the other hand, chloroform, when mixed with hydrogen, gave, when burnt in air, the hydrocarbon bands very strongly.

On a review of the whole series of observations, certain points stand out plainly. In the first place, the indigo, violet, and ultra-violet bands, characteristic of the flame of cyanogen, are conspicuous in the arc taken in an atmosphere of nitrogen, air, nitric oxide, or ammonia, and they disappear almost, if not quite, when the arc is taken in a non-nitrogenous atmosphere of hydrogen, carbonic oxide, carbonic acid, or chlorine. These same bands are seen brightly in the flames of cyanogen and hydrocyanic acid, but are not seen in those of hydrocarbons, carbonic oxide, or carbon disulphide. The conclusion seems irresistible that they belong to cyanogen; and this conclusion does not seem to be at all invalidated by the fact that they are seen weakly, or by flashes, in the arc or spark taken in gases supposed free from nitrogen by reason of the extreme difficulty of removing the last traces of air. They are never, in such a case, the principal or prominent part of the spectrum, and in a continuous experiment they are seen to fade out in proportion as the nitrogen is removed. This conclusion is strengthened by the observations that cyanogen (or hydrocyanic acid) is generated in the arc in atmospheric air in large quantity.

In the next place, the green and blue bands, characteristic of the hydrocarbon flame, seem to be always present in the arc, whatever the atmosphere. This is what we should expect if they be due, as Ångström and Thalèn suppose, to acetylene; for the carbon electrodes always contain, even when they have been long heated in chlorine, a notable quantity of hydrogen. In the flames of carbon compounds they by no means always appear; indeed it is only in those of hydrocarbons or their derivatives that they are well seen. Carbonic oxide and carbon disulphide, even when mixed with hydrogen, do not show them; and if seen in the flames of cyanogen, hydrocyanic acid, and carbon tetrachloride mixed with hydrogen, they are faint, and do not form a principal or prominent part of the spectrum. This is all consistent with the supposition of Ångström and Thalèn. The fact that the bands are not produced even in the presence of hydrogen, when it is not present in the flame in the form of a compound with carbon, is very significant; for we know that acetylene is present, and can easily be extracted from the flame of any hydrocarbon, and that it is formed as a proximate product of decomposition of hydrocarbon by the electric discharge, but we have no evidence that it is producible as a product of direct combination of carbon with hydrogen at the comparatively low temperature of the flames described.

The hydrocarbon bands are best developed in the blowpipe flame, that is under conditions which appear, at first sight, unfavourable to the existence of acetylene in the flame. However, by the use of a Deville's tube, acetylene may readily be withdrawn from the interior of such a flame, and from that part of it which shows the hydrocarbon bands most brightly.

The question as to whether these bands are due to carbon itself or to a compound of carbon with hydrogen, has been somewhat simplified by the observations of Watts, Salet, and others on the spectrum of carbonic oxide. It can hardly be doubted now that that compound has its own spectrum quite distinct from the hydrocarbon flame spectrum. The mere presence of the latter spectrum feebly developed in the electric discharge in compounds of carbon supposed to contain no hydrogen, weighs very little against the series of observations which connect this spectrum directly with hydrocarbons.

In the next place, it appears conclusively from the experiments, that the development of violet bands of cyanogen, or the less refrangible hydrocarbon bands, is not a matter of temperature only. For the appearance of the hydrogen lines C and F, observed by the authors in the arc taken in hydrogen, indicates a temperature far higher than that of any flame. Yet the violet bands are not seen in hydrogen at that temperature, while the green bands are well developed. The violet bands are, nevertheless, seen equally well at the different temperatures of the flame, arc, and spark, provided cyanogen be the compound under observation in the flame, and nitrogen and carbon are present together at the higher temperatures of the arc and spark.

The accompanying diagram (Fig. 1) shows approximately the relative position of the bands in that part of the spectrum of the flame of cyanogen fed with a jet of oxygen which is more refrangible than the Fraunhofer line F. Only those bands which are less refrangible than the solar line L have been before described, but photographs show two shaded bands slightly less refrangible than the solar line N accompanied by a very broad diffuse band of less intensity on the more refrangible side of N; also a strong shaded band, which appears to be absolutely coincident with the remarkable shaded band in the solar spectrum, which has been designated by the letter P; and near this, on the less refrangible side, a much fainter diffuse band, which also seems to coincide with a part of the solar spectrum sensibly less luminous than the parts on either side of it. This spectrum is remarkably persistent at all temperatures of the flame. Watts found that it did not disappear when the flame was cooled down as much as possible by diluting the cyanogen with carbonic acid; it retains its characters when the cyanogen is burnt in nitric oxide. The flame in the last case must be one

[1] For fuller details see *Proc.* R.S., xxx. pp. 152, 494.

of the hottest known, from the large amount of heat evolved in the decomposition of cyanogen and nitric oxide, namely, 41,000 and 43,300 units respectively. There is in the case of cyanogen, as in the case of so many other substances, a difference in the relative intensities of the different parts of the spectrum of the flame at different temperatures, but no other change of character. In the upper part of the flame where much or all of the cyanogen is oxidised or decomposed the spectrum is continuous, but at the base of the flame where it is issuing from the nozzle the cyanogen bands are always seen both when the cyanogen is burning in oxygen and when it is burning in nitric oxide. This is what we should anticipate, provided intermediate, and not the final, compounds are the active sources of the banded spectrum.

Each of the five sets of bands shown in the diagram is attended on its more refrangible side by a series of rhythmical lines extending to a considerable distance, not shown in the diagram, but easily seen in the photographs.

Coal gas burning in oxygen gives no bands above that near G within the range of the diagram, Fig. 1; but beyond this photographs show a spectrum of a character quite different from that at the less refrangible end, which the authors have traced to be due to water and described elsewhere (*Proc.* R. S., No. 205).

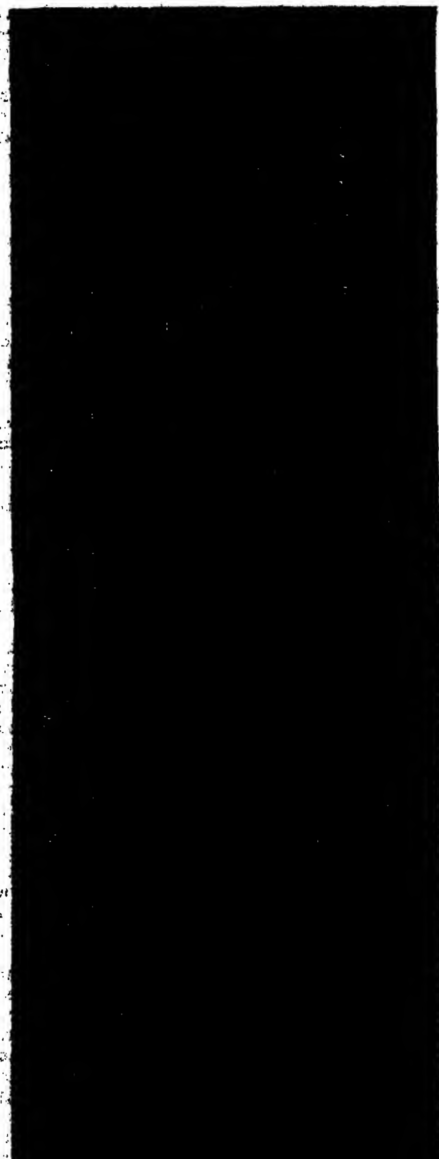
The authors then describe experiments with carbon tetrachloride, conducted with great care and numerous repetitions because of the prominence given to an experiment with this compound by Mr. Lockyer in a recent "Note on the Spectrum of Carbon," and because their results in every case differ from those which he obtained.

The form of sparking tube employed was similar to that used by Salet. This was attached by thick rubber tubing to a straight glass tube of which one half, about 6 inches long, was filled with phosphoric anhydride, and the other half with small fragments of soda-lime to prevent any chlorine from the decomposition of the tetrachloride by the spark from reaching the Sprengel pump. The tetrachloride used had been fractionated until it had a constant boiling point of 77° C. Sufficient of it was introduced into the sparking tube to fill nearly one quarter of the bulb at the end, and the whole interior of the tube thoroughly wetted with it in order to facilitate the removal of the last traces of air.

When the tube containing the tetrachloride had been so far exhausted that little but condensible vapours were pumped out, the bulb was heated so as to fill the apparatus with vapour of tetrachloride, the pump still going, and this was repeated as long as any incondensible gas was extracted. Sparks were then passed through the tube for a short time, the pump still being kept going. After a short time it was unnecessary to keep the pump going, as all the chlorine produced by decomposition of the tetachloride was absorbed by the soda-lime. On now examining the spectrum, no trace of any of the cyanogen bands could be detected, either by the eye or by photography, however the spark might be varied. The violet lines of chlorine described by Salet were more or less visible, coming out brightly when a condenser was used. Several tubes were treated in this way, and many photographs taken, but always with the same result; no trace appeared of either the seven blue, the six violet, the five ultra-violet, or of the still more refrangible bands of the cyanogen flame. It is true that all the photographs showed three lines in the ultra-violet, but these do not at all closely resemble the cyanogen bands, they are not shaded like them. The least refrangible of the three is coincident with the middle maximum in the ultra-violet set of five bands, but the other two do not coincide with other of these maxima. When a condenser is used, these three lines come out with much greater intensity, and two other triplets appear on the more refrangible side, as well as other lines.

The general character of the violet part of the spectrum of the spark in carbon tetrachloride taken without a condenser, but not the exact position to scale of wave-lengths of all the lines, is shown in Fig. 2. Fig. 3 shows the brightest of the additional lines which come out with the use of a condenser. Photographs of sparks taken in hydrochloric acid showed a precisely similar group of ultra-violet lines, so that there is no doubt that the three lines which the photographs show near the place of the ultra-violet cyanogen bands are due to chlorine.

Repeated trials in which the arrangements were varied having shown that pure carbon chloride, if free from nitrogen, does not give any of the bands ascribed to compounds of carbon with nitrogen, the next step was to determine whether the addition of nitrogen would bring them out, and if so what quantity of nitrogen would make them visible. For this purpose the binding of the rubber tube connecting to the pump a sparking tube containing tetrachloride and found to give no cyanogen bands, was loosened, and, after letting in very little air, immediately closed again. On now passing the spark the six violet bands at once appeared, and the seven blue bands also were in a short time well seen.



After trying some other experiments of a similar kind which indicated that a very small uantity of nitrogen was sufficient to develop the cyanogen bands in one of these tubes, a minute fragment of bichromate of ammonia, carefully weighed and wrapped in platinum foil, was introduced into the neck of one of the

sparking tubes containing carbon tetrachloride, the tube connected to the Sprengel pump, and the air removed as before. On examination of the spark with the spectroscope no trace of any cyanogen band could be detected. A pinch-cock was now put on the rubber tube, and the bichromate was heated by a spirit lamp to decomposition (whereby it is resolved into nitrogen, water, and oxide of chromium). On now passing the spark the six violet bands were well seen. There was no change in the condition of the coil or rheotome, so that the spark was of the same character as it had been before when no cyanogen bands were visible, and the change in the spectrum cannot be attributed to any change in the spark. The weight of the bichromate was between ·0005 and ·0006 grm., and the nitrogen this would evolve would fill just about $\frac{1}{10}$ of a cubic centimetre at atmospheric pressure. The tube held 30 cub. centims., so that vapour of carbon tetrachloride when mixed with $\frac{1}{300}$ part of its volume of nitrogen, gives under the action of the electric spark the cyanogen bands distinctly. Other similar experiments confirmed this result.

Similar experiments with carbon bisulphide, benzol, and well-purified naphthaline, gave like results when care was taken to remove air completely.

As Watts laid much stress on the occurrence of the cyanogen bands in the spectrum of the spark taken in carbonic oxide at atmospheric pressure (though they do not appear in carbonic oxide at reduced pressures), as a proof that these bands were due to carbon only, the authors made a series of careful experiments with carbonic oxide at atmospheric pressures.

In the first experiments with this substance the gas was made by the action of sulphuric acid on dried formiate of sodium, and it was found that the cyanogen bands disappeared as air was expelled from the apparatus, reappearing brightly when air, not exceeding $\frac{1}{100}$ of the whole gas in the apparatus, was admitted.

Carbonic oxide was next generated by heating, in a tube of hard glass in an ordinary combustion furnace, a mixture of pure and dry potassium oxalate with one quarter of its weight of quicklime, the mixture having been previously heated for some time so as to expel traces of ammonia. The tube was connected with a Sprengel pump, and the air exhausted before heating the oxalate. The distant end of the tube with the oxalate was then heated, and the whole apparatus filled with carbonic oxide; it was then again exhausted with the pump, refilled by heating more oxalate, and the gas allowed to stream out through the pump for some time. The heat was then lowered, sparks were passed, and the spectrum observed. No trace whatever of the cyanogen bands could be detected, however the spark might be varied. The pump was now set going again, and the pressure of the gas reduced to one inch of mercury, while the spectrum was observed from time to time. Still no trace of the cyanogen bands could be detected. More of the oxalate was next heated, and the observations repeated again and again, always with the same result. The conclusion was that carbonic oxide, if quite free from nitrogen, does not give, at the atmospheric or any less pressure, the cyanogen bands.

From Dr. Watts's account of his experiments, it appeared that he had used carbonic oxide prepared by the action of sulphuric acid on ferrocyanide, and it was probable that it might have been contaminated with nitrogen, or with nitrogenous compounds, from the ferrocyanide. The authors accordingly repeated their experiments with carbonic oxide so prepared, and found that the cyanogen bands were then always distinctly seen.

They have also repeated Ångström and Thalén's experiments with the spark between carbon poles in nitrogen and carbonic acid gas. They observed that in nitrogen the cyanogen bands were plainly visible through a great range of variations of the character of the spark; even the use of a condenser of moderate size did not diminish them. Photographs were taken with and without the use of the condenser, and these showed the violet and ultra-violet cyanogen bands, including those near N and P. The nitrogen was then swept out by a current of carbonic acid gas, and on now passing the spark the cyanogen bands could no longer be detected, and photographs taken as before showed no trace of any of them.

Other experiments showed the sensitiveness of the spectroscopic tests for compounds of carbon with nitrogen, and that all traces of water can hardly be removed from apparatus and reagents which do not admit of being heated red hot.

The first point the authors had before them in these investigations is whether the groups of shaded bands seen in the more refrangible part of the spectrum of a cyanogen flame are due to the vapour of carbon uncombined, or, as they conclude, to a compound of carbon with nitrogen.

Now the evidence that carbon uncombined can take the state of vapour at the temperature of the electric arc is at present very imperfect. Carbon shows at such temperatures only incipient fusion, if so much as that, and that carbon uncombined should be vaporised at the far lower temperature of the flame of cyanogen is so incredible an hypothesis that it ought not to be accepted if the phenomena admit of any other probable explanation. On the other hand it has been shown that cyanogen or hydrocyanic acid is generated in large quantity in the electric arc taken in nitrogen, and Berthelot has shown that hydrocyanic acid is produced by the spark discharge in a mixture of acetylene and nitrogen, so that in the cases in which these bands shine out with the greatest brilliance, namely, the arc in nitrogen and the cyanogen flame, we know that nitrocarbon compounds are present. Further, the authors have shown that these bands fade and disappear in proportion as nitrogen is removed from the arc. Ångström and Thalén had previously shown the same thing with regard to the spark discharge between carbon electrodes; and the conclusion to which they have come would probably have commanded universal assent if it had not been for the fact that these bands had been seen in circumstances where nitrogen was supposed to be absent; but where, in reality, the difficulty of completely eliminating nitrogen, and the extreme sensibility of the spectroscopic test, had been inadequately apprehended.

To clear up the question from this point of view, the experiments last described have been made, and they appear to the authors quite conclusive. Were the evidence less conclusive than it is, it would still be as rash and as illogical to conclude from the appearance of the cyanogen bands in a case where nitrogen was presumed, not proved, to be absent, that they were not due to a compound of carbon with nitrogen, as it would be to deny that the well-known yellow lines were due to sodium, because they had been seen in cases where sodium was supposed to be absent. The argument of the authors is an induction from a very long series of observations which lead up to one conclusion, and hardly admit of any other explanation. But Mr. Lockyer attempts to explain the disappearance of the bands when nitrogen is absent by the statement "that the tension of the current used now brings one set of flutings into prominence, and now another." This is no new observation. It is well known that variations in the discharge produce variations in the relative intensities of different parts of a spectrum. Certain lines of magnesium, cadmium, zinc, and other metals, very brilliant in the spark, are not seen, or are barely seen, at all in the arc. His remark might be applied to the spectra of compounds as well as to those of elements. Variation in the discharge accounts very well for some of the variations of intensity in the bands if they be due to a compound of carbon with nitrogen; it will not, however, account for the fact that the bands, or those of them which have the greatest emissive power, and are best developed by the particular current used, come out on the addition of a minute quantity of nitrogen, when there is every reason to think that no variation of the current occurs.

Much the same may be said with regard to the changes of the spectrum produced by changes of temperature. We cannot infer from any of these changes that the spectrum is not due to a compound. The bands in question are singularly persistent through a great range of temperatures, from the temperature of a cyanogen flame cooled by admixture with carbonic acid gas, as related by Watts (*Phil. Mag.*, 1869, p. 258), to that of the spark of an induction coil with condenser.

But again, Mr. Lockyer attempts to get over the difficulties of his case by the supposition that "the sets of carbon flutings represent different molecular groupings of carbon, in addition to that or those which give us the line spectrum."

Now, until independent evidence that carbon can exist at all in the state of vapour uncombined at the temperature of a cyanogen flame can be adduced, and further independent evidence of the existence of different groupings in such vapour, the hypothesis here enunciated is a gratuitous one, so long as any other hypothesis for which independent evidence can be adduced, as is true of the existence of nitrocarbon compounds in the flame, arc, and spark, will sufficiently explain the facts.

The authors have not expressed any opinion whether or no the cyanogen bands are visible in the solar spectrum. The observa-

tion above recorded that there is in the spectrum of cyanogen a strong shaded band coincident with the very characteristic dark shaded band P, strengthens materially the evidence in favour of the existence of these bands in the solar spectrum; the more so as the series of lines at P has far more of the distinctive character of the cyanogen spectrum than any other series in the ultra-violet part of the solar spectrum.

However that may be, they contend against the hypothesis that if present the bands can be due to any vapour of carbon uncombined in the upper cooler region of the chromosphere. One object of their investigations has been to determine the permanence of compounds of non-metallic elements and the sensitiveness of the spectroscopic test in regard to them. It appeared probable that if such compounds existed in the solar atmosphere their presence would be most distinctly revealed in the more refrangible part of the spectrum, and it seems sufficiently clear that the presence of nitrogen in the solar atmosphere may be recognised through cyanogen when free nitrogen might escape detection.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The Millard Scholarship in Natural Science lately founded at Trinity College has been awarded for the first time. The successful candidate is Mr. R. Bodey, from the Mining School, Bristol, and from the Royal School of Mines.

At Exeter College the Natural Science Scholarship has been awarded to Mr. B. Spencer, from King's College, London.

According to the report of the Delegates for unattached students, the number of students not attached to any college or hall has increased by twenty during the past year. Seventy unattached students have become members of colleges or halls during the year.

CAMBRIDGE.—The University of Cambridge Commissioners have apparently proposed their final arrangements as regards the University. There are many modifications from the original scheme in the direction of giving more freedom to the University, and on the whole in favour of scientific objects. A general financial board is to manage all University property and expenditure, and to control especially the college contributions. The rating of the colleges for University purposes is modified in the direction of increased fairness. The common University Fund derived from the colleges is to provide for all classes of University teachers, for the salaries of demonstrators, superintendents, and curators, for the erection, maintenance, and furniture of museums, laboratories, libraries, lecture-rooms; and in addition grants of money may be made from it for special work in the way of research, and for investigations in any branch of learning or science connected with the studies of the University. The amount of payments for buildings, and their maintenance, furniture, and apparatus, is not to exceed one-third of the income of the fund in any one year.

Practically speaking, there may be available in each year to the end of 1884, 2,000*l.* a year for these latter purposes and 4,000*l.* for investigators and teachers, and the college payments will rise definitely to 30,000*l.*, of which 10,000*l.* may be used for the purposes of buildings, and 20,000*l.* for teachers of all kinds.

It is no longer sought to force particular professors on particular colleges; the college may, if it prefers, pay the income of a Professorial Fellowship to the common fund. There are to be twenty-nine Professorial Fellowships, not assignable to particular professors, but distributed among the colleges.

The stipends of the Professors, payable by the University, are to have 200*l.* deducted from them if the Professor holds a Professorial Fellowship or a Headship. The stipends of Professors as now proposed are not so unequal as in the first proposed statutes. The payments (subject to the above-mentioned deduction) to the Regius Professor of Physic would be 700*l.*, Professor of Chemistry and the Cavendish Professor of Physics 850*l.* each, Physiology 800*l.*, Pathology 800*l.*, Botany, Zoology, and Woodwardian of Geology 700*l.* each, Anatomy 600*l.* The new Professorships are to be for (1) Physiology, (2) Pathology, (3) Mental Philosophy and Logic. The first two professors are not to undertake the private practice of medicine and surgery. When these shall have been established, the University may establish any other professorships it pleases, or has funds for.

The proposals for readerships are also to be remarkably modified; the minimum number of readers is now twenty. The subjects are to be within the control of the University; the readers are to be appointed as soon as funds can be provided conveniently from the common University Fund or from other sources. Readerships may be suppressed or created, according to the needs of study. The stipend is to be 400*l.* The readers are to be appointed by grace of the Senate on the recommendation of the General Board of Studies now to be created; but in each case the special Board of Studies with which the readership is connected must concur in the appointment, or it will lapse to the Council of the Senate.

University Lecturers (the next grade of teachers) may be college lecturers who throw open their lectures to the University, or they may be other persons approved by the Boards of Studies.

The payment to these lecturers from the University must be not less than 50*l.* The University may also appoint lecturers on subjects not immediately connected with any special Board of Studies, for shorter or longer terms. The separation of the Board of Studies in Physics and Chemistry from that of Biology and Geology is maintained. The constitution of the General Board of Studies is carefully and completely defined; but it is to do such work as the Senate commits to it, and in future a general University budget is to be prepared and submitted to the Senate.

The Cambridge Museums and Lecture Rooms Syndicate find the increase of annual grant from the University from 1,500*l.* to 2,000*l.* a year inadequate, owing especially to new outlay on new departments. They now have a balance of 821*l.* against them; and they ask for an additional 1,000*l.* per annum at once, feeling quite unable otherwise to maintain the museums in moderate efficiency with strict economy.

SCIENTIFIC SERIALS

Journal of the Franklin Institute, September.—Experiments on the compression of air by the direct action of water, by J. P. Frizell.—Experiments on the strength of yellow pine, by R. H. Thurston.—The absolute economy of electric lighting, by R. Briggs.—Note on the artificial production of diamonds by the processes of Despretz, by E. J. Houston.

SOCIETIES AND ACADEMIES

LONDON

Entomological Society, October 6.—H. T. Stainton, F.R.S., vice-president, in the chair.—Sir Arthur Scott of Birmingham and Mr. F. E. Robinson were elected as ordinary Members.—Mr. McLachlan stated that last year he had exhibited

specimens of *Anthocoris nemorum*, an hemipterous insect supposed to be damaging the hops grown near Canterbury, but had then expressed his opinion that the insect was not the true culprit, its habits being probably carnivorous. This year he had received from the same correspondent some small larvæ which had been found in the cones, and these he considered were not only the true enemy of the hops, but were also the food of the *Anthocoris*.—Sir Sydney Saunders exhibited a series of apterous females of the new species of *Seteroderma*, adverted to at the previous meeting, and read remarks thereon.—Messrs. Kirby, Fitch, Ralfe, and the Rev. E. N. Gilbert exhibited several varieties of lepidoptera taken in this country and on the Continent, some of which, from the structure of the antennæ, were considered "hermaphrodite" forms.—Mr. Hildebrand Ramsden communicated a note on *Pyrophorus causticus*, a Cuban fire-fly.—Mr. Swinton read two papers entitled Some Experiments on the Variability of Lepidoptera undertaken during the year 1880, and exhibited specimens and figures in illustration.—Mr. Butler communicated a paper entitled Observations on the Lepidopterous Genus *Terias*, with descriptions of hitherto un-named forms from Japan.—Mr. Waterhouse communicated a paper on the Buprestidæ from Madagascar.—Messrs. Kirby, Distant, and McLachlan called attention of the Society to a method of publishing descriptions of new species pursued by M. André in recent parts of his work on European Hymenoptera. These were not only inserted on the *cover* of his quarterly parts, but even at the end of sheets of advertisements laid loosely between the pages of a part. It was regretted that no other course than that of protest and disapprobation could be applied in the interest of science to such a practice.

Paris

Academy of Sciences, October 18.—M. Wurtz in the chair.—M. Faye presented the *Connaissance des Temps* for 1882 (204th volume), and indicated several improvements, viz., tables giving, for all points of the globe where the next Venus transit will be visible, the instants of all phases of the transit, a table for determining the direction of the meridian from the Pole star, the positions of 300 important stars every ten days, and of ten polar stars daily, and empiric corrections of ephemerides of the moon.—Longitude of the coast of Brazil, by M. Mouchez. A scientific mission from the United States under Messrs. Green and Davis has, with the aid of the Transatlantic cable from Europe, fixed the position of the six points, Para, Pernambuco, Bahia, Rio de Janeiro, Montevideo, and Buenos Ayres; and the results show that the author's figures for the same places, obtained in 1860 and following years, by astronomical and chronometric methods, were nearly exact, the greatest error being 2·34s. (The *Connaissance des Temps* had adopted different numbers, which are shown to be in error 27·4s.) The author's errors being all of the same sign, a mere shifting of the Brazil coast about 2 sec. westwards (nearly 1km.) would make the longitudes exact to a few tenths of a second. He compares the chronometric and astronomical methods, showing that chronometers, in absence of the telegraph, offer the surest and most simple means of determining longitude. The influence of temperature he corrected by means of a simple coefficient.—On the saccharine matters contained in the fruit of the coffee-tree, by M. Boussingault. He analysed some berries (from Brazil) that had been put in alcohol immediately after plucking, also the alcohol. The berry is poor in saccharine pulp compared with cherries and other stone fruit from which alcohol is got (it has 66 per cent. as against 90 for cherries and 95 for prunes). The distillation of the berries of coffee would hardly be lucrative or practicable (as Humboldt imagined).—Order of appearance of the first vessels in the inflorescence of *Mibora verna*, by M. Trécul.—On the resistance of animals of bovine species to splenic fever, and on the preservation of these animals by preventive inoculations, by M. Chauveau. He mentions that, contrarily to what is observed in France, it is in animals of bovine species that anthracoid diseases are more frequently met with in Algeria. He is inquiring what it is that favours the effects of spontaneous infection in the bovine species, so resistant to provoked infection, and hopes soon to be able to furnish the explanation. The preventive effect of inoculation he has proved in eight subjects of bovine species (four of which were Algerian).—On the photophone of Prof. Bell and Mr. Sumner Tainter, by M. Breguet. A drawing is given of the arrangement found most effective. At M. Breguet's place the phenomena have been obtained with the electric light over a distance of 15m. The articulation, though not perfect, was demonstrated.—Spectroscopic studies of the sun at Paris Observatory, by M. Thollon. The sun has entered on a period of activity. M. Thollon gives figures of several striking recent protuberances. He frequently observes protuberances 1′ in height, and has seen several exceeding 2′ and 3′, and one about 8′. Some of them may nearly reach the limits of the corona. He indicates his new method of ascertaining the direction of the solar equator.—Principles of an algebraic calculus which contains, as particular species, the calculus of imaginary quantities and of quaternions, by M. Lipschitz.—On algebraic equations, by M. West.—Vibratory forms of circular pellicles of saposaccharic liquid (second note) by M. Decharme. This refers to the relative position of the nodals of each system. One finds identical laws for vibratory forms of any circular liquid surfaces, and for those of soapy pellicles; only the width of the zones is about six times smaller in the case of the former.—On the presence of cerium in the coal-formation of the valley of Saint-Étienne, by M. Mayençon.—On a very perfect reptile found in the Permian formation, by M. Gaudry. M. Roche found it at Igornay, and has presented it to the Paris Museum. M. Gaudry proposes to call it *Stereorachis dominans*. Its vertebræ are in striking contrast with those of other reptiles in the same bed; the centrums are in one piece, which adheres to the neural arc. Another mark of superiority is that its humerus has, in the distal part, a neuro-arterial canal. The *Stereorachis* was a pretty large carnivore. It has affinities with the Ganocephali and Labyrinthodonts, and perhaps still more with some of the animals in Mr. Cope's group of Pelycosaurians, in North America.—On the existence of a reptile of ophidian type in the *Ostrea columba* strata of the Charentes, by M. Sauvage.

Berlin

Geographical Society, October 9.—President Dr. Nachtigal, who congratulated Dr. Bastian on his return from his two years' exploration.—A letter from Dr. Buchner was read, dated September 27 of last year from Kimbundo. Since then, it has been learned, he has not only reached the residence of Muata Janvo, but has carried his exploration much farther. It is probable that he has gone northwards.—News was received from Dr. Lenz, which we refer to in our Geographical Notes. By the last news Herr Flegel had reached the confluence of the Niger and Binué, and his expedition was doing well.—The German expedition to East Africa was, according to the last news, at Muhatta, with Capt. Ramaecker's Belgian expedition, on the way to Tabora.—Prof. Credner of Halle read a paper on the glaciation of North Germany during the glacial period.
